The correct concentration of each factor will have to be determined in order to optimize the recapitulation of a particular phenotype. Once established, these concentrations should not be tampered with unless there is a scientific reason for doing so. For instance, addition of EGF to the culture medium was critical for the development of a nonneoplastic human cell line from reduction mammoplasty, and its removal led to selection and/or promotion of a cell variant that became malignant. Abolition of the EGF complement was based on the knowledge that a vast majority of breast tumor cells are EGF independent for their proliferation. Thus, by manipulating the defined culture medium, it was possible to achieve what was usually only achieved by introducing permanently activated oncogenes in cells.

2.2 The Multiple Facets of Setting Culture Conditions

There are at least five different ways to produce the ECM environment necessary for 3D cell culture within the usual laboratory settings: The ECM environment could be (1) from natural origin (e.g. purified denatured BM from tissues), (2) made from single ECM components such as hydrated collagen gels with or without other defined ECM components (can be purified from rat tails), (3) composed of BM mixtures such as Matrigel™ (purified from a mouse sarcoma), (4) made of cellulose sponges with mixtures of ECM components, or (5) composed of engineered ECM-like gels, which are becoming increasingly available but with mixed success. In addition, some of these exogenous ECMs can be used under different conditions so that cells and multicellular structures are either totally embedded or simply maintained on the surface of the exogenous ECM gels.

2.2.1 Making the Gel

3D cell culture is essentially based on the use of hydrated gels. Indeed culturing cells on a coat of dried ECM may be helpful to allow the expression of a few differentiated functions, but does not generally lead to full tissue-like differentiation. Most commonly, cells are embedded within the gel by mixing them in the exogenous ECM used in a liquid form just before plating so that the cells are equally distributed within the depth of the ECM scaffold. After the 40 to 60 min necessary for gel formation with most biologically derived ECMs, the desired medium is added to maintain hydration and to supply nutrients. This technique allows cells to have a fairly homogeneous gel environment and for most epithelial cells it creates an optimum condition for differentiation.

While so far the laminin-rich Matrigel™ has been the workhorse of those who use 3D cultures, the use of collagen I as the primary scaffold may confer additional advantages. Indeed, since purified ECM components can be mixed with collagen I gel to provide additional ECM specificity, the same basic system can be used to compare the effect of different ECM components on a given cell type. However, for each cell type for which conditions have been determined in Matrigel™, strict comparison with the Matrigel™ cultures are necessary to make sure that appropriate markers are being expressed and that the structures formed reflect the *in vivo* situation.

Examples of gel preparation:

1. *Collagen I gels*: Techniques for attached and floating collagen gels have been described in detail.
2. *Matrigel™*: Vials are thawed on ice several hours before use. 2×10^5 mammary epithelial cells are mixed with 0.3-mL chilled Matrigel™ per well of a 24-well dish. Gel formation occurs at 37 °C for about 40 min; then 1 mL of defined medium is added. Medium is changed according to the cell type used. For mammary acinar differentiation, medium is changed three times a week with addition of fresh additives.
3. *Variations on Matrigel technique*: These have been outlined in Fig. 3. Preparation of thinner 3D culture is possible depending on the cell type. Techniques for thin gel preparation are described in Sect. 2.2.2.
4. *Mixed gels*: Optimal gel conditions for mammary acinar differentiation are typically 2×10^5 epithelial cells per 0.5 mL of collagen gel containing 10% laminin or Matrigel™ per well of a 24-well dish. Gel formation occurs at 37 °C for a minimum of an hour, with subsequent addition of 1 mL of defined medium.
5. *Other 3D techniques*: There are a number of variations on the above techniques (e.g. the sponge technique described in Sect. 2.3.1 below). While these are not discussed in detail here, there is much room for innovations. There are already other advanced techniques described for other tissues such as skin (discussed later in section 4.3).

2.2.2 Biochemical and Imaging Manipulations of 3D Cultures

Almost all analytical techniques can be performed on structures produced on, or in, 3D gels. Isolation of multicellular structures requires treatments with ECM-specific proteases (collagenase for collagen I gels and dispase for Matrigel™). Gel solubilization typically takes 30 min at 37 °C with dispase grade II and 30 min at 37 °C with collagenase D. It is critical to wash out proteases: using three washes with

regular additive-free culture medium and a fourth wash in the buffer of choice (e.g. phosphate buffered saline (PBS) with protease and/or phosphatase inhibitors). Each wash is followed by 5-min centrifugations. Please note: it is important NOT to separate cells from each other using trypsin and/or ethylenediaminetetraacetic acid (EDTA) since these treatments will affect cell contacts, the internal cellular organization and gene expression, and consequently may alter the outcome of the experiments. Following washes, the pellet of multicellular structures can be treated for cell fractionation using classical protocols to investigate protein content in the different cellular compartments. We have obtained successful preparations of different types of cell extracts from 3D cultures including nuclear and cytoplasmic extracts, chromatin fractions, or crude membrane extracts by simply applying usual lysis and preparation buffers. The separation of nucleus from cytoplasm is achieved using a dounce homogenizer. We recommend carefully monitoring the separation by examining an aliquot of the cell sample under phase contrast microscope after sets of defined number of strokes, until separation is satisfactory. Indeed, depending on the multicellular structures used, separation may require a higher number of strokes compared to the protocol followed with cells obtained from 2D cultures.

RNA can be directly extracted from 3D cultures. The technique described by Gudjonsson and colleagues (2002a) is particularly simple yet clean enough to obtain RNA that can then be used for microarray analysis. This technique uses Trizol according to the manufacturer's instruction. If necessary more pipetting or even vortexing may help solubilize the gel following incubation with Trizol.

If immunostaining has to be performed, cultures can be embedded in sucrose and frozen in Tissue-Tek optimal cutting temperature (OCT). Fluorescence or horseradish peroxidase staining can be utilized on cryosections according to classical immunostaining protocols used for tissue biopsy.

Immunostaining may also be performed directly on fresh intact cultures. This option is quite useful whenever there is a risk that cryosectioning could damage the multicellular organization, or when the entire depth of the multicellular structure has to be imaged in order to get a global idea of tissue organization, or when freezing samples may interfere with the subtle organization of the subcellular domains to be imaged. It is possible to prepare thinner gels as long as the parameters measured are not impaired (i.e. the differentiation process should be compared to that obtained with the thick gels). For differentiation of mammary epithelial cells in acini, we found that 70 $\mu L\ cm^{-2}$ of an efficient Matrigel™ lot still produced well organized and functional tissue-like structures, permitting a reliable penetration of antibodies and the use of laser scanning microscopy. The thin gel method can also be used to introduce function-blocking antibodies into live cells. It is also possible to use a drip method, in which mammary epithelial cells are mixed with 4% of Matrigel™ before being plated on top of a coat of Matrigel™ (40 $\mu L\ cm^{-2}$) or even on plastic in case of mouse cells. In another drip method we have developed, cells are plated in half the usual volume of medium. The other half of the medium is then mixed with Matrigel™ to achieve 10% final concentration of the gel and dripped slowly over the entire culture surface. Others have described this technique with

slight variations. The Matrigel™ drip need not be repeated again when medium is changed. ECM molecules will rapidly bind to the cells, a process that usually initiates morphogenesis (Fig. 3). It is important to note, however, that the type of secondary fluorochrome-conjugated antibody and the Matrigel™ lots could influence the amount of background staining in the 3D cultures. Thus, immunostaining is performed as usual, except that when necessary, blocking should be performed for 2 h at room temperature, and each washing step should last for 20 min in order to reduce nonspecific background in the Matrigel™. Confocal microscopy and reconstruction of 3D images can be performed easily with these cultures, which are particularly appropriate for immunostaining done to visualize supramolecular patterns of protein distribution in the cell nucleus.

2.3 Biochemical, Structural, and Functional Validations

3D cell cultures could mimic physiologically relevant processes and thus offer a wide range of possible investigations into molecular mechanisms of regulation, as long as quality controls are applied frequently and the desired phenotypes are achieved reproducibly.

In this section, we will give a few examples of the type of controls that are important for determining how well the 3D conditions recapitulate the *in vivo* situation. Obviously, markers (quality controls) would differ with the type of cells and tissues used. This necessitates a thorough knowledge of the physiology and the anatomy of the tissue of interest, and as such will have to take the limits of the 3D culture systems into account.

Earlier we discussed conditions for recapitulation of the mammary acinus in 3D cultures. Whereas mammary acini require laminin-1 (see also the following), a tissue such as annulus would require a different microenvironment.

2.3.1 Modeling Human Annulus in Culture

In order to successfully mimic intervertebral disc formation, it is particularly important to assess the level and the nature of ECM molecules produced *in vivo*. These tissues make copious amounts of type II collagen, aggrecan, and chondroitin-6 sulfotransferase *in vivo*. In a series of tests performed by Gruber and colleagues, collagen sponge was determined to be the best carrier not only because of the correct profile of gene expression but also because sponge induced high levels of correct ECM molecules to be deposited compared to other carriers such as collagen gels.

2.3.2 The Relation Between Functional Integrity Accuracy and Structural in Mammary Acini

Three-dimensional cell cultures are powerful for analysis of signaling and functional regulation, and they also provide an interesting challenge: The acini formed by mammary epithelial cells in 3D culture, for example, are traditionally constructed with only one cell type: the luminal epithelial cells. However, acini formed *in vivo* in the mammary gland contain a dual ''tube'' consisting of luminal and myoepithelial cells (see Fig. 2). Although the cultured acini for all practical purposes resemble the acini formed *in vivo* (even the sizes are similar; see Fig. 1), the basal pole of luminal cells is touching only the BM whereas, it is in contact with the myoepithelial cells in the normal gland. Thus, in monoculture in 3D, basal polarity markers

hemidesmosomes are formed between the luminal cells and the BM, rather than between the myoepithelial cells and the BM as is the case *in vivo*. Interestingly, however, the hemidesmosomes appear to be normal and are made through connections with $\alpha 6\beta 4$ integrins, which is the correct integrin dimer. This means that luminal cells in culture in the absence of myoepithelial cells turn on the expression of myoepithelial markers, hence becoming a ''hybrid'' between the two cell types. Thus, quality control includes not only the assessment of the expression of differentiation markers but also the assessment of their localization within the luminal cells to verify the formation of a baso-apical polarity axis (see Fig. 2). Whereas the cultured acini appear to perform many of the functions of the acini in the gland (e.g. milk production in the case of the mouse mammary cells), it is unlikely that they would be able to perform every function the acini perform *in vivo*. Thus, it is desirable to add the other cell types to the mix to eventually make a complete gland. Whether or not the acini formed by the mixed cell population are equivalent to the double-layered acini *in vivo* remains to be determined. As described in Sect. 4.3 of this chapter, it has recently been possible to coculture mammary epithelial and myoepithelial cells, and induce the formation of double-layered structures. A comparison of gene expression between the acini *in vivo* and the epithelial versus epithelial plus myoepithelial cell cultures should determine the exact contribution of the myoepithelial cells to the ability to form acini; these experiments are in progress in a number of laboratories including ours.

We have reported often on the many differences in signaling that are observed between 2D and 3D cultures. In general, we find that the patterns of gene expression and localization of markers within multicellular structures obtained in 3D culture closely resemble the patterns *in vivo*. However, formation of multicellular structures in 3D takes only a few days and is in a different context than what occurs in natural development of the gland. Thus, it is possible that some of the mechanisms observed during the formation of tissuelike structures in 3D cell culture may not reflect what happens *in vivo*. Whenever possible, it is quite important to confirm the existence of novel genes or patterns of gene expression and localization observed in 3D cultures with sections of tissues *in vivo*.

3 Current Applications of 3D Cell Culture

The use of 3D cell culture has opened new directions for both research purposes and medical applications. In the next three sections of this chapter, we will briefly discuss some of the possible applications.

3.1 Biochemical and Architectural Signaling in Physiologically Relevant Context

3.1.1 3-D Cell Culture Unravels Complex Interactions Among Signal Transduction Pathways

An increasing number of studies have now revisited signal transduction in multicellular structures that recapitulate either phenotypically normal or pathological behaviors.

Both the epidermal growth factor receptor (EGFR) and the $\beta 1$-integrin signaling pathways have been widely studied on monolayer cultures, and were shown to be involved in the control of proliferation and survival. Using 3D cultures of neoplastic mammary epithelial cells

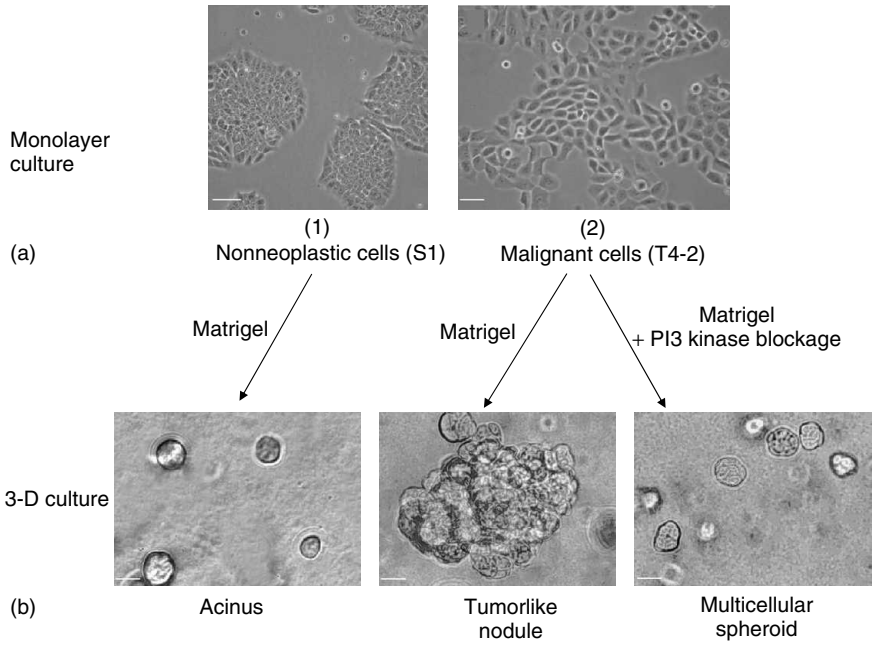

Fig. 4 Morphology of mammary cells in 2D and 3D. (a) Morphology of nonneoplastic S1 and malignant T4-2 HMT3522 cells cultured on plastic. (1) Phase contrast image of nonmalignant breast epithelial cells (HMT3522-S1) cultured for 10 days. Cells form circular, smooth colonies with the inner cells being somewhat compacted. (2) Phase contrast image of tumorigenic T4-2 cells, derived from S1 cell, cultured for 5 days. The cells are larger than S1 cells and do not compact in the center. The cells at the edges only rarely show any distinct organization. Size bars = 25 μm. (b) Phase contrast micrographs of S1, T4-2, and revertant T4-2 cell colonies following treatment with EGFR inhibitor (cells also revert using β-1 integrin inhibitory antibody or PI-3 Kinase inhibitors (see text). When plated inside Matrigel, S1 cells form growth-arrested multicellular structures resembling mammary acini within 10 days of culture, whereas untreated T4-2 cells form disorganized multicellular structures in which cells keep proliferating. (Size bar = 30 μm). (From Myers et al., in: Julio C. (Ed.) *Cell Biology: A Laboratory Handbook*, 3rd edition, 2005, in press.)

that can be "reverted" using inhibitors of either EGFR or β1-integrin pathways (Fig. 4), it was demonstrated that these two pathways were coupled, meaning that downmodulation of one pathway led to downmodulation of both signaling and the level of the relevant receptor in the other pathway. In contrast, no such coupling was observed in cells cultured on 2D substrata.

Beyond its importance for better understanding the differentiation of mammary epithelial cells, the discovery of coupling between a number of signaling pathways in 3D, demonstrated that there exists a higher order control of tissue phenotype, a process that is disrupted when cells are on 2D monolayers. Interestingly, other studies showed that uncoupling EGFR and integrin regulation by overexpressing EGFR in nonneoplastic mammary epithelial cells resulted in the maintenance of Erk activation and inhibition of apoptosis associated with downregulation of Bim. Another example of higher order signal

transduction came from studies of ''premalignant'' phenotypes: 3D cell cultures of ErbB2-MCF10A mammary epithelial cells were shown to recapitulate features of breast ductal carcinoma *in situ* (DCIS), a noninvasive stage of mammary neoplasia. Using this model, it was recently shown that cooperation between ErbB2 and TGF-β is critical for triggering the invasive behavior of ErB2-MCF10A cells, and that sustained activation of Erk is critical for ErbB2 and TGF-β cooperation.

3.1.2 3-D Cell Culture Can Lead to the Discovery of Additional Functions for Known Proteins

Overexpression of human carcinoembryonic antigen (CEA) and family member (CEACAM6) was shown to prevent differentiation of two colonic cell lines into polarized glandular structures in 3D cultures. Since the cell surface levels of these CEA proteins inversely correlate with the degree of cellular differentiation in freshly excised colonocytes, the 3D assay provides a plausible explanation for the differences in levels of CEA observed in colon carcinoma. In the long run, they also provide a good rationale for testing CEA as a potential target to fight colon cancer. Another example is how 3D cultures have enabled us to study the concept of ''architectural'' signaling in physiologically relevant assembly of cells. It is known that the internal organization of cells is dependent on the differentiation status. However, the use of 3D cell culture has permitted the discovery that the reverse is also true: the structural organization itself can regulate the degree of differentiation. For instance, the nuclear organization of the structural protein NuMA was significantly modified between early and late stages of breast acinar differentiation in 3D cultures. To demonstrate that this distribution pattern was physiologically relevant, we showed that the characteristic distribution of NuMA in full acinar differentiation in 3D culture was similar to that observed in tissue sections of normal human breast epithelium, but was not observed on monolayers in 2D cultures, even when cells were growth arrested. Conversely, we showed that altering NuMA organization in acinar cells impaired the proper formation of the polarity axis, thus suggesting a potentially important but unappreciated role for NuMA in acinar differentiation.

3.2 Recapitulation of Stem Cell Growth, Developmental Fate and Pathological Conditions in 3D Cultures

3.2.1 Insights into Mechanisms that Control Normal Tissue Formation

Formation of organs involves a combination of different cell types and tissues according to a particular spatial organization. Such complex structures are difficult to recapitulate even in 3D cell culture. However, while formation of complex organ structures in 3D culture is still in its infancy (see also Sect. 4.3), even monotypic 3D cultures have begun to enable us to unravel potential molecular key players for cell/tissue replacement therapies.

For example, myocardial repair is being actively investigated in 3D cultures. A recent study reported that culturing embryonic cardiac myocytes on a tubular scaffold engineered from aligned type I collagen efficiently induced a phenotype resembling neonatal ventricular myocytes *in vivo*.

Stem cells research is bringing additional exciting applications for 3D cell culture. Stem cells are attractive sources for the production of engineered tissues since identifying the conditions that permit the recapitulation of a particular

cell type will permit the replacement of different types of damaged tissues starting from very few progenitor cells. For instance, human mesenchymal stem cells have been induced to differentiate into osteoblasts and adipocytes when cultured on fibrous matrices. Their culture is associated with the secretion of an extensive ECM network composed of collagens I and IV, fibronectin, and laminin that align with fibrils of the exogenous artificial matrix. Differentiation of enteric neuronal precursor cells is being studied using enteric neurospheres in 3D culture in order to better apprehend the development of the enteric nervous system, and putative mammary progenitor cells have been shown to differentiate into terminal ductal lobulal units (TDLU). Many more studies of this kind are sure to follow.

3.2.2 3D Culture Systems that Mimic Neoplasias

The recapitulation of ''tumor growth'' in 3D cultures, and the ability to generate new information on tumor reversion, apoptosis, and resistance to chemotherapy have attracted much attention in recent years. Three-dimensional cell culture models that mimic malignant phenotypes should provide tools to better understand the mechanisms of malignancy and help develop novel anticancer strategies. Most tumor cell lines have been obtained from invasive tumors and they grow in both collagen I and Matrigel™, giving rise to characteristically disorganized colonies and masses. Moreover, tumor cell lines often produce copious amounts of cytokines, growth factors, and aberrant ECM components that allow them to be cultured in the 3D microenvironment (Fig. 4), despite the fact that cultures of primary cells from tumors are not often easy to grow – probably because they require additional factors from stromal cells; this means that epithelial cancer cell lines turn on stromal components to compensate. Indeed, it is now possible to recreate a reasonable replica of breast tumors by including stromal components in a collagen gel.

One of the most dramatic phenotypes of tumor cells that has been successfully recapitulated in culture is invasion through a thin coat of Matrigel™ deposited on a porous filter. If cells are found on the other side of the filter a few hours after plating, they are considered to possess invasive capabilities (Fig. 4a). This is not strictly a 3D culture technique because cells are cultured for short periods of time and do not form 3D structures. However, invasion can be visualized also in 3D in Matrigel™ after formation of tumorlike nodules. In this case, invasive potential can be visualized by the formation of invasive expansions emanating from the tumorlike nodules (Fig. 5). While the invasive phenotype of malignant cells is fairly easy to recapitulate, especially with cell lines, behavior of benign or premalignant cells has been a challenge to model. 3D cell culture models of premalignant and preinvasive lesions are particularly important to develop because the mechanisms that control formation and progression of these lesions are poorly understood. The HMT3522 progression series recapitulates the formation of nonmalignant breast tissue lesions where spontaneously derived precursors to T4-2 cells form disorganized masses in 3D culture but are not yet malignant in nude mice. Other models also have been developed by overexpression of various oncogenes that alter cellular structure but are not yet sufficient for malignancy. One such induced ''pre-malignant'' model was developed by activating the ErbB2 signaling pathway, using an inducible system, in nonneoplastic mammary epithelial

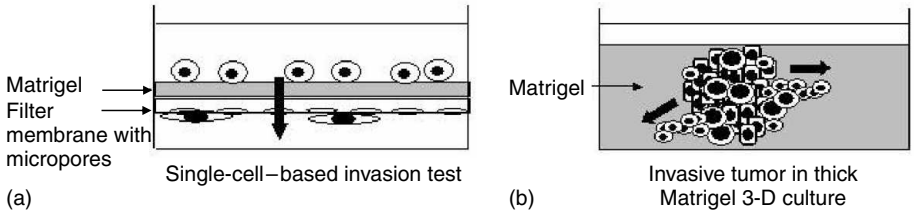

Fig. 5 Assays to assess the invasive phenotype of tumor cells. (a) Classical invasion test performed within 6 to 18 h of culture. The thick arrow shows the direction of invasion through the pores. (b) Invasive phenotype observed in thick Matrigel after 6 to 10 days of 3D culture. Thick arrows show the invasive expansions emanating from the tumorlike nodule. ECM (Matrigel) is shown in light gray. Cell nuclei are shown in black.

cells once they had formed acini. ErbB2 activation induced cell proliferation characterized by filling of the lumina, while the BM remained intact, hence mimicking carcinoma *in situ*, a preinvasive lesion that is associated with an increased risk of developing breast cancer.

Three-dimensional cell cultures have made it possible also to ''revert'' malignant cells into phenotypically normal acinus-like structures providing a venue to investigate the molecular mechanisms of this poorly studied area. The importance of targeting the microenvironment as well as the tumor itself for cancer therapy is gaining acceptance and modeling this process in 3D would allow increased momentum.

Three-dimensional culture systems are critical also for anticancer drug testing. It was shown almost 15 years ago that the sensitivity of tumor cells to drugs used for cancer treatment is radically different in cells cultured in monolayers compared to cells organized into multicellular spheroids. This has been dramatically illustrated further for drugs that cause apoptosis and chemotherapeutic resistance. Ideally therefore, drug testing should be performed on human cancer cells cultured in 3D and compared with studies in rodents *in vivo*.

3.3 Large-scale Cell Culture and Bioengineering

In the preceding sections, we have discussed techniques and experiments that can be easily performed in basic laboratory settings. There is, however, a need for high-throughput 3D cultures used for drug testing and to produce tissue replacement for medical use.

3.3.1 High-throughput Drug Testing

In order to standardize tumor spheroids for drug testing, techniques such as hanging drops have been suggested. This technique is based on the principle that most cells tend to attach to each other without the need for artificial scaffold. The use of this technique has been recommended because it induces the formation of homogeneously sized spheroids that could be used for automated drug screening. Although homogeneity is an important factor for reproducible drug testing, techniques that use an exogenous ECM scaffold may recapitulate certain alterations in phenotype and/or tumor structure more accurately. The technique we have developed referred to as ''on top + drip'' (Fig. 3) allows a rapid, 4-day

formation of structures that can be used for high-throughput drug testing as well as imaging.

3.3.2 Bioreactors: The Power of Rotation and Hydrodynamics

This type of 3D culture requires specific equipment, and often a complex exogenous ECM scaffold. The use of bioreactors for 3D culture is based on the idea that these systems may allow feeding of a large number of cells via a spatially homogeneous distribution of the fluid flow, and hence permit the development of highly complex and/or thick tissue structures. The rationale for using microfluidics technology with 3D cell culture systems is based on the hypothesis that it may further help generate an environment similar to the one that exists *in vivo*. Such complex systems have been successfully used to model microscale blood vessels using microfluidic channels. Bioreactors have been used also to recapitulate the differentiation of high-density tissues. For liver cell culture, for example, bioreactors were designed to provide a large surface area for the attachment of a high number of cells, and increased capacity for oxygen and nutrient supplies. One of the most recent culture systems is composed of 10-stacked layers of microfluidic channels made of poly(dimethylsiloxane) (PDMS); the system is linked also to an oxygen chamber. PDMS has high gas permeability and provides high oxygen supply to cells. As in small-scale 3D cultures, primary hepatocytes are plated as single-cell suspension in bioreactors. Upon rapid formation of spheroidal aggregates, differentiation proceeds as shown by the formation of tight junctions, glycogen storage, and canaliculi. 3D microcarrier scaffolds with fluid flow throughout the scaffold have been used also in rotating systems to enhance the elaboration of mineralized bone matrix by osteoblast-like cells.

It is important to emphasize that 3D cultures performed in bioreactors, as described above, are quite different from spinner flasks or rotary cell culture systems used to induce microgravity-like conditions. Bioreactors aim at promoting tissue-like differentiation on a large scale; in contrast, spinner flasks and more recently microgravity-inducing systems, are mostly used to produce large cell aggregates. These latter systems have been popular in the field of cancer research. However, we feel that these systems do not accurately imitate physiologically relevant conditions associated with tumor formation. This is especially so with microgravity where changes in proliferation properties, cytoskeleton, and nuclear organization have been recorded upon comparison with gravity controlled cultures. Thus, the use of purely microgravity-inducing devices should be intended mainly for experiments that investigate the effects of microgravity.

3.3.3 Tissue Production in Bioengineering

3D cultures have major applications in tissue engineering. Typically, cells taken from a donor are placed in 3D culture, on different exogenous substrata, in order to produce tissues that are readily transplantable. A few types of bioengineered tissues are already used for transplantation. However, for most tissue types, the use of 3D cultures is still at the exploratory stages.

Bioengineered tissue transplants have been successfully produced for skin replacement therapies. An example of bioengineered graft is composed of a bovine collagen lattice containing living human

fibroblasts overlaid with a fully differentiated layer of human keratinocytes. Studies performed with nude mice have shown that this system provides a normal healing process, and that the implanted collagen is progressively degraded and replaced with new endogenously produced ECM molecules, such as elastin, synthesized by the living human cells contained within the graft.

Engineering of bone tissue is being actively pursued. The goal is to culture osteoblasts or osteoprogenitor cells within a 3D scaffold, under conditions that favor tissue growth and mineralization. One of the major technical problems is to provide nutrients equally throughout the culture so that cell viability is maintained in all parts of the culture system. Passive nutrient diffusion is not appropriate for such a culture and different techniques of dynamic internal fluid perfusion are being tested. The topography of the culture surface may also be important for the optimal expression of the osteoblastic phenotype. Indeed, it was shown that micropore sizes of polycarbonate membrane surfaces influence protein synthesis and alkaline phosphatase activity. Notably, membranes with larger pore sizes seem to favor differentiation and matrix production.

For tissues with elastic properties such as cartilage, the challenge is to obtain a matrix architecture that has structural and mechanical equivalence to elastic cartilage *in vivo*. A solution to such a challenge may be to use biomimetic hydrogel in a mechanically stable biomimetic composite matrix. Another challenge in bioengineering consists of inducing selective gene expression, notably by triggering proper cell shape. It has been shown that the type of collagen scaffold plays a critical role in determining an optimal cell shape for the production of intervertebral disc tissue.

4
A Glimpse into the Future

In the last section, we presented areas of research that will bring 3D culture to the next level by permitting the recapitulation of complex tissue structures (i.e. tissues that contain several cell types, with each cell type displaying a specific differentiation status). To do so, research efforts focus on designing highly malleable and complex exogenous culture scaffolds and acquiring a better knowledge of the mechanical characteristics of tissues.

4.1
The Continuing Search for New Biological and Engineered Extracellular Matrices that Resemble the Physiological Status *In Vivo*

Exogenous matrices used for 3D cultures have to provide a malleable scaffold as well as the necessary chemical properties for the initiation of tissue differentiation. Natural ECM molecules have inherent properties that greatly influence cell adhesion and shape. For instance, in contrast to many other ECM proteins, tenascins only permit weak adhesion and do not promote cell spreading. Lack of tenascin has been associated with abnormalities in the nervous system, regenerative processes, and skin properties. These observations suggest that, in addition to classical adhesion-promoting ECM proteins, adhesion-modulating/repelling molecules such as tenascin also should be included in biomaterials used for the production of certain types of tissue. This simple example of a particular and critical property of an ECM molecule illustrates the challenges faced by bioengineers. Indeed, for successful tissue engineering, one needs to design complex exogenous scaffolds that

take into account the intricate relationship between different ECM molecules.

4.1.1 Biological Matrices

One of the problems with current biological matrices such as Matrigel™ that are abundantly used in the laboratory is the lack of reliable composition from one batch to another. The inconsistency in the composition of Matrigel™ is inherent to the fact that this material is produced from tumors induced in rodents. Although Matrigel™ has been a useful material for carefully monitored laboratory experiments, other physiological matrices obtained from normal tissues may be required for bioengineering purposes. These matrices have the advantage of providing the complexity of the ECM environment in a more reproducible manner.

Porcine small intestinal submucosa (SIS)-based ECM scaffolds come from ECM produced naturally from normal tissue and thus their composition is fairly constant from one sample to another. SIS-based ECM has been used for several years in tissue bioengineering. Implantation of SIS *in vivo* was shown to facilitate the repair of long-bone defects in rats. SIS has also been shown to be a promising biodegradable scaffold for bladder tissue regeneration *in vivo*. Physiological and complex basal lamina have been used also from living tissues attached to underlying stroma. BM was obtained also following separation from large preovulatory follicles in chicken. The ultrastructure of the isolated BM remains similar to that of the BM observed in the intact ovarian follicle. Although this BM has been successfully used for culturing granulosa cells, it has not been tested widely on other cell types.

4.1.2 Future Directions in Engineered Matrices

Biomaterials for tissue engineering are used for different purposes including facilitation of tissue regeneration, production of carriers to deliver cell transplants, or formation of matrices used to induce tissue morphogenesis in culture before tissue transplantation. Clinical perspectives for tissue engineering require the use of biomaterials that recapitulate physical and chemical properties of natural ECM, while ensuring biocompatibility. It is particularly important that synthetic scaffolds or matrices mimic the hydrogel characteristics of natural ECM in order to maintain tissue-like viscoelastic properties, diffusion, and interstitial flow.

The incorporation of biological characteristics into classical synthetic polymer hydrogels is particularly promising to improve the ECM scaffold required for the recapitulation of complex tissue structures. These gels form *in situ* in the presence of cells, thus facilitating 3D culture setup. Certain gels may even include enzymatic activity that favors cell migration and tissue remodeling. Other promising biomaterials consist of nanofibrillar components that mimic the fibrillar architecture of the ECM, and are formed by self-assembling processes *in situ*. Self-assembly occurs via noncovalent-intermolecular interactions (e.g. assembly of self-complementary amphiphilic peptides in physiological medium). Some of these novel scaffolds can form gels containing more than 99% water and have been shown to maintain and/or promote differentiation of different cell types including chondrocytes and liver progenitor cells. Furthermore, biomolecular signals can also be incorporated in these self-assembling scaffolds by inclusion of ECM-like peptides, for example,

the laminin-based peptide IKVAV. Another interesting approach consists of creating highly defined synthetic ECM analogs, the distribution and concentration of which can be set up as desired on a passive scaffold. These structures may facilitate cell migration or be sensitive to metalloproteinases. Other matrices are designed to permit growth factor concentration and cell-mediated release, hence mimicking natural ECM growth factor presentation and delivery. Finally, certain types of hydrogels formed from self-assembling artificial proteins can undergo controlled gelation and dissolution. These scaffolds are formed by gelation of proteins with terminal leucine zipper domains flanking a central water-soluble polyelectrolyte segment. Formation of the 3D polymer networks is induced in near neutral aqueous solutions. Temperature or pH elevation induces dissolution of the gel and a return to the viscous state. These types of gels are particularly interesting for tissue engineering as they may permit an easy recovery of multicellular structures for experimental analysis.

4.2 Multiple Elements: Force, Tension and Compliance

The importance of mechanical forces in the communication between cells and their ECM is now well established. Understanding how external directional forces affect cell behavior and patterns of gene expression will be of tremendous help for the design of appropriate 3D microenvironments.

Mechanical stress is the pressure, shear, or stretch that influences the development, remodeling, and pathology of tissues. The ECM transduces internal and external mechanical loads into changes in cellular structure and function. Thus, the ECM plays an important role in maintaining a mechanical environment compliant with proper tissue structure and function. The modification of the mechanical environment may affect the maintenance of tissue structure and differentiation by inducing changes in the ECM. These changes can include profound ECM remodeling, as shown by the increase in collagen synthesis and metalloproteinase activity in the presence of higher mechanical load. Mechanical stress is thought to regulate the production of ECM components by inducing the release of growth factors or by directly triggering intracellular signaling pathways. One important family of ECM receptors, integrins, has been shown to be critical for the transmission of mechanical cues to the cells. MAPK and NF-kB pathways are activated in response to variations in mechanical stress. In addition, tension within the cytoskeleton has been shown to be important for mechanotransduction, since ''relaxation'' induced by inhibiting Rho-dependent kinase prevents the induction of tenascin C in stretched fibroblasts. Interestingly, enhancer sequences that respond to static stretch have been identified in the tenascin and collagen XII promoters. Thus, in addition to ECM-response elements, the genome also possesses stretch-response elements within the sequence of specific genes.

The interaction between the ECM and cells plays a role in tissue homeostasis by controlling tissue remodeling, the migration of cells within the tissue, as well as the ECM integrity. An elegant design using different alignments of fibroblasts compared to the mechanical load (as defined by guidance cues) showed that the level of metalloproteinase expression remained high under conflicting guidance

cues, hence suggesting a potential mechanism for the control of ECM remodeling during wound healing. Since cell–ECM interactions are dependent on the mechanical load, the preparation of ECM or ECM-like scaffolds for tissue bioengineering will have to take into account the type of tensional forces that these scaffolds would create. Indeed, different preparations of collagen I (e.g. variations in concentration and pH of the polymerization reaction) were shown to influence fibril density, length, and diameter, and thus tensile mechanical properties of the ECM.

4.3 The Need for Additional Complexity: 3D Cocultures

This chapter has focused mainly on 3D culture settings that deal with ''monotypic'' cell models. However, tissues are made of complex interactions, occurring either by direct contact or via paracrine effects between multiple cell types. The next challenge in 3D culture is to develop systems that take into account an increasing number of tissue parameters. The knowledge obtained from monoculture of cells in 3D has been providing crucial information for this endeavor.

The influence of coculturing different cell types on phenotypes was observed early on by mixing epithelial and mesenchymal cells. The study of epithelial–mesenchymal interactions has gained increasing popularity for the understanding of tumor behavior. Indeed, peritumoral fibroblasts appear to promote epithelial tumor progression. In breast, carcinomas are typically associated with myofibroblasts. It has been shown that these myofibroblasts originate primarily from resident fibroblasts, although there are other precursor cells as well. Using a collagen matrix and breast tumor epithelial cells, a number of years ago, we developed a ''tumor microenvironment'' assay to recapitulate critical aspects of breast carcinoma in 3D cultures. These heterotypic cell culture models are likely to provide clues with regard to the influence of stromal cells on epithelial tumor progression. In addition, state-of-the-art techniques, such as microarray analysis, can be adapted for this kind of coculture setting and allows the identification of changes in gene expression profiles induced by heterotypic cell–cell interactions.

Cocultures are also being used to mimic normal tissue differentiation, and to maintain a specific cell population. Coculture of hematopoietic cells and stromal cells on a porous carrier has permitted a better expansion of hematopoietic progenitor cells, without the need for exogenous cytokines, compared to 2D coculture. A coculture system including Schwann cells and dorsal root ganglion neurons in the presence of laminin, is sufficient to provide a microenvironment that favors myelination. *In vivo*, breast luminal epithelial cells are surrounded by myoepithelial cells in the acinar structures. Recently, the use of separated luminal and myoepithelial cells has allowed recapitulation of the ''double-layered'' tube of breast terminal duct lobular units. The presence of myoepithelial cells was sufficient to induce luminal cell polarity in acini formed in 3D cultures in collagen I, whereas epithelial cells did not show correct polarity when cultured alone in collagen I (Fig. 6). Using this heterotypic cell culture model, it was demonstrated that normal myoepithelial cells dictate acini polarization through their ability to synthesize laminin-1. Thus, the development of new 3D coculture systems that include different cell types

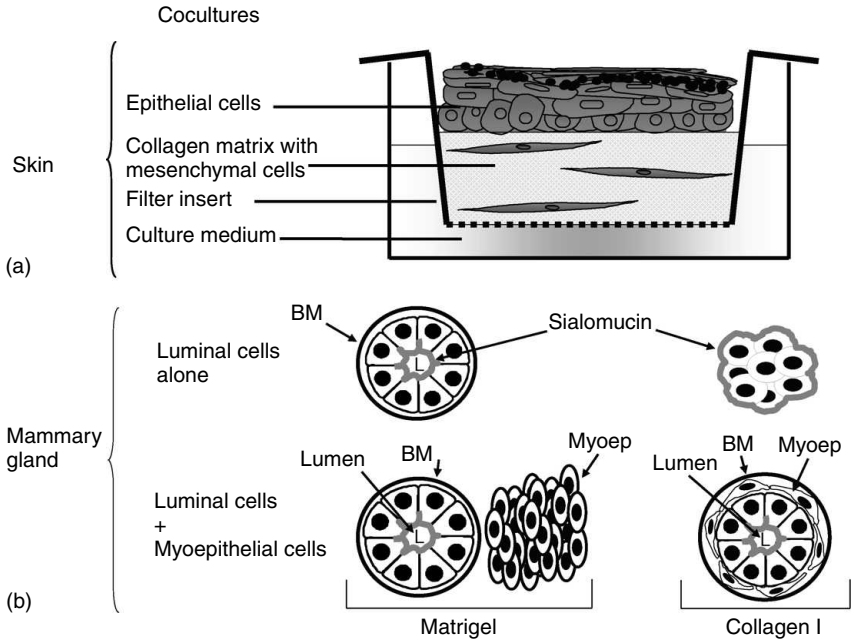

Fig. 6 Coculture models for skin and breast: (a) An experimental model to analyze differentiation of cultured keratinocytes *in vitro*. Keratinocytes have been cultured in organotypic cultures for many years. This particular system results in skinlike ''tissues'' that in the future could be used as grafts *in vivo*. To achieve this, keratinocytes are cultured on the top of a filter in the upper chamber, and the bottom chamber consists of collagen 1 gels mixed with mesenchymal cells. Medium is below the filter. (From Stark, H.J., Szabowski, A., Fusenig, N.E., Maas-Szabowski, N. (2004) Organotypic cocultures as skin equivalents: a complex and sophisticated in vitro system, *Biol. Proced. Online* **6**, 55–60 and by permission of the authors.) (b) Formation of complete breast epithelial structures (acini) in cocultures. Left panels: Matrigel culture of luminal epithelial cells alone (top) and a mixture (1 : 1) of luminal epithelial and myoepithelial cells (bottom). In Matrigel, luminal, and myoepithelial cells do not mix and each forms distinct colonies. Right panels: Collagen I culture of luminal epithelial cells (top) and a mixture (1 : 1) of luminal epithelial and myoepithelial cells (bottom). Mucin-1 (sialomucin) location is shown in light gray. Coculture in collagen I promotes formation of some dual layered and correctly polarized acinus. Symbols: BM = basement membrane; L = lumen; Myoep = myoepithelial cells. Cell nuclei are shown in black. (Schematic drawings of results from Gudjonsson et al., 2002a.)

found in normal and pathological tissues helps uncover specific interaction properties between cell types. Each new discovery brought by 3D cell culture models will further our knowledge in basic principles of tissue homeostasis and foster the development of optimal settings for tissue bioengineering.

Acknowledgments

We thank Penelope Siig for indispensable expert assistance with the preparation of this manuscript. We thank Drs. G. Steven Martin, Eva Turley, Celeste Nelson, Jordi Alcaraz, and Patricia Abad for critical reading of the manuscript. The work from

the authors' laboratories was supported by the US Department of Energy, Office of Biological and Environmental Research (DE-AC0376 SF00098 to Mina J Bissell), the National Cancer Institute (CA64786-02 to Mina J Bissell and CA57621 to Zena Werb and Mina J Bissell), US Department of Defense Breast Cancer Research Program (DAMD17-00-1-0226 and W81XWH-04-1-0670 to Sophie A Lelièvre), an Innovator Award from the US Department of Defense Breast Cancer Research Program (DAMD17-02-1-0438 to Mina J Bissell), and the Purdue Research Foundation and ''Friends You Can Count On'' Foundation (to Sophie A Lelièvre).

DNA Probe
DNA fragment carrying a suitable labeling marker that can hybridize with the target DNA.

Hybridization
To form double-stranded DNA between respective complementary single-stranded DNA and/or RNA by heating and cooling.

Polymerase Chain Reaction (PCR)
Amplification method of DNA with two primer sets by repeating denaturation, annealing, and extension with a heat-stable polymerase.

Single Nucleotide Polymorphism (SNP)
One nucleotide variation located on a chromosomal DNA in individuals, which is observed in the population at a frequency greater than 1%.

The investigations concerned with downsizing and integration of chemical experiments and processes on a chip attract great attention. These researches have not only brought about integration or miniaturization of whole chemical processes to the scale of a semiconductor integrated circuit but also provided several advantages such as the reduction of chemicals, waste, reaction space, and reaction and measurement time. These devices generally exploit micro size fluidic lines on the flat surface made of glass or plastic. The device thus obtained is called a *microfluidic device* and the system is called μTAS (Micro Total Analysis Systems) or Lab-on-a-Chip. Such devices have been evolving in the biotechnology area, especially as a gel electrophoretic DNA separation module for DNA sequencing. On the other hand, the research fields connected with the integration of many different DNA sequences on a small space also have been actively explored to provide a tool for high-throughput analysis of events associated with genes. This system is called a *DNA chip* and helps to collect genetic information closely associated with many genetic diseases. A DNA chip is expected to provide a future gene diagnosis method, since this research combined with the microfluidic system has been studied to develop a rapid pretreatment method of the sample. An electrochemical detecting method is more suitable for such a miniature system than the conventional fluorescent one currently in use.

1 Introduction

The Lab-on-a-Chip analysis technology is based on an idea that allows one to duplicate many of the experimental procedures normally carried out in a flask or beaker in the chemical laboratory on a small substrate or chip. The advantage of doing everything in a tiny space lies

in the fact that the time and the quantity of reagents required for analysis can be reduced drastically. In addition, the whole system may be automated easily by integrating complicated analytical procedures in the form of a circuit. To date, significant progress has been seen and a practical Lab-on-a-Chip analysis technology is now available for biochemical analysis and medical diagnosis. One of the large tasks in biochemical research is how to separate, identify, and quantify biomacromolecules such as nucleic acids and proteins efficiently. Analysis of their interactions with each other and small molecules simultaneously is another task in the biochemical and medical areas. Microfluidic devices carrying microdrains or microchannel on the chip made of silicon, glass, or plastic have been developed for the former purpose of the Lab-on-a-Chip. The latter goal was attained by microfluidics and a unit was furnished in this device; and biomolecules were detected by this unit. The separation in this system is commonly conducted by electrophoresis in the microfluidic device. Many researches concerned with electrophoretic separation of DNA especially have been reported and one of them is used for DNA sequencing on the chip. The latter example is represented by a DNA chip or protein chip. This system enables simultaneous analysis of massive amounts of samples at a time or high-throughput analysis of biomolecules, where one can estimate the specific interaction of the target biomolecules through their amount held on the reactants arranged as many matrix-patterned dots on a small substrate. This technology has been used not only in basic studies such as DNA expression analysis but also in drug discovery. Although this technology is useful and important, it contains many manual procedures such as the introduction step of the sample. DNA chips or protein chips furnished with whole procedures are becoming more and more important in the diagnostic area and an assembly of total analysis of biochip has been tried. In the Lab-on-a-Chip analysis technology, highly sensitive detection is required because of limited availability of biomolecules. Fluorescence markers are often used to label biomolecules directly or indirectly to ease analysis. For the trial of a self-contained DNA chip or protein chip, an electrochemical detector was devised to integrate all the components in these chip substrates.

Here, recent development of microfluidic devices and DNA chips are summarized as a Lab-on-a-Chip analysis technology. The integration of PCR for DNA amplification on the chip or the integration of an electrochemical detector discusses the former topic as realization of a self-contained chip system. In the latter topic, the basic principle of the DNA chip is reviewed with an emphasis on recent development in related areas. Combination of microfluidic parts with a DNA chip should enable pretreatment on the chip resulting in a self-contained DNA analyzing system.

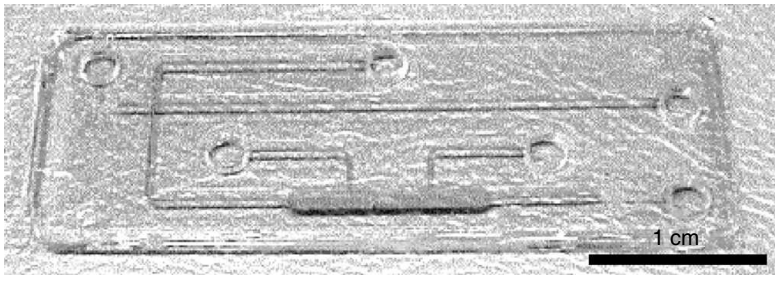
2 Principle of the μ-TAS

Here, the principle of an electrophoretic separation system of a microfluidic device is described as a typical example and an outline of the DNA chip is also described chronologically.

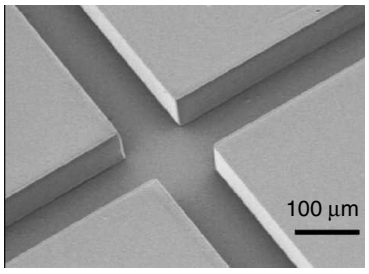
2.1 Microfluidic Device System

Separation and analysis with a microfluidic device were achieved on a drain or

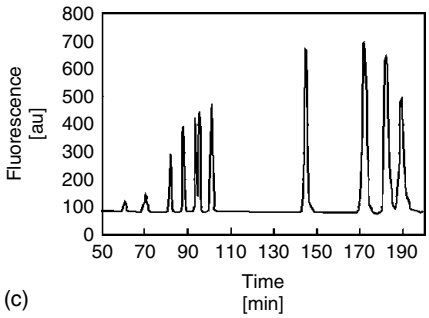
fluidic channel of about 100 μm width on the substrate made of silicon, glass, or plastic. At first, silicon was mainly used as an extension of the photolithographic technique commonly used to prepare integrated circuits in electronics. Since then, glass or plastic have been used from a viewpoint of the construction of an inexpensive disposable system. Poly(dimethylsiloxane) (PDMS) initially used in this system was insufficient to dissipate the Joule heat and acrylic polymers overcame this problem. Figure 1 shows an example of a plastic microfluidic device prepared by injection molding. The drains or microchannels are filled with gel and electrolyte and DNA is separated according to its size by electrophoresis like in capillary gel electrophoresis. The linear polyacrylamide has been used as the filling gel in this system but nanosized particles in place of such a polymer enable better separation. Figure 2 shows the cross-type microfluidic channels carrying circular wells called a *reservoir* at each terminus. A typical separation procedure is explained with this system. The sieving material such as polyacrylamide and electrolyte are filled over the microchannel. The locations of the circular wells are shown in Fig. 2A(a–d). The DNA sample is injected into the well as shown in Fig. 2A and electrodes are dipped in (a) and (b), and a high voltage is applied between (a) and (b) to transfer the sample to the channel between (a) and (b) by an electroosmotic and electrochemically driven flow. When the sample reached and filled the position of the cross-type channel on the microfluidic device (Fig. 2B), the electrodes are switched to wells (c) and (d),



(a)



(b)



(c)

Fig. 1 (a) Example of a microfluidic device made of polymethylmetacrylate (PMMA) by injection molding (Enplas Laboratories, Inc., Saitama, Japan) 100 μm in width and 50 μm in depth (b) and separation of Hae III digestion fragments of. φX-174 DNA (c), which was stained with ethidium bromide and monitored by its fluorescence intensity.

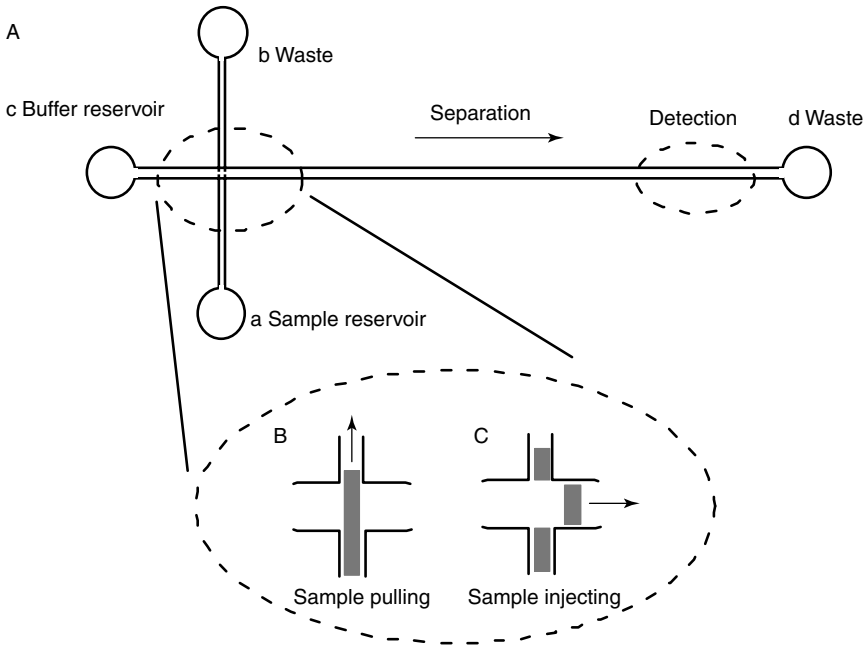


Fig. 2 Separation principle of a gel-filled microfluidic device for gel electrophoretic DNA separation.

and a high voltage is applied between (c) and (d) (Fig. 2C). The sample occupying the cross section is cut off and transferred to the fluidics line between (c) and (d). Continuous application of the voltage between (c) and (d) separates the sample in the separation channel, and the separated analyte is detected near site (d) usually by the fluorescence signal of labeled analyte emitted upon excitation with a laser. Such a type of microfluidic device allows introduction of an extremely small volume (100 pl in the case of 100-μm width and 20-μm depth) for each sample in the cross section of the fluidics line with high reproducibility. Theoretical investigation revealed that the diffusion rate constant of analytes in the microchannel increases with an increase in the strength of electric field but the separation efficiency is not improved. Nevertheless, this microfluidic device can effectively dissipate the heat (in Joule), produced by applying a high voltage during electrophoresis, and shorten the separation time without band broadening by the applied higher voltage from that in the ordinary capillary gel electrophoretic separation system. An optimized microfluidic system gave a 10 to 100 times shorter separation time than the conventional slab or capillary gel electrophoresis system. The microfluidic device was also applied to gene type testing and achieved ultrafast allelic profiling of short tandem repeats (STRs). This typing was successfully achieved by a microchannel that was 2.6 cm in length in 30 s, as compared with 2 to 3 h of slab gel electrophoresis and 10 to 30 min of capillary gel electrophoresis. Recently, some companies launched a microfluidic device for the separation of biomolecules. For example, a glass type microfluidic device is commercially available from Cariper Technologies Corporation

and Agilent Technologies, and a plastic one from Aclare Biosciences Inc.

DNA sequencing is another application of the microfluidic device. The advantages of this system are effective cooling of the Joule heat generated by applying a high voltage in DNA sequencing because of a large surface area compared with the inner solution of the channel and integration of many channels on the device. A DNA sequencing system furnished with 96 channels on a silicon wafer of 10 cm diameter was reported by Mathies's group. A rotary confocal scanner suitable for this device was also developed by the same group, which enabled analysis of one sample within 90 s. A raw DNA sequencing rate >150 kb h^{-1} per microchannel was achieved, which is much faster than that attained with the conventional DNA sequencing.

The electrophoretic separation in the microfluidic device was carried out by the molecular sieve mechanism of polymer molecules in the microchannel. This separation was tested by microfabrication of many nanosize pillars in the microchannel. Such a type of device was realized by constructing many pillars of 30 nm diameter 500 nm apart from each other on the microchannel. When DNA goes through the pillars in the microchannel, the pillars serve as obstacles to retard DNA migration. The retardation time depends on its molecular size. Nanopillars that were 2700 nm in length, 500 nm in width, and 500 nm in spacing (with a high aspect ratio of height/width $= 5.4$) in a microchannel on quartz have been fabricated by the electron beam lithography technique and used for DNA separation. DNA fragments carrying a range from 1 to 38 Kb were separated as clear bands at the detection window of 1450 μm from the entrance of the nanopillar channel (25 μm in width and 2.7 μm in height) in 170 s. The theoretical plate number of the channels (380–1450 μm in length) is as high as 1000 to 3000 μm ($0.7–2.1 \times 10^6$ plates m^{-1}).

2.2 DNA Chip

DNA chips have become an indispensable tool in genome exploration, disease diagnosis, drug discovery, and toxicological research. The DNA chip is a small substrate carrying different kinds of single-stranded DNA fragments immobilized on its specified position as a probe. Where DNA sequences complementary to the probe are present in the sample, a double-stranded DNA is formed on the substrate surface by a process called *hybridization*. The resulting hybrid DNA is detected somehow, and to facilitate analysis sample, DNA is labeled usually with a fluorescence dye prior to hybridization. A typical experiment using a DNA chip is shown in Fig. 3. Many different kinds of DNA fragments are immobilized in the specified position on the substrate as a capture probe. After labeling sample DNA with a fluorescence dye, it is allowed to hybridize with the capture probe on the chip. When target DNA exists in the sample, a DNA duplex is formed on the spot carrying the complementary DNA sequence. After washing the chip, the hybrid DNA is visualized by surveying by confocal microscopy. The intensity of labeling dye on the chip is proportional to the efficiency of hybridization or the amount of the specific DNA fragment. Comparative gene expression experiments are a typical example of the application of the DNA chip, in which two different kinds of cells, for example, normal and diseased, are studied.

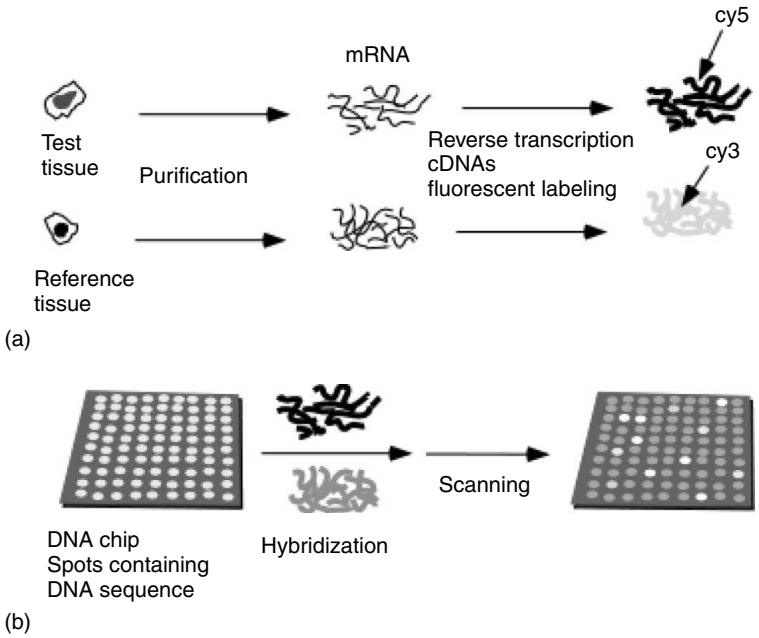

Fig. 3 Comparative gene expression analysis as an example of typical DNA chip experiments.

The purpose of this experiment is to quantify mRNA in the specific cell. In the first step, the extracted mRNAs are converted to cDNA by reverse transcriptase. cDNAs obtained from different cells are labeled with different colored fluorescence dyes, cyanine derivatives, Cy3 and Cy5, being used most often. cDNAs prepared from equal amounts of the cells are allowed to hybridize on the DNA chip. After hybridization and washing of the DNA chip, fluorescence images are taken by scanning. Information of gene expression in the cell can be obtained from the position and intensity of the fluorescence spot. Since the concept of DNA chip technology was conceived by Southern and coworkers in the early 1990s, many technologies have been devised with a focus on the immobilization method of capture DNA probe on the substrate. Two methods are mainly adopted to attach a capture probe on the substrate such as glass. The first approach of DNA chip preparation is direct DNA fragment (oligonucleotide) synthesis on the substrate by the computer-generated photolithographic mask, which defines the exposure site of the surface. In this approach, the light-directed synthesis of oligonucleotides is carried out combinatorially and all of the possible DNA sequences can be constructed on the surface with a limited number of synthesis. For example, the synthesis times of 4×7 give 4^7 kinds of DNA sequences. To reduce the cost associated with the photolithographic mask, *in situ* synthesis of oligonucleotides on the surface has been developed without relying on the photolithographic mask. The second approach to array fabrication is off-chip synthesis, which is more flexible and economical than the on-chip one.

The synthesized or extracted DNA fragment is spotted and covalently attached on the surface. The DNA chip produced by on-chip synthesis is commercially available from Affymetrix Inc. (Santa Clara, CA). Although the DNA chip technology is powerful, many manual procedures are involved such as the preparation of capture probes on the DNA chip surface and labeling of sample DNA with a fluorescent dye. To improve the performance of the DNA chip technology, especially for clinical disease diagnosis, it is important to upgrade the DNA chip technology with respect to cost, speed, and robustness, and also a totally self-contained gene analysis system needs to be assembled.

Recently, DNA chip technologies have been extended to proteome analysis, for example, in the form of a protein chip. Protein chips developed to date are categorized by antibody chip, peptide chip, protein chip, bead, or particle chip, which can be used as labeled particles in solution and specialized surface chemistry to perform combinatorial chemistry. The advantages conferred by its miniaturization might even be greater than those of the DNA chip systems.

3 Applications

3.1 Combination with Polymerase Chain Reaction (PCR)

It is necessary to concentrate the DNA as analyte on the microfluidic device to apply for DNA diagnosis. Polymerase chain reaction (PCR) is a useful technique suited for this purpose. A microfluidic device carrying a PCR unit has been developed from this point of view. PCR is a gene amplification reaction, where heat denaturation into the single-stranded form of DNA and enzymatic extension reaction to generate a double-stranded form are repeated several dozen times. A high-speed temperature changing device is necessary for PCR. Miniaturization of the reaction cell can improve the thermal exchange rate by increasing the ratio of the device surface to the reaction solution volume. When a heating and cooling system is introduced in a reservoir as shown in Fig. 2(a), the PCR product amplified there can be separated by the separation system on the microfluidic device described in Fig. 2. Ultrashort thermal cycling times of 17 s per cycle was achieved by infrared (IR) radiation-mediated heating and compressed air cooling of amplified DNA in capillary or on-chip microchambers was integrated onto microfluidic devices. Precise temperature control was achieved by controlling the light intensity by a system furnished with a tungsten lamp as an IR radiation source, thermocouple feedback computer interface coupled with an airstream.

A PCR system based on a microchannel was reported, where the microchannel crosses three distinct temperature zones of thermostatted copper blocks as shown in Fig. 4. As the PCR cocktail is pumped through the channel, it flows between the regions of different temperatures defined by three parts under the channel. The melting, annealing, and extension steps are executed by passing through the different temperature zones. In this system, the PCR cocktail is flowed to the different temperature channel instead of a temperature change in the same position of the microreactor. The channel incorporates 20 cycles giving a theoretical amplification of 2^{20}. A flow rate that provided a total cycling time of 10 min gave

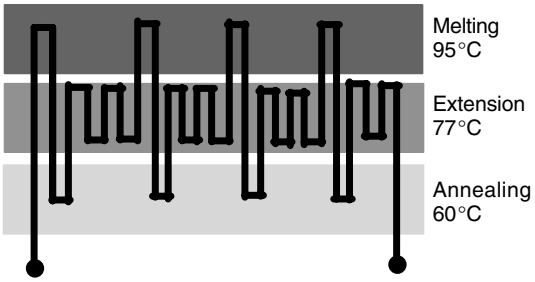

Fig. 4 PCR based on the microchannel. Three well-defined zones are maintained at 95, 77, and 60 °C by means of thermostatted copper blocks. The PCR cocktail is hydrostatically pumped through a single channel etched into a glass plate. The melting, extension, and annealing steps are defined by the channel passing through the three temperature zones.

70% of the yield of a fast commercial PCR themocycler in which the equivalent cycles took 50 min. A fivefold improvement in time was seen with little product degradation, free from the thermal inertia effect. Furthermore, the device allows multiple PCRs to run at a time on the same device, for example, by introducing a separate reaction loop.

3.2 Integration of an Electrochemical Detector on the Device

Fluorometric methods are commonly used for the detection of electrophoretically separated biomolecules such as DNA fragments on the microfluidic device. Following labeling of a sample directly (through a covalent bond) or indirectly (staining with a fluorescence dye), the fluorescence is detected by laser-induced fluorescence spectroscopy. However, it is difficult to incorporate a laser-induced fluorescence detector into this system to obtain a self-contained miniaturized and portable device. An electrochemical detection system would be an alternative to this and enables the development of a self-contained miniaturized analysis system with high sensitivity. Furthermore, both the detector and instrument may be miniaturized and the optical path can be omitted. In addition, even turbid sample solutions may be amenable to analysis. In summary, an inexpensive, low-power, and high-compatibility device can be constructed by advanced micromachining and microfabrication. To enable electrochemical detection of electrophoretically separated samples in the microfluidic device, the electrodes for detection (working, counter, and reference electrodes in the ordinary case) need to be incorporated into the outlet reservoir (Fig. 2A(d)). In this case, it is critical to position the detection electrode to avoid high potential at the separation microchannel (between c and d in Fig. 2A). Mathies and coworkers first reported an electrophoretic microfluidic device with an integrated amperometric detector where a dual-lead, platinum-working electrode 10 μm in width, is positioned just 30 μm beyond the end of the separation channel in the reservoir by the photolithographic technique. This is important, as this detection electrode finds itself just outside the high electric field applied for separation, and is effectively shielded from this field as a result. To place the working electrode just outside the exit of the separation channel, several types of electrochemical detectors were proposed by different types of arrangement between the microchannel and working electrode and the position of electrodes relative to flow direction. The distance between the separation channel outlet and working electrode affects the band broadening. When the working electrode is close to the separation channel, the

electrochemical response may be observed without band broadening, but may be less well shielded from the separation voltage. These detectors have mainly relied on microfabricated working electrodes as a thin or thick film, with the reference and counterelectrodes to complete the potentiostatic circuit, placed in the detector reservoir. Practical application of the electrophoretic separation based on a microfluidic device furnished with an electrochemical detector was reported not only for nucleic acids but also for neurotransmitters such as catecholamine, nitroaromatic explosives, organophosphate pesticides, or endocrine-disturbing chemicals such as chlorophenol derivatives. A complete self-contained microfluidic device will be realized through an on-device integration of the potentiostatic circuit and other functional elements such as preconcentrator.

3.3 Electrochemical DNA Chip

Incorporation of an electrochemical detector to the microfluidic device for the laser-induced fluorescence detector should yield a true Lab-on-a-Chip analysis device. The current DNA chips require a large-sized detecting system of a laser-based fluorescence scanner. Therefore, when an electrochemical detector is replaced for the fluorescence detector of a DNA chip, this also realizes a true DNA chip resulting in a portable gene diagnosis chip. The research along this line is still in its infancy. Nanogen Inc. (San Diego, CA) constructed a variety of microelectronic chips including 25–10 000 addressable electrodes and has developed an electronic DNA chip preparation process. Since oligonucleotides and DNA have negative charges at the phosphate backbone, their movement can be electrochemically controlled, leading to the electrochemically accelerated hybridization and electrochemical denaturation on the chip. Controlled electric fields have been used for discriminating oligonucleotide hybrids with varying binding strengths such as those between the completely matched and single-base mismatched and for removing unhybridized DNA. Such fine-tuned electronic stringency selection obviates the need for extensive washing. This approach is now successful in the analysis of single nucleotide polymorphisms (SNPs), STRs, insertions, deletions, and other genetic mutations. The electronically regulated sample preparation process was demonstrated for the dielectrophoretic separation of *Escherichia coli* from blood cells. After the isolation, the bacteria are lysed by a series of high-voltage pulses. Hybridization on this chip is detected fluorometrically. Electrochemical detection of DNA hybridization is a long-sought goal, as it will enable label-free detection of DNA or protein binding as well as curtailing the amount of reagents and processing costs, and amenability to portability and miniaturization.

As an approach to electrochemical detection of DNA hybridization, Motorola Clinical Micro Sensors Inc. (Pasadena, CA) and TUM-gene Inc. (Chiba, Japan) did pioneering work. They aim at a point-of-care diagnostic chip with a small battery-operated instrument. Motorola constructed a multielectrode chip and introduced a ferrocene-labeled oligonucleotide as an electrochemically active DNA probe, instead of the fluorescence-labeled one. Two DNA probes carrying a complementary target DNA sequence were prepared as a DNA probe on the electrode and a ferrocene-labeled DNA probe. Since sample DNA is allowed to hybridize with these DNA probes, the ferrocene is fixed on the electrode only in the presence of target DNA

in sample DNA in the sandwich assay. The hybridized DNA is detected from the electrochemical response due to the ferrocene. TUM-gene has developed a simultaneous multiple mutation detection (SMMD) method, which enables simultaneous discrimination of several genetic mutations such as SNP, insertion, deletion, translocation, and STR, using a multielectrode DNA chip and a double-stranded nucleotide specific threading intercalator, ferrocenylnaphthalene diamide (FND). In this method, target genome is amplified by the first PCR and then the second asymmetric PCR with a specially designed primer set. The second PCR products are applied on two electrodes containing either a wild-type (Wt) or a mutant type (Mt) probe. After completion of the hybridization and ligation reactions of the PCR products with the probes, each electrode is washed and immersed in an electrolyte containing FND, and the electric current at specified potential for FND is measured. Genotype (Wt/Wt, Wt/Mt, Mt/Mt) were determined by calculating the ratio of current signals from the Wt probe and Mt probe. The validity of the SMMD method was examined for lipoprotein lipase gene mutation by blind testing 50 patients' samples including 2 Mt/Mt homozygotes and 6 Wt/Mt heterozygotes. As expected, all of samples of human lipoprotein lipase (LPL) mutations, which are connected with hypertriglyceridemia or high neutral lipid concentration in the blood, were identified by this method correctly, indicating that the SMMD method can be used reliably for screening of the genetic mutations for routine clinical patient samples. Both techniques succeeded in detecting hybridization electrochemically with a DNA chip, which will eventually turn to a self-contained, miniaturized, and portable device. However, it is noted that time-consuming manual procedures such as extraction of DNA from the sample and PCR are still involved.

3.4 Combination of a DNA Chip with a Microfluidic Device

Microfluidic devices capable of carrying out sample pretreatment, PCR, and detection on a DNA chip are needed for automated clinical diagnosis. Such a system has not yet been completed, but various attempts have been made. Fusion of microfluidics and DNA chips will be useful with the advantages for both sides. Microfluidic channels can be utilized as an autotransport system to deliver controlled volumes of sample and reagents in a DNA chip. Nanogen developed a way to regulate hybridization electrochemically as discussed earlier and DNA sample and reagents are introduced to the DNA chip through fluidic networks made by injection molding. The automatic, real-time monitoring of hybridization of target DNA with the capture DNA fixed on the DNA chip will be achieved by the combination of precise temperature and fluidic control. This will in turn enable automatic selection of assay parameters such as buffer species and the precise volume and temperature. Finally, this microfluidic device and DNA chip fusion system will automatically select optimal parameters for hybridization on the chip. Furthermore, this fusion system will allow kinetic monitoring of the hybridization reaction on the chip.

Affymetrix Inc. reported for the first time a highly integrated monolithic device made of polycarbonate for automated multistep genetic assays. The detector of this device is a DNA chip made by photolithography and the overall device dimensions are less than those of a credit card. The device

can accommodate more than 10 reagents for over 60 sequential operations and is capable of extracting and concentrating nucleic acids from milliliter aqueous samples and performing microliter chemical amplification, serial enzymatic reactions, melting, mixing, and nucleic acid hybridization. The performance of the device was tested for mutations in a 1.6-kb region of the HIV genome from serum samples, where starting concentrations were as few as 500 copies of RNA. This device was produced in plastic rather than glass or silicon for economic reasons, since a disposable device is required for these clinical applications. Fluids were moved pneumatically from one chamber to the next in this chip.

Motorola groups have been developing plastic microfluidic devices carrying an electrochemical DNA chip and a micropump. Hybridization kinetics was studied using this chip and they tried to improve the hybridization efficiency by oscillation of hybridization mixture using a micropump. A self-contained, fully integrated device was constructed consisting of microfluidic mixers, valves, pumps, channels, chambers, heater, and DNA chip for sample preparation, PCR amplification, and DNA chip analysis. Instead of incorporating a DNA chip into the microfluidic device, a DNA array was prepared in the microfluidic channel hot-embossed in poly(methyl methacrylate) to allow detection of low-abundant mutations of *K-ras* in gene fragments that carry point mutations of high diagnostic value for colorectal cancers.

The DNA probes carrying a complementary DNA sequence for both sides of the point mutation were prepared: one has a point mutation site and zip-code sequence for being caught on the capture probe on the DNA array and the other has a near IR-dye IRD-880 for highly sensitive detection. When sample DNA has target point mutation, two kinds of DNA probes are joined together enzymatically by a process called an *allele-specific ligase detection reaction (LDR)*. Near IR fluorescence imaging of the DNA microarray on the microfluidic device could reveal the existence of the linked DNA probe on the corresponding zip-code sequence. This system can reduce the hybridization time from 3 h with the conventional DNA chip to less than 1 min and detect a point mutation in the *K-ras* oncogene at a level of 1 mutant DNA in 10 000 wild-type sequences. A disposable polymer microfluidic device holding a 1000-spot DNA array has been manufactured by microinjection molding. This device provides a powerful tool for highly parallel studies of kinetics and thermodynamics of duplex formation on the DNA microarray in the microfluidic channel to show that the hybridization in microfluidic hybridization assays is diffusion-limited due to the small diffusion coefficients of the DNA and RNA molecules involved.

3.5 Application in Protein Analysis

Application of a microfluidic device in protein research is becoming more and more important. At first, the device was used for sodium dodecylsulfate-polyacrylamide gel electrophoresis (SDS-PAGE) separation and detection of proteins after staining with a fluorescence dye. This novel technology offers an important tool for immunoassay, clinical diagnostics, biomedical science, and industry. Electrospray mass spectroscopy (ESI-MS) coupled with a microfluidic device especially is useful in the analysis of protein and peptides obtained by protease treatment. In proteome

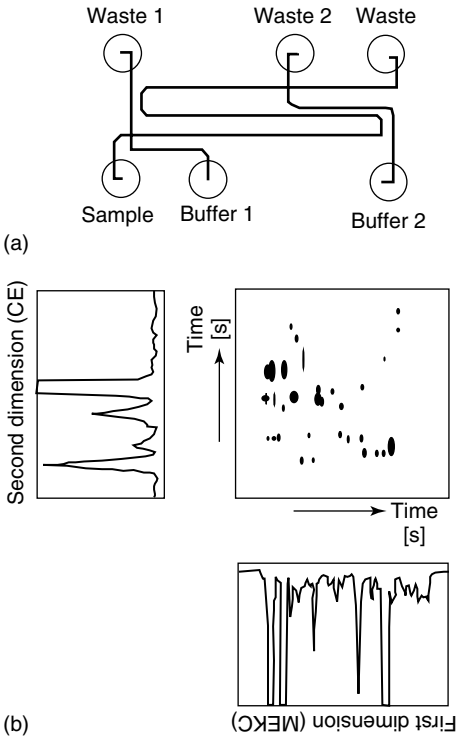

Fig. 5 (a) Illustration of a microfluidic device that enables 2-D electrophoretic separation of labeled peptides by MEKC and CE on a system. The 1-D separation channel extends from the first cross intersection to the second. The 2-D separation channel extends from the second cross to the point of detection. (b) Schematic cartoon of a 2-D separation map, which can be constructed from chromatograms of individual microfluidic separations.

analysis, two-dimensional electrophoresis is a powerful technology for separation of protein. Samples are separated in one dimension first by isoelectric focusing followed by SDS-PAGE separation in the second dimension. In this method, protein is first separated by the difference in isoelectric points and is further separated by the difference in molecular mass in the second dimension. Up to 10 000 different proteins can be separated on a gel, though a typical resolution is of the order of 5000. However, two-dimensional SDS-PAGE is a slow process taking up to two days for complete separation. This problem may be alleviated by a microfluidic system. The micellar electrokinetic chromatography (MEKC) with rapid channel electrophoresis (RCE) was used for the two-dimensional separation of peptides by using the microfluidic device carrying specially ordered microchannel construction as shown in Fig. 5(a). The peptides are separated by MEKC while at the same time the MEKC eluent is rapidly sampled for separation by RCE in this device and detected by laser-induced fluorescence. This device allows rapid sampling and separation, which are not easily achieved by conventional techniques. Figure 5(b) shows a two-dimensional map of separated protein, which can be constructed from the chromatograms from individual microfluidic separations.

4 Perspectives

Microfluidic devices, DNA chips, and the combination of both technologies were described here, focusing mainly on high-throughput analysis of genetic information. In this sense, these technologies are not simple extensions of the existing methods but a totally innovative analytical means suitable for research in the postgenome era. Powerful as they are, the current technologies suffer various weaknesses and they are being improved steadily. The information obtained by these technologies is useful in various areas, in pharmacogenomics, in particular, as it will help clarify the mechanism and side effects of drugs and boost molecular design of more effective

drugs. Such a device is the right step toward developing techniques that can replace two-dimensional electrophoresis. The application of a microfluidic device, integrating a flow cytometry unit, to the separation of cells was also reported. Like a microfluidic device, miniaturization of microplates has also been studied, which will be useful for high-throughput screening in drug discovery. Thus, the utilization of the microfluidic device has definitely spread very wide.

Keywords

Apoptosis
An organized form of cell death.

Canonical Pathway
NF-κB activation mediated by IKKβ phosphorylation of IκB.

IκB
Inhibitor of NF-κB.

IKK
IκB kinase, which contains at least three subunits named α, β, γ.

NF-κB
Nuclear factor that binds to κB enhancers.

Rel
The protein family that includes NF-κB.

NF-κB is a transcription factor found in most cells that plays a central role in the inflammatory, immunologic, apoptotic, and stress responses. NF-κB is a dimer composed of members of the Rel family of transcription factor subunits. It is normally sequestered in the cytoplasm by its inhibitor, IκB. Nearly all NF-κB-activating stimuli activate the IκB kinase, which phosphorylates IκB and thereby targets it for degradation. Newly freed NF-κB then enters the nucleus and mediates its various effects by activating its target genes. NF-κB activity is modulated by numerous mechanisms, including combinatorial specificity of its subunits and inhibitors, several forms of posttranslation modifications, and differences in signal transduction. NF-κB is of great therapeutic interest and we highlight its role in cancer and review modern drugs used to inhibit it. Finally, we discuss the role of NF-κB in learning, a hint that NF-κB has functions beyond those traditionally associated with it.

1 Introduction

In 1986, Sen and Baltimore isolated a small nuclear factor (protein) able to bind to the enhancer of and activate transcription of the immunoglobulin κ light chain gene in B cells, which they termed NF-κB. Originally this transcription factor was thought to be restricted to lymphoid cells, but it quickly became clear that NF-κB is present in most cell types

and that it regulates much more than immunoglobulins. Today, it is apparent that not only is NF-κB a transcription factor central to the regulation of the immune system, but it is also important in fundamental processes like apoptosis and cellular response to stress. For this reason, NF-κB is a topic of intense interest in a wide variety of laboratories.

NF-κB is an inducible transcription factor that responds to a bewildering array of stimuli including inflammatory molecules, viruses, bacteria, ''stresses,'' and medications. The list of the target genes of NF-κB is equally extensive, and includes immune cytokines and receptors, antiapoptotic genes, and various stress response genes. Given the pleiotropic nature of the signals, functions, and targets of NF-κB, one expects NF-κB to be subjected to a great deal of regulation and indeed this is the case. This review takes a bottom-up approach to the many layers of NF-κB regulation. First, we discuss the nature of NF-κB's targets, and examine the NF-κB molecule itself to understand how its structure influences its function as a transcription factor. Then we consider modes of direct regulation in the form of posttranslational modifications and interactions with its inhibitor IκB. We continue to ''zoom out'' and consider the major NF-κB-regulating signaling pathways and finally end with discussion of the broader implications of NF-κB in biology, medicine, and disease progression.

By way of introduction, we briefly describe here the consensus ''canonical pathway'' so that molecular details of NF-κB in Sect. 1–3 can be placed in proper context (see Fig. 4 and discussed further in Sect. 4.1). In the absence of stimulation, NF-κB is sequestered in the cytoplasm, bound to its inhibitor IκB. Nearly all NF-κB-activating signals converge on the activation of the IκB kinase (IKK). IKK phosphorylates IκB and thus targets this NF-κB inhibitor for degradation by an ubiquitin-proteasome pathway. Newly freed NF-κB then translocates to the nucleus and activates transcription of its target genes. Among these targets is the α-isoform of IκB, and newly synthesized IκBα enters the nucleus, binds to NF-κB and exports it to the cytoplasm. This returns the system to its original state and thereby provides signal downregulation.

2 Target Genes

Originally NF-κB was isolated as a factor that bound to the enhancer of the κ immunoglobulin light chain, and it was thought to be a transcriptional regulator restricted to B cells. However, it soon became clear that NF-κB was not only found in nearly all cell types but that it also regulated a wide variety of genes. Comprehensive lists of *bona fide* NF-κB targets indicate NF-κB regulates on the order of 200 to 300 genes, plus dozens more putative targets. A sample of such targets is provided in Table 1. The consensus NF-κB binding sequence for these genes is 5′-GGGRNNYYCC-3′ (G = guanine, C = cytosine, R = adenine or guanine, Y = thymine or cytosine, N = any nucleotide).

Grouping the target genes into broad families indicates why NF-κB is considered a central mediator of the immune response. NF-κB induces expression of chemokines and cytokines that modulate the immune response, many immunologically important cell surface molecules, cell adhesion molecules involved in movement and spatial targeting of leukocytes, and components of

Tab. 1 Selected target genes activated by NF-κB. See http://people.bu.edu/gilmore/nf-kb/target/ for a comprehensive list.

Class	*Example target genes*
Cytokines	IFNβ/γ, IL−1$\alpha/1\beta/2/6/8/9/10/11/12/13/15$, LT$\alpha/\beta$, TNF$\alpha/\beta$, TRAIL, RANTES
Immune-related	B7.1, CCR5/7, CD23/40/48/83/137/154, IL2Rα, IgCγ1/Cγ4/ε/κ, MHCI, β2m, TCR, TLR9, complement B/C4, CRP, LBP, β-defensin, tissue factor-1
Cell adhesion	ELAM-1, ICAM-1, P-Selectin, VCAM-1
Stress response	Angiotensin, COX-2, iNOS, SOD, Ferritin-H, CYP2E1, CYP2C11
Apoptosis	Bfl1, Bcl-xL, Bcl-2, c-FLIP, IAP, TRAF1, TRAF2, Fas, FasL
Growth factors	BMP2, G-CSF, GM-CSF, M-CSF, EPO, PDGFβ, VEGF
Transcription factors	c-Rel, RelB, p100, p105, IκBα, A20, c-myc, p53, junB, IRF-1/2/4/7, Stat5a
Viruses	Adenovirus, CMV, EBV, HBV, HIV-1, HSV, JCV, HPV16, SIV, SV40
Neuroreceptors	μ-opioid receptor, NPY receptor, NMDA (putative)

the complement system, among others. Interestingly, the expression of some viral proteins is also induced by NF-κB, which may allow some viruses to proliferate in immunostimulatory conditions and thereby avoid elimination by the immune system.

NF-κB target genes extend beyond the immune system. Of special importance is the fact that NF-κB upregulates various antiapoptotic genes, such as IAPs, c-FLIP, and Bcl-2, making it an important factor in cell survival. Also, since NF-κB is activated by reactive oxygen species, UV radiation, heavy metals, and similar noxious agents, and since NF-κB can upregulate antioxidant enzymes and factors like angiotensin II, iNOS, and COX-2, it has been proposed that NF-κB is more generally a central mediator of the cell stress response. However, ''stress'' is admittedly an amorphous concept, and the signaling pathways activated by stress are poorly characterized and not greatly specific to NF-κB activation as we shall see in Sect. 5.5.

It seems unreasonable to expect that any NF-κB-activating stimulus results in transcription of all its target genes. Indeed, there are several mechanisms by which specificity might be maintained. This includes differences in NF-κB promoter affinity, NF-κB/IκB/IKK composition and modification, activity kinetics, and signal-specific pathways. These forms of regulation are the subject of the next several sections.

3 Protein Domains and Crystal Structure

NF-κB is a dimer composed of five possible subunits, p65 (RelA), c-Rel, RelB, p50, and p52, (see Fig. 1) with the p65/p50 being the predominant heterodimer in most cells. (In this review, unless otherwise noted, we use NF-κB to denote p65/p50.) Thirteen of the 15 possible pairs of the 5 subunits can form *in vivo*, with the notable exception of RelB/c-Rel and RelB/RelB. These dimers not only differ in DNA-binding specificity, thereby contributing to specific gene activation and specific dimer functions, but

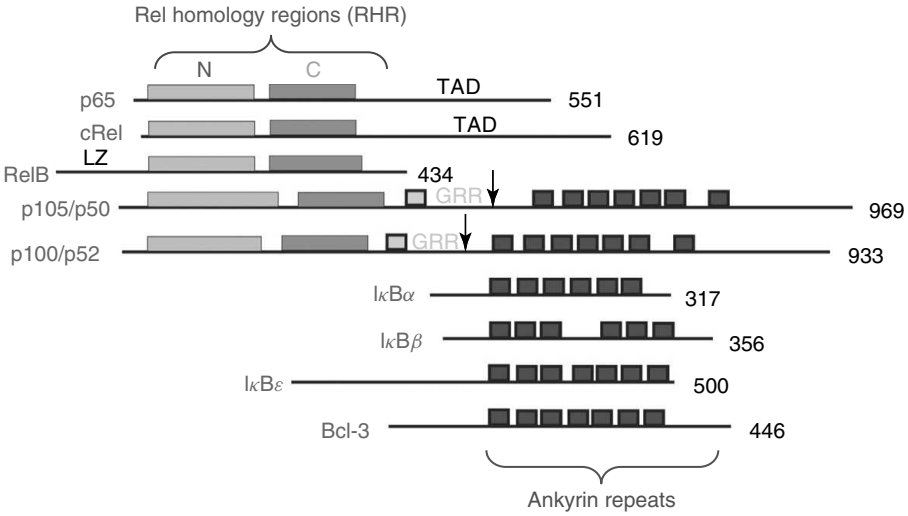

Fig. 1 Rel and IκB family members. p65, c-Rel, RelB, p105, and p100 share an N-terminal Rel-homology region (RHR) composed of two domains and a nuclear localization signal (NLS, see Fig. 2)). RelB also contains an N-terminal leucine zipper (LZ). p65, c-Rel, and RelB are transcriptionally active and contain C-terminal transcriptional activation domains (TAD). p105 and p100 are processed to p50 and p52 respectively by C-terminal proteolysis to the indicated point (arrow), which requires the glycine-rich region (GRR). p105, p100, IκBα, IκBβ, IκBε, and Bcl-3 contain 5–7 ankyrin repeats that mediate binding to Rel family members. The figure is based on ClustalW alignment of NCBI protein sequences NP_068810 (p65), NP_002899 (c-Rel), NP_006500 (RelB), NP_003989 (p105), NP_002493 (p100), NP_065390 (IκBα), NP_002494 (IκBβ), NP_004547 (IκBε), and NP_005169 (Bcl-3).

also differ in stability and affinity with the various IκB isoforms and therefore can be differentially regulated. In fact, stimulus-dependent alteration in dimer composition provides a direct mechanism by which NF-κB activity is modulated over time.

All five NF-κB subunits are related to v-rel, an oncogene encoded by the avian reticuloendotheliosis retrovirus that can induce acute leukemia in chickens. More generally, the Rel family is a group of evolutionarily conserved proteins and includes, for example, the *Drosophila* proteins Dorsal, Dif, and Relish, which are not only homologous in protein sequence but also have functions and participate in signaling pathways similar to that of NF-κB in humans. Interestingly, NFAT (nuclear factor of activated T cells) is a transcription factor that also has significant homology to Rel family members, but is primarily responsive to calcium/calcineurin signals.

All five subunits contain a ~300 amino acid N-terminal Rel-homology region (RHR), which is responsible for dimerization, DNA binding, and nuclear localization. Crystal structures of the p65, c-Rel, p50, and p52 homodimers as well as the p65/p50 heterodimer reveal that the RHR is composed of two domains each with immunoglobulin-like β-strand structure. When bound to DNA, NF-κB dimers adopt a unique butterfly-like structure (see Fig. 2). One set of ''wings'' is formed by the C-terminal domains of each RHR, which dimerize via interdigitating

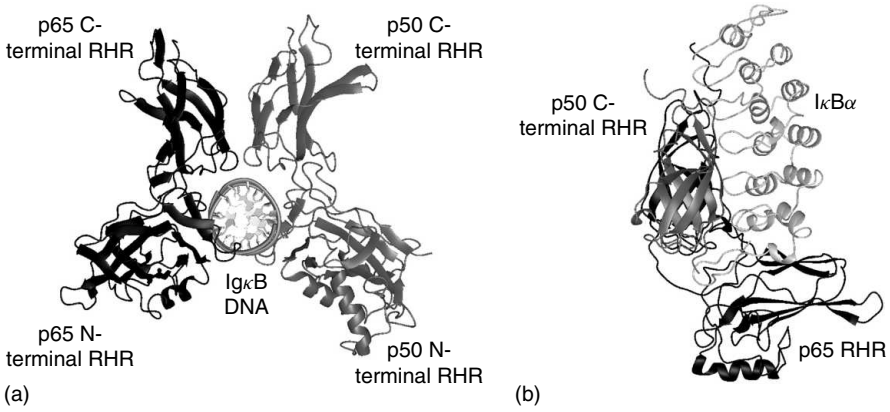

Fig. 2 Crystal structures of NF-κB. p65/p50 heterodimer bound to IgκB DNA (a) and bound to IκBα (b). p65 is shown in black, p50 in dark gray, IκBα in light gray (b), and IgκB in light gray (a). Images were created from protein databank accession numbers 1VKX (Chen, F.E., et al., (1998)) and 1IKN (Huxford, T., et al., (1998)) using Molw PDB Viewer 4.0 (Molecular Images) and Molmol 2.5.1.

hydrophobic side chains. These side chains as well as nearby polar/ionic amino acid interactions influence dimer stability. Another set of "wings" is formed by the N-terminal domains that form extensive contacts with the phosphate backbone of the DNA. The C-terminal domain also contributes to the dimer-DNA interface, although specific base pair recognition is mediated by the N-terminal domain. About a half-dozen key residues in the N-terminal domain mediate specific DNA binding, and combined with relative orientations of the subunits, largely accounts for the different binding affinities of the various NF-κB dimers to different DNA sequences. Additionally, only the major groove of DNA is bound by NF-κB dimers, and in some of them, no protein loops block the minor groove, which is thus open for potential simultaneous binding by other proteins such as HMG-I(Y). Finally, the C-terminal domain contains a nuclear localization signal (NLS), which allows free NF-κB to translocate to the nucleus.

Additionally, the p65, c-Rel, and RelB subunits contain a C-terminal transcriptional activation domain (TAD). However, p50 and p52 lack such a domain, which makes them transcriptionally inactive, with p50 and p52 homodimers serving to repress NF-κB target genes. Instead of a TAD, the C-terminus of p50 and p52 only contains a short glycine-rich region (GRR), a remnant of the C-terminus of their larger precursors p105 (NF-κB1) and p100 (NF-κB2). Interestingly, the C-terminal halves of these precursors, which are degraded, contain ankyrin repeats homologous to those of the IκB family. Thus, p105 and p100 can inhibit the other NF-κB subunits or the processed versions of themselves, a topic discussed in Sect. 4.2.

The NF-κB inhibitors, that is, the IκB family of proteins, have in common a series of 5–7 ankyrin repeats that mediate binding to and sequestration of the NF-κB proteins. In mammalian cells, the IκB family is generally considered to be limited to the three major isoforms IκBα, IκBβ, IκBε, as well as the p105 and

p100 NF-κB precursors, and the proto-oncogene Bcl-3. Discussion of the different functions of the IκB isoforms is postponed to Sect. 4.1, but here we note that there are also three lesser-studied members: IκBγ, which is identical to p105 C-terminus and is produced by alternative splicing; IκBζ, an apparently inducible IκB form; and IκBR, possibly a p50/p50-specific inhibitor. Additionally, Bcl-3 can also promote NF-κB activity by transcriptional derepression, that is, by inhibiting p50 homodimer binding to DNA, which has no transcriptional activity.

Crystal structures of IκBα bound to p65/p50 show that the ankyrin repeats of IκBα stack upon each other to form a slightly bent cylinder. Repeats 4–6 bind to the C-terminal domains of the RHR of p65 and p50, either causing the formation of or stabilizing the RHR N-terminal domains in a ''closed'' conformation incapable of DNA binding. Also, ankyrin repeats 1 and 2 interact with the NLS on p65, masking it from the nuclear import machinery. Together, these interactions help explain early observations that IκB not only sequesters NF-κB in the cytoplasm but also detaches NF-κB bound to DNA. IκBα (and IκBβ) also contains an N-terminal region that is phosphorylated in response to various signals and a C-terminal region that contains a PEST domain that regulates constitutive degradation, but neither of these regions were fully included in the crystal structure. Overall, the crystal structure of IκBβ bound to p65 homodimer is similar to the structure of the IκBα–p65/p50 complex, with the major differences relating to a longer loop between repeats 3 and 4 and an increased distance between repeat 6/C-terminus of IκBβ and NF-κB. It has been proposed but not shown conclusively that these differences could account for, respectively, the observations that IκBβ masks both NLSs of NF-κB and that it does not prevent DNA binding. In all, the reported crystal structures are immensely helpful in explaining a large volume of data regarding interactions between IκB, NF-κB, and DNA, and also provide an easy test for the plausibility of future proposed interactions.

4 Posttranslational Regulation of NF-κB

Posttranslational modifications provide an avenue of direct influence on the behavior of proteins and are a common mechanism of transcription factor regulation. NF-κB is no exception (see Fig. 3) and the major forms of posttranslational modifications known to affect its function are phosphorylation, acetylation, and ubiquitination. (Proteolytic processing may also be considered a form of posttranslational modification, but its discussion is postponed to Sect. 4.2, where it is considered in the context of the alternative pathway.) However, much of the work elucidating these mechanisms is relatively recent and, as a result, many questions remain unanswered.

The p65 subunit was early on recognized as a target for induced phosphorylation and it is evident today that p65 can be phosphorylated on numerous residues by a variety of kinases activated by different signals. The best-characterized phosphorylation site is serine 276. Initial evidence of its importance came as early as 1993, when it was discovered that mutation of the analogous site in c-Rel (S275) abrogated DNA binding. Phosphorylation of S276 in p65 by PKA or MSK1 increases the affinity of NF-κB for DNA and also promotes binding of coactivators like CBP/p300, which can then recruit the general transcriptional machinery. Other

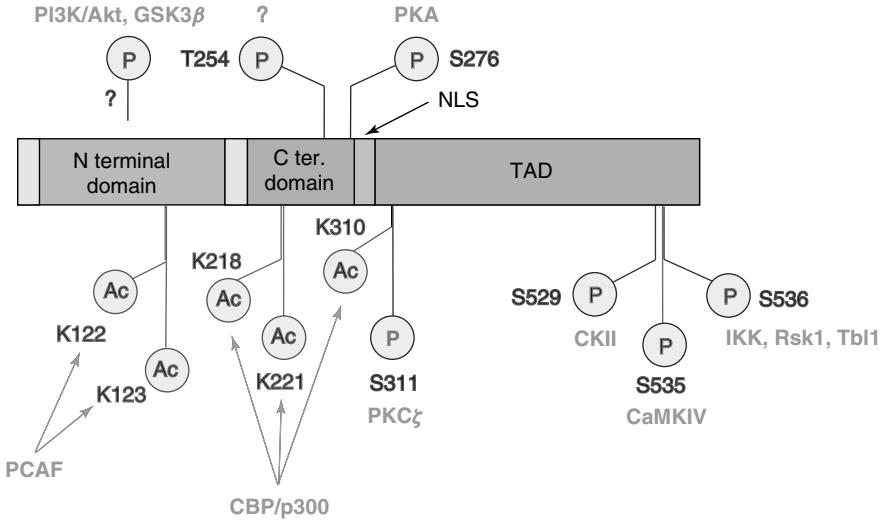

Fig. 3 Various phosphorylation and acetylation sites on p65 are indicated along with the corresponding enzymes. The sites are shown to scale and are explicitly identified. See text for more details.

C-terminal serines have been implicated as phosphorylation sites, including S311 phosphorylated by PKCζ, S529 phosphorylated by CKII, S535 phosphorylated by IKK/Rsk1/Tbk1, and S535 phosphorylated by CaMKIV. Finally, PI3K/Akt and GSK3β have been implicated in inducing p65 phosphorylation at unknown sites. Phosphorylation at any of these sites is associated with positive effects on NF-κB activity, but additional experiments are needed to establish the relative importance and biological role of these phosphorylation sites.

In recent years, acetylation of NF-κB has emerged as another important regulatory posttranslational modification. NF-κB is acetylated at several conserved lysines, although unlike phosphorylation, this modification may be activating or inhibitory depending on location. CBP/p300 can acetylate p65 at lysines 218, 221, and 310, which increases enhancer binding, decreases affinity for IκBα, and increases overall transcriptional activity. As CBP/p300 has also been implicated as a coactivator that binds to phosphorylated p65 (see above), this raises the possibility that NF-κB is brought to full transcriptional activity by phosphorylation followed by acetylation. NF-κB activity can then be downregulated by further acetylation of p65 at lysines 122 and 123 by p300 and PCAF (CBP-associated factor), reducing affinity of NF-κB for DNA. p50 also can be activated by acetylation at lysines 431, 440, and 441, hinting at a broad role of acetyltransferases in the regulation of different NF-κB dimers. Histone deacetylases like HDAC3 play a role in reversing these modifications and provide a potential mechanism whereby acetylation can reversibly regulate NF-κB activity.

A recent development has implicated ubiquitination in p65 regulation. The E3 ubiquitin ligase SOCS-1 mediates proteolysis of p65, and the peptidyl–prolyl isomerase Pin-1 protects p65 from this

degradation, provided p65 is phosphorylated at threonine 254 by a yet unidentified kinase. Pin-1 further promotes NF-κB activity by inhibiting association between p65 and IκBα. It is not clear whether these effects are limited to the specific tissues (breast epithelium and breast cancer cells) in which they were discovered, but this finding does demonstrate that there remains much to understand about the regulation of NF-κB at the level of the molecule itself.

5 Canonical and Alternative Pathway: Roles of IκB and IKK

5.1 Canonical pathway

Early experiments demonstrated that NF-κB and its inhibitor IκBα were locked in a negative feedback loop:

1. Nuclear and cytosolic protein extracts show no κ enhancer binding activity, but treatment of those fractions with detergents reveals as much NF-κB as found in the nucleus of stimulated cells, implying the presence of an inhibitor that keeps NF-κB inactive in the cytosol. This inhibitor, termed IκBα, was soon purified and later cloned.
2. Transient treatment by phorbol ester or TNFα causes degradation of IκB with concomitant NF-κB DNA-binding activity, followed by upregulation of IκBα mRNA, and replenishment of IκB with concomitant loss of NF-κB DNA-binding activity. This indicated that NF-κB regulates its own inhibitor.
3. The IκBα promoter contains at least one NF-κB binding site and failure to activate NF-κB leads to failure of IκBα transcription. Also, blockage of protein synthesis leads to persistent NF-κB activity and continued accumulation of IκBα mRNA. This demonstrated that NF-κB directly regulates its own inhibitor.

These observations formed the basis of the canonical pathway, which we discuss in detail in this section (see Fig. 4).

The canonical pathway hinges on the ability of NF-κB, IκBα, and their complex to move between the cytoplasm and nucleus, but attempts to understand the details of this mechanism have uncovered a more complex story. Nuclear import of free NF-κB is made possible by an NLS in the C-terminus of the RHR of p65, but p50 may contain a nuclear export signal (NES), which would antagonize NF-κB activity. Movement of free IκB and export of IκB–NF-κB complex is likewise believed to be mediated by an NES and NLS on IκB, but the exact sequences remain to be resolved. The consensus is that the ankyrin repeats of IκBα control nuclear localization, but it is unclear if this is due to a Ran-independent NLS near the second repeat, or if the ankyrin repeats recruit another protein, which then allows nuclear import via a Ran-dependent mechanism. IκBα contains a putative C-terminal NES, but multiple studies show that the true NES is actually in its N-terminus and its function is CRM-1 dependent. Nonetheless, it is clear that IκBα is capable of nuclear import and export on its own, which leads to the possibility that IκBα–NF-κB could move in and out of the nucleus independent of stimulus. Indeed, blocking nuclear export by pharmacologic inhibition of CRM-1 by leptomycin B leads to accumulation of IκBα and NF-κB in the nucleus. This demonstrates that despite the predominantly cytoplasmic localization of IκBα and NF-κB, they constitutively

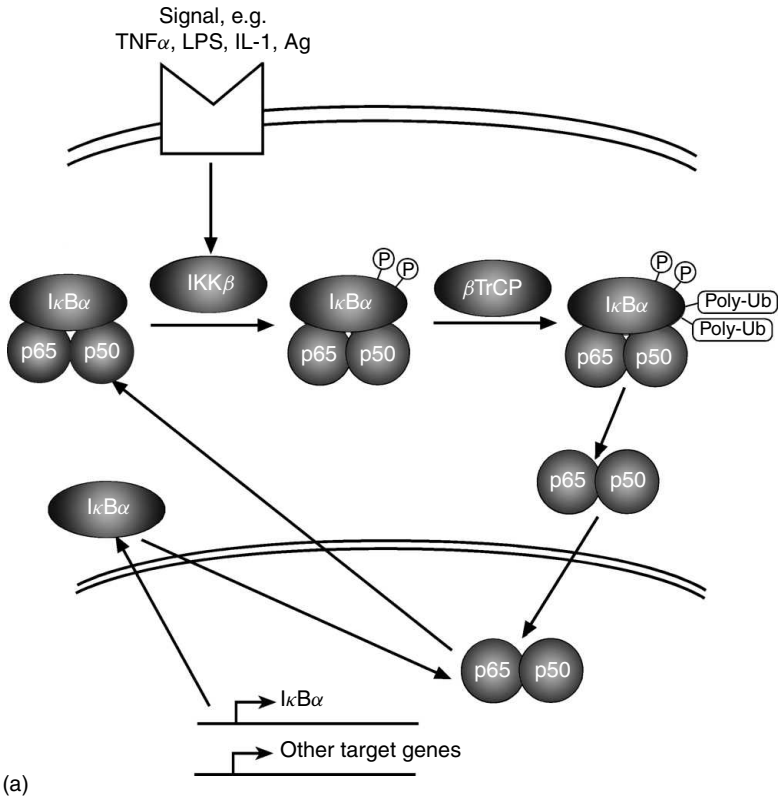

Fig. 4 Canonical and alternative pathways. (a) most stimuli activate NF-κB through the canonical pathway, which involves IKKβ-mediated degradation of IκB and involves a negative feedback loop through IκBα. (b) Some stimuli activate NF-κB through the alternative pathway, which involves IKKα-mediated processing of p100 to p52.

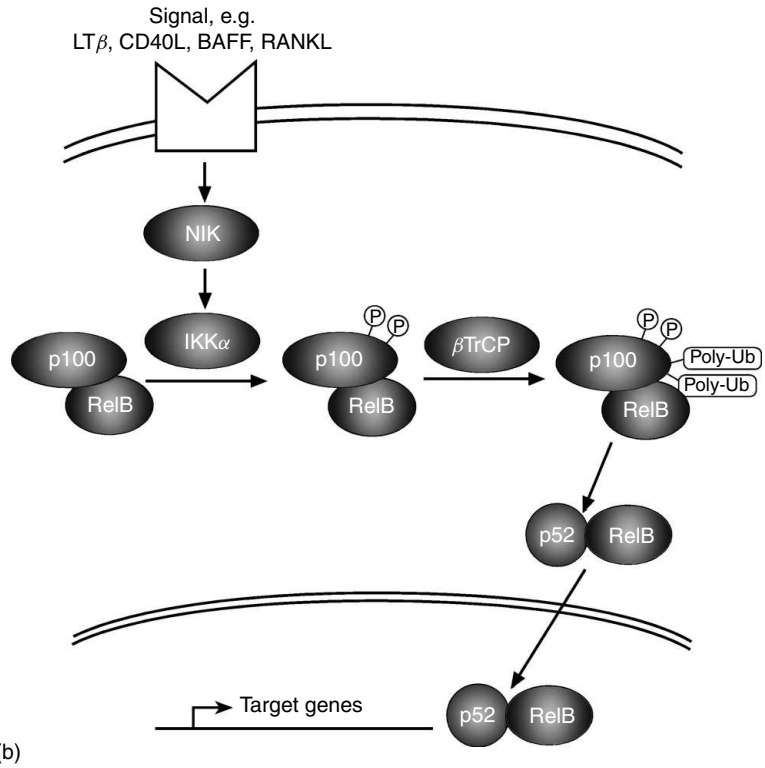
shuttle between the cytoplasm and nucleus. Consistent with this idea, shuttling is also observed in IκBε, which contains an NLS and NES similar to that proposed for IκBα, but not observed in the case of IκBβ, which has no identified NLS or NES. Shuttling of IκBα–NF-κB complexes may also be aided by the inability of IκBα to fully mask the NLSs of NF-κB. A quantitative model of shuttling suggests that it functions to inhibit the small amount of NF-κB not bound by IκB, due to a small but finite dissociation rate, but this model implies that the import and export rates of IκBα depend on whether or not it is bound to NF-κB, but how their interaction alters translocation rate is unclear. Needless to say, the mechanism and biological role of shuttling is still an open question. So, while it is clear that IκB and NF-κB are joined in a negative feedback loop, the dynamics of their interaction remain to be resolved.

More upstream in the canonical pathway, after discovery of the autoregulatory pathway, it soon became evident that a



(b)

Fig. 4 (*Continued*)

multitude of NF-κB-activating signals all resulted in phosphorylation of IκB at two conserved C-terminal serines (S32 and S36 in IκBα). Phosphorylation at these sites allows IκBα to be recognized by β-TrCP, the recognition subunit of an SCF-type E3 ubiquitin ligase that polyubiquitinates IκBα at lysines 21 and 22. This finally targets IκB for degradation by the 26S proteasome. However, several authors have noted that the primary form of β-TrCP is localized in the nucleus, which would imply that separation of NF-κB from IκB in the cytoplasm is not a prerequisite for accumulation of nuclear NF-κB, which is directly at odds with the canonical model. It is not currently clear how to resolve this paradox, but it seems likely that any explanation would have to take into account the aforementioned shuttling property.

IκBα is essential for regulating NF-κB, as evidenced by the observation that IκBα$^{-/-}$ knockout mice die perinatally due to multiorgan inflammation. However, the role of the two other major isoforms IκBβ and IκBε is unclear. The phenotype of IκBβ$^{-/-}$ knockout mice is unpublished but reportedly mild. Also, despite their clear differences in structure and response kinetics, IκBβ can substitute for IκBα with no obvious deleterious effects. IκBε$^{-/-}$ mice likewise have no discernible phenotype except a decrease in a subpopulation of T cells. Additionally, IκBε appears to interact primarily with

p65/c-Rel or p65/p65 dimers. Two features that IκBβ and IκBε have in common that distinguish them from IκBα is that they respond much slower to the same stimuli and they are not transcriptionally activated by NF-κB. Consequently, IκBβ and IκBε might function to dampen oscillations that arise out of the NF-κB–IκBα negative feedback loop, thereby sustaining a prolonged secondary response to persistent stimuli.

Recognition of the need for IκB phosphorylation to initiate an NF-κB response led to intense interest in identification of the responsible kinase. The IκB kinase complex was first isolated in 1997 and is now known to be composed of at least three subunits termed IKKα, IKKβ, and NEMO (also called IKKγ). IKKα and IKKβ are highly homologous catalytic subunits with kinase activity, with the former chiefly involved in the alternative pathway (see below) and the latter critical to cytokine-mediated NF-κB activation. NEMO is considered a regulatory subunit with no enzymatic activity and genetic studies also confirm it is a necessary component for cytokine-mediated activity. A fourth subunit, IKKε, was proposed as a member of the IKK complex, however, its requirement is limited to a subset of NF-κB-activating stimuli. Likewise, the ELKS protein was recently coimmunopurified with the IKK complex and identified as another regulatory subunit that appears to recruit IκBα to the complex, but further characterization of ELKS is needed to understand its role. The IKK complex has an apparent molecular mass of 700 to 900 kDa as determined by gel filtration, although the individual components total about 300 kDa. As a result, the exact stoichiometric makeup is of some debate and may not even be constant, although some have proposed IKKα–IKKβ–$NEMO_3$ and $(IKK\alpha–IKK\beta–NEMO)_2$. The mechanism of IKK activation is even more unclear, though the lack of conclusive evidence of an IKK kinase has lead to the general belief that autophosphorylation or proximity-induced trans-phosphorylation between IKKα and IKKβ leads to activation of IKK. More detailed structural analysis of the components than currently available is probably required to resolve this question.

5.2 Alternative Pathway

Several studies revealed that aly/aly (alymphoplasia, which harbors a natural mutation in NF-κB-inducing kinase, NIK) and $nf\kappa b2^{-/-}$ knockout mice had an overlapping phenotype of disturbed development or loss of peripheral lymphoid organs. This seemed to suggest that NIK and p100 were linked together in a common pathway controlling lymphoid development, and, indeed, in 2001 evidence emerged that NIK induces p100 degradation resulting in p52 formation through a phosphorylation–ubiquitination mechanism. Additionally, it was found that NIK can phosphorylate and activate IKKα, and that $IKK\alpha^{-/-}$ and inactive mutant $IKK\alpha^{AA}$ show a similar phenotype. Consistent with these observations, it was soon shown that IKKα, but not IKKβ, is preferentially involved in p100 processing. Further work by several laboratories demonstrated that p100 processing is specifically activated by LTβ, CD40L, BAFF, and RANKL binding to their respective receptors but not by canonical pathway activators like TNFα. So, the signaling pathway consisting of NIK → IKKα → p100 processing is distinct from the canonical pathway, and thus is termed the alternative pathway.

Despite characterization as such, the alternative pathway is tied to the canonical pathway on several levels. Signals that activate the alternative pathway also activate the canonical pathway and the canonical pathway can initiate transcription of p100. Also, NIK is a binding partner of TRAF2 (TNF receptor associated factor 2), which is an essential factor for canonical signaling by TNFα and p100 processing depends on the same βTrCP as the canonical pathway. Finally, LTβR can activate an overlapping but not identical set of genes via the alternative versus the canonical pathway. This raises intriguing questions about how the overlaps/differences in the components of the canonical and alternative pathways translate into shared/specific gene activation, questions that remain to be answered.

In contrast to p100, p105 is constitutively processed and is completely degraded following appropriate stimulus. Processing of both p100 and p105 clearly requires the GRR, which may act as a stop signal for the proteasome. However, the GRR is not alone sufficient and the sequences/mechanisms that mediate partial versus complete proteolysis remain to be identified. Signal-induced proteolysis of p105 is mediated by a canonical-like pathway, requiring phosphorylation at serines 927 and 932 by the IKK complex (independent of IKKα) and βTrCP-mediated ubiquitination on multiple lysines. This mechanism is somehow also dependent on phosphorylation of p105 at series 903 and 907 by GSK3β; however, the role of this kinase in the pathway is unclear. Degradation of p105 allows three distinct pathways to be activated. First, p105 releases p50, which can enter the nucleus and stimulate NF-κB-responsive genes. Second, p105 releases TPL-2, an MAP 3-kinase that mediates MAP kinase activity stimulated by LPS. Thirdly, p105 releases ABIN-2 (A20-binding inhibitor of NF-κB) a protein of unknown function that appears to downregulate the NF-κB response. Thus, while constitutive p105 processing probably provides a steady supply of p50 (for example, for association with p65), signal-induced p105 proteolysis is in part a *bona fide* arm of the canonical pathway.

6 NF-κB-regulating Signaling Pathways

Continuing to move upstream of NF-κB, here we further describe pathways that converge on NF-κB activation. There are more than 450 known NF-κB activators, including cytokines; bacterial, viral, or parasitic pathogens; and physical, chemical, or oxidative stress. It is beyond the scope of this chapter to review all of these stimuli in detail; however, we do turn our attention to those NF-κB-activating signals that have attracted the most attention (see Fig. 5).

6.1 TNFα

Tumor necrosis factor alpha (TNFα) is a soluble trimeric protein originally discovered as an antitumor factor produced during the immune response. Today, it continues to be recognized as a major proinflammatory cytokine, which is perhaps the best studied of the major activators of NF-κB. Furthermore, TNFα alone is a topic of great interest as it and its receptor are members of much larger families with functions perhaps as diverse as that of NF-κB itself.

TNFα activates the canonical pathway by first binding to and trimerizing its primary receptor, TNFR1. This causes SODD (suppressor of death domain), which is bound to TNFR keeping it

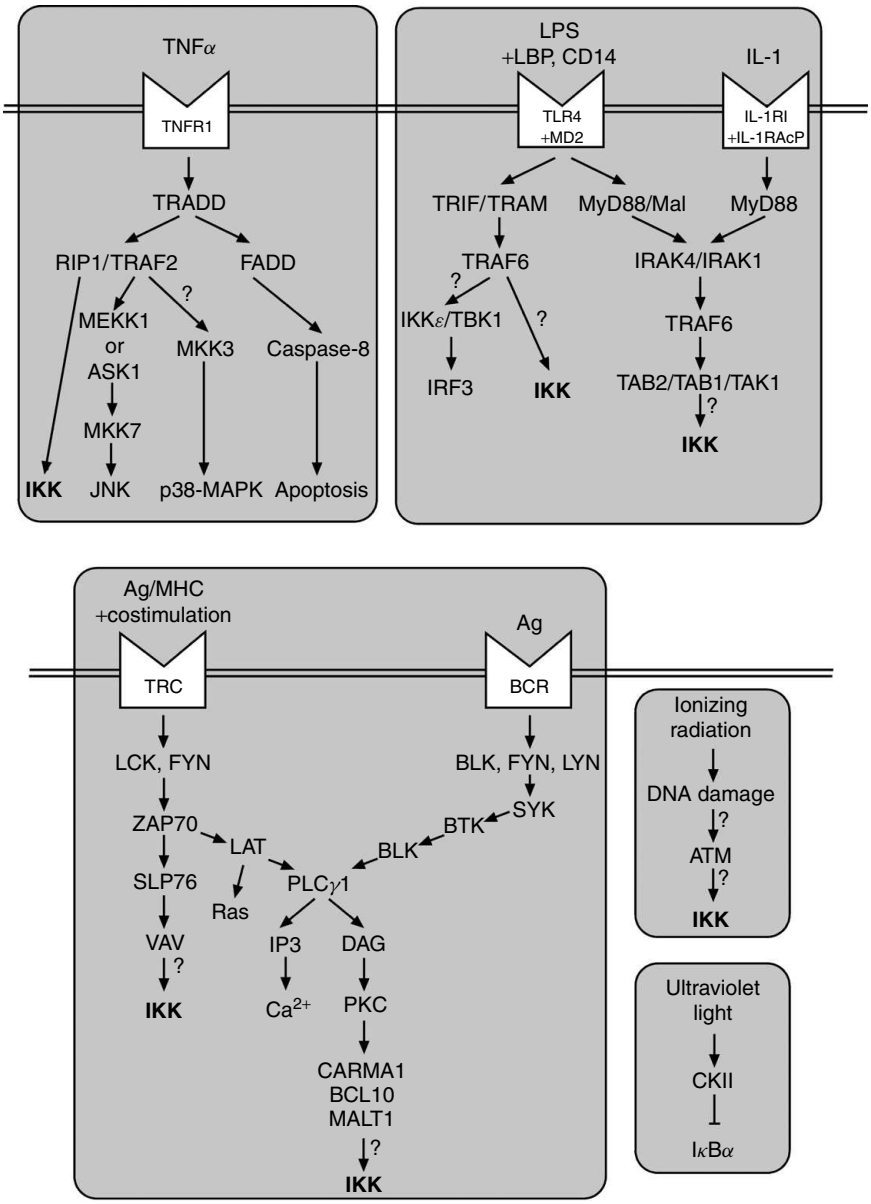


Fig. 5 NF-κB-dependent signaling pathways. The pathways from TNF, LPS, IL-1, antigens, ionizing radiation, and ultraviolet light to NF-κB are shown. Pathways that end in IKK continue via the canonical pathway. Indirect connections are indicated by question marks. See text for description.

in an inactive state, to be displaced by TRADD (TNFR-associated death domain). TRADD acts as a scaffold to recruit TRAF2 (TNFR-associated factor 2) and RIP (receptor interacting protein). In a simple model, TRAF2 further recruits IKK to the receptor with RIP required to activate IKK. However, the nature of interaction is more complex, as TRAF2 appears to destabilize IKK, whereas RIP may counter this action, and the kinase activity of RIP is not required for IKK activation. Nevertheless, somehow the RIP/TRAF2/IKK interaction appears to be sufficient for IKK activation. A few groups have proposed that RIP and TRAF2 recruit another kinase(s) capable of IKK activation, with the leading candidates being MEKK1 and MEKK3. However, neither has been shown to be absolutely essential in knockout studies. The lack of a genetically verified IKK kinase has lead to the hypothesis that proximity-induced autophosphorylation may instead activate IKK. Active IKK then phosphorylates IκB, stimulating the canonical pathway as previously discussed.

In addition to signaling via NF-κB, TNFR1 can activate at least three other pathways. One is the extrinsic apoptotic pathway, which for TNFR1 is widely believed to be mediated by TRADD. TRADD may bind FADD via their homologous death domains, and FADD can recruit the apoptosis initiator caspase-8 to the receptor to form the DISC (death inducing signaling complex). Now in close proximity on the DISC, the caspases molecules can cleave and activate each other. This initiates a cascade of proteolysis, as caspase-8 can proteolytically activate other caspase family members, which in turn cleave a wide assortment of target proteins, ultimately leading to apoptosis. It should be noted, however, that while the DISC has been isolated on *bona fide* death receptors like Fas, the same cannot be said about TNFR1, raising the question whether TNFR1-DISC is unstable or whether apoptosis is mediated through some alternative mechanism(s).

The second pathway clearly activated by TNFR1 is JNK (c-Jun N-terminal kinase). This may occur by either of two cascade mechanisms: TRAF2-dependent activation of the MAP 3-kinase MEKK1 phosphorylating MKK7, which in turn, phosphorylates JNK, or TRAF2-dependent activation of ASK1 phosphorylating MKK7, which phosphorylates JNK. JNK can then regulate other molecules by its kinase activity, most notably activating the c-Jun transcription factor. Though the evidence is somewhat equivocal, JNK appears to have a generally proapoptotic effect. For example, JNK has been implicated in the activation of proapoptotic molecules, such as Smac, Bim, and Bmf and the inhibition of antiapoptotic molecules such as cIAP, but the respective mechanisms are poorly characterized.

Finally, TNFR1 can robustly activate the p38 (a MAPK) pathway. This pathway appears to pass through TRAF2/RIP and the MAP 3-kinase MKK3. p38 has roles in mediating the inflammatory response, but may also antagonize the actions of NF-κB. This raises intriguing questions about how the NF-κB and p38 pathways interact, but additional work in this area is required.

One interesting aspect of TNFR1 signaling is that its stimulation can result in two entirely opposite effects. Under different circumstances, and depending on cell type, it can stimulate cell proliferation or induce apoptosis. Although normally TNFα binding does not lead to apoptosis, in situations in which NF-κB activity is diminished, this potential effect becomes apparent. This is most aptly demonstrated by $p65^{-/-}$ knockout mice

that suffer embryonic lethality due to massive liver apoptosis, a phenotype that can be rescued by also knocking out TNFR1 or TNF. These two different effects are probably a result of the ability of TNFR1 to activate both the antiapoptotic NF-κB pathways, the directly apoptotic DISC pathway, and the conditionally apoptotic JNK pathway, thereby raising important questions about how these pathways interact. NF-κB activates transcription of many survival factors including c-FLIP and IAPs, and these inhibit apoptosis at the level of the DISC. Likewise, other target genes of NF-κB, such as GADD45β and XIAP also inhibit JNK activation. On the other side, multiple components of the canonical pathway can be cleaved by effector caspases. So, while TNFα primarily elicits a proinflammatory response and not apoptosis, the cross talk between the various TNFR1 signaling pathways may function as a switch, which under some circumstances, commits the cell to death.

6.2 LPS

Lipopolysaccharide (LPS) is a component of the outer membrane of gram-negative bacteria. Systemic infections by such bacteria lead to accumulation and disseminated exposure to this potent toxin, which initiates an overexuberant inflammatory response ultimately leading to vasodilation, a severe drop in blood pressure, and septic shock. LPS is also a well-known activator of NF-κB, whose upregulation of many humoral mediators contributes significantly to this syndrome. Understandably, the signaling initiated by LPS is of major interest in infectious disease and immunology.

The receptor for LPS is Toll-like receptor-4 (TLR4), which was firmly established in 1998 by the discovery that C3H/HeJ mice that were resistant to LPS contained a single point mutation in the intracellular domain of TLR4. TLR4 is homologous to Toll, a *Drosophila* receptor tied to a very similar signaling pathway. More generally, the Toll-like receptor family (TLR) recognizes the so-called pathogen associated molecular patterns (PAMPs) and have an evolutionarily conserved function to combat infectious disease. TLRs are, in turn, part of the IL-1/TLR superfamily, which explains the great overlap between LPS and IL-1 signaling described later.

LPS does not bind its receptor by itself; rather several extracellular proteins are involved. In the simplest scheme, LPS is recognized in the bloodstream by LPS-binding protein (LBP). Soluble or membrane-bound CD14 then recognizes the LPS–LBP complex, which promotes loading of LPS onto the receptor. Furthermore, TLR-4 requires MD-2 to be associated with it to transduce LPS signals. Other additional molecules such as HSP70, HSP90, CD11, CD18, CD55, chemokine receptor 4, and growth differentiation factor-5 have also been implicated as components of the LPS receptor complex but their roles are unknown at this time. In this context, then, LPS induces TLR4 to dimerize and initiates signaling.

TLR4 can signal through at least two pathways, termed MyD88-dependent or MyD88-independent, both of which can activate NF-κB via IKK. MyD88 (myeloid differentiation factor 88) was the earliest known adaptor protein for TLR4 and is able to bind the receptor through homotypic interaction of the TIR (Toll/IL-1R) domains on each protein. In MyD88-dependent signaling, a second essential adaptor called Mal (MyD88 adaptor-like) is also required, but its exact role is unclear. Nevertheless, MyD88 binds IRAK-1 (IL-R1 associated

kinase-1) and promotes its activation by IRAK-4 mediated phosphorylation. Active IRAK-1 then leaves the receptor complex and binds to TRAF6, which in turn binds to TAB-2. The TRAF6/TAB-2 complex activates the adaptor-MAP kinase complex TAB-1/TAK-1. Finally, TAK-1 has not only been implicated in the activation of IKK, and thereby in NF-κB, but also in the JNK and p38 pathways. Alternatively, it has been proposed that TRAF6 activates IKK via other MAPK cascade members. However, the proposed links between TRAF6 and IKK have been criticized for lack of genetic experiments clearly demonstrating the role of these components in IKK activation.

TLR4 can also activate NF-κB via the MyD88-independent pathway, albeit in a delayed and much less potent fashion. This pathway relies on the TLR4 adaptors TRIF (TIR domain-containing adaptor inducing interferon β) and TRAM (TRIF-related adaptor molecule). The subsequent downstream events are unclear, but it has been suggested that IKK activation is again dependent on TRAF6. Also, as the name suggests, TRIF and TRAM can activate interferon-β expression. The mechanism is likewise unclear, but appears to involve IKKε and TBK-1 activation of IRF3, a transcription factor whose targets include interferon-β. Interestingly, p65 has also been implicated in the interferon arm of the MyD88-independent pathway. Thus, LPS is intimately linked to NF-κB by several mechanisms and therefore NF-κB plays a key role in the host response to pathogens.

6.3 IL-1

Interleukin-1 (IL-1) is the founding member of an ever-increasing family of cytokines that modulate inflammation and the immune response. IL-1 is primarily produced by macrophages and mediates a variety of physiologic effects, including stimulating fever and inducing synthesis of a variety of inflammatory mediators and adhesion molecules. It has a particularly prominent role in rheumatologic disease. The cloning of IL-1 cDNA in 1984 opened the door to understanding, on a molecular level, how IL-1 mediates so many different effects, and here we will briefly consider how IL-1 signals through NF-κB.

IL-1 actually represents a family of three proteins, IL-1α, IL-1β, and IL-1Ra. IL-1α and IL-1β both bind to the type I IL-1 receptor (IL-1RI) and have nearly identical effects, and indeed prior to their cloning the presence of two different molecules was a source of great confusion about whether one molecule could be responsible for such a broad range of effects. IL-1α is an acidic form not usually secreted into the extracellular environment, whereas IL-1β is a neutral form that is found in the bloodstream. For this reason, IL-1 generally refers to IL-1β unless otherwise noted. IL-1Ra also binds to IL-1R and acts as a receptor antagonist.

IL-1RI is the signaling receptor for IL-1 and is the founding member of the IL-1R/TLR superfamily. This superfamily is linked by a common intracellular TIR domain that mediates binding to TIR-containing adaptors. Members of the IL-1R subfamily contain three extracellular immunoglobulin domains, which differ from the extracellular leucine-rich region in the TLR subfamily. IL-1RI alone is not sufficient for IL-1 signaling, as IL-1RAcP (IL-1R accessory protein), also a member of the IL-1R/TLR superfamily, is required. However, IL-1 only binds IL-1RI, and it is not clear if IL-1RI is constitutively or inducibly associated with IL-1RAcP. In

any case, IL-1 causes trimerization of IL-1RI and initiates a signaling cascade to NF-κB identical to that of the MyD88-dependent pathway TLR4 (see above), with the important exception that IL-1 signaling does not require the Mal adaptor. IL-18, whose receptor is also a member of the IL-1R/TLR superfamily, likewise signals through the same MyD88 pathway. So, it is through these conserved pathways that NF-κB once again can be seen as a central mediator of the inflammatory response.

6.4 Antigens

The adaptive immune response is initiated when an antigen drives activation and proliferation of specific T and B lymphocytes. These cells cooperate to produce antibodies against the antigen and target and kill cells displaying such antigen, thereby mounting a specific host defense against the antigenic source. Antigens activate T and B cells through TCR (T-cell receptor) and BCR (B-cell receptor), respectively, and both of these receptors activate NF-κB, among other pathways. Thus, NF-κB is intimately linked with the adaptive immune response, and combined with the above descriptions of the role of NF-κB in inflammation and the innate immune response, one can see why NF-κB is often referred to as a central regulator of the immune system as a whole.

We first address connections between TCR and NF-κB, remembering that the pathways relaying BCR to NF-κB are quite similar. The TCR is activated when it binds to antigen held by an MHC (major histocompatibility complex) on the surface of an antigen-presenting cell (such as dendritic cells or macrophages) in the presence of costimulation, for example, B7 binding to its T-cell surface receptor CD28. TCR lacks intracellular enzymatic activity, and like TNFR1, IL-1R, and TLR4, requires adaptors to initiate signaling. Engagement of TCR causes tyrosine phosphorylation of its ITAM (immunoreceptor tyrosine-based activation motifs) by the Src-like kinases Lck and Fyn. This allows TCR to recruit ZAP-70 (TCR zeta-chain associated protein kinase, 70 kDa), another tyrosine kinase. At this point, there are two proposed routes for the signal to reach IKK and subsequently NF-κB. One route is that ZAP-70 phosphorylates the adaptor SLP-76 (SH2-domain containing leukocyte protein, 76 kDa), which in turn activates Vav, a GTP exchange factor. Vav then activates IKK through an unknown mechanism. The other pathway emanating from ZAP-70 goes through LAT (linker for activation of T cells), an adaptor that activates PLCγ1 (phospholipase C). PLCγ1 acts through its classical pathway, generating IP3 and DAG from the phospholipid PIP2. DAG can activate PKCθ (protein kinase C), an essential factor for NF-κB activation by the TCR. PKCθ then signals through CARMA1, Bcl10, and MALT1 in sequence, and MALT1 activates IKK through an unknown mechanism. IKK activates NF-κB through a canonical mechanism, which helps upregulate target genes such as IL-2 (a T-cell growth factor), antiapoptotic factors, and cell proliferation factors such as cyclin D, all of which promote T-cell activation.

With such a complex and indirect signaling pathway to NF-κB, it is not surprising that TCR can concomitantly robustly activate other major signal transduction systems. For example, IP3 produced by PLCγ1 causes release of calcium from intracellular stores, thereby activating the calcineurin-NFAT pathway. Likewise, LAT contains Grb-2 binding sites that may provide a link between the TCR and the Ras

pathway. Both the NFAT and Ras pathways cooperate with NF-κB to activate, among other targets, IL-2 and promote the growth of T cells specific to the encountered antigen.

The B-cell receptor is likewise important for B-cell development and activation, and NF-κB is one important pathway activated by BCR. As alluded to above, this activation occurs through a mechanism analogous to that of the TCR. An antigen molecule can bind to the BCR directly and induce its aggregation, which stimulates tyrosine phosphorylation of its ITAM motifs by Src-family kinases like Blk, Fyn, and Lyn. This recruits the tyrosine kinase Syk to BCR, and subsequently Btk via a PI3K-dependent mechanism. Btk activates the adaptor BLNK, which recruits PLCγ2 to the membrane. PLCγ2 mediates the production of DAG, which activates PKC. There are some questions about which PKC is activated, with possibilities including PKCβ or PKCλ, but these different observations may be accounted for by differences in B-cell maturation. PKC subsequently acts through CARMA1, Bcl10, and MALT1 to activate IKK, which finally activates NF-κB. This pathway, like that of the TCR, branches at several points to activate calcium, ERK, JNK, and p38 MAPK-dependent pathways, among others, hinting at the substantial complexity of the BCR signaling network.

6.5 Stress

Stress is an amorphous concept because stressors often lack tangible molecular receptors, in contrast to the pathways discussed above. Additionally, the stress itself may be intangible (e.g. radiation), come in multiple forms (e.g. various chemical oxidants), or is seemingly very nonspecific (e.g. osmotic stress). Nonetheless, as cells are routinely subject to stressful environments or stimuli, understanding the nature and response cell stress is of undeniable importance in cell physiology. It is additionally important from a clinical point of view in both pathophysiology and treatment, raising questions, for example, as to how oxidation contributes to major diseases like atherosclerosis, or how ionizing radiation (IR) therapy affects cancerous versus normal tissue. NF-κB is induced by a wide variety of apparently stressful stimuli and upregulates genes whose products might be useful in weathering the stress. In this section, we examine the most studied NF-κB-inducing stressors: oxidation, ionizing radiation, and ultraviolet light.

Oxidants like hydrogen peroxide were long known to activate NF-κB and early hypotheses even implicated oxygen radicals as second messengers in the TNF and IL-1 signaling pathways. However, increased understanding of the components of these pathways in the 1990s led to a consensus that oxygen radicals did not play a central role in NF-κB signaling. Furthermore, the importance of radical oxygen species (ROS) in activating NF-κB itself came under criticism, as effects of oxidant on NF-κB were found to be cell type- or stimulus-specific and the known components of NF-κB-regulating signaling pathways were found to be responsive to the redox state of the cell. Sadly, little progress has been made on these fronts and there is no clear mechanism by which the cell senses ROS and relays this information to NF-κB. Additionally, although many antioxidants are known to inhibit NF-κB, their effect may not be due to decreased upstream generation of ROS. Rather, they may instead target NF-κB signaling components. At this time, it is unclear what the relative importance of

ROS in stimulating NF-κB might be, although it is likely that ROS merely plays a facilitating role by modulating components of various signaling pathways.

Ionizing radiation has also long been known to activate NF-κB. Since NF-κB has antiapoptotic effects, the IR-NF-κB connection is of great interest to oncologists studying radiosensitivity, that is, the ability of IR to kill some cells and not others. One model of IR signaling to NF-κB that has been put forth involves ATM, a PI3-kinase mutated in the human disease ataxia-telangiectasia, in which afflicted patients are hypersensitive to radiation. ATM might sense IR by direct or indirect activation following DNA damage, and active ATM appears to be essential to NF-κB activity in response to IR. NF-κB activation by ATM clearly depends on IκBα phosphorylation, but the exact mechanism is unclear; some evidence for ATM directly phosphorylating IκBα and activation of IKK via an MAPK has been accumulated. Additionally, this may not be the only way NF-κB responds to genotoxic stress, as ATM-independent connections have been described.

Ultraviolet light is yet another atypical stimulus long known to activate NF-κB. This is of research interest for such disparate topics as the role of UV light in skin cancer and UV-induced transcription of HIV-1. Additionally, UV-induced DNA damage is often used as a model system for genotoxic stress. However, this is questionable as enucleation experiments have shown that DNA damage is not required for NF-κB activation for any UV wavelength. This has led to postulation that UV light affects NF-κB through the generation of ROS but this suggestion is difficult to evaluate given the existing problems in studying ROS (see above). Rather, it appears that UV light acts through a p38-MAPK dependent mechanism to stimulate CKII phosphorylation of the C-terminus of IκBα, a region known to regulate constitutive turnover of IκBα. This makes UV light particularly special, as it joins the very few NF-κB inducers that are known to act independently of IKK.

7
Other Roles of NF-κB in Normal Biology and Pathology

Given the pleiotropic functions of NF-κB, as well as its involvement in a number of key pathways, and detailed knowledge of many such pathways, it is not surprising that NF-κB is of interest to multiple fields of biomedical research. Indeed, a PubMed search (Nov 2004) reveals over 16 000 articles published about NF-κB. Clearly NF-κB is and has long been of great interest to immunologists, and the idea that it is a central regulator of the immune response has already been detailed in the previous sections and so will not be further discussed here. NF-κB is also of interest in virtually any disease with an inflammatory or cell death component. Here, we focus on the role of NF-κB in cancer, which is a good example of how the various properties of NF-κB have pathological importance. To get an idea of the wide variety of research now underway, we also examine the pharmacologic attempts to inhibit NF-κB and the more unusual role of NF-κB in the neurobiology of memory. Together, these examples hint at the broad scope of scientific research that NF-κB has ignited.

7.1
NF-κB in Cancer

The role of NF-κB in cancer–whether it is a tumor promoter or suppressor – is of

great controversy. Evidence of NF-κB as a tumor suppressor comes in two general categories. First, NF-κB is clearly required for the development and function of the adaptive immune response, one function of which is to survey the body for preneoplastic cells and eliminate them (''immune surveillance''). Second, although NF-κB is considered generally antiapoptotic, there are some circumstances in which activated NF-κB plays a proapoptotic role. In such circumstances, it would be disadvantageous to inhibit NF-κB as it could encourage tumor proliferation; for example, melanoma cells appear to be protected from apoptosis through downregulation of NF-κB. There has also been a proposal that the tumor suppressor/promoter status of NF-κB is regulated in part by the transcriptional coactivator/corepressor bound to it. However, there is no general consensus as to the mechanisms by which NF-κB can suppress tumor growth, and indeed, it may be cell-type or stimulus-dependent.

Evidence for NF-κB as a tumor promoter comes in many forms. The earliest hint came from classification of NF-κB as a member of the Rel family, as v-rel, another member of this family, is an avian leukemic oncogene. In humans, c-Rel amplifications are found in several types of lymphoma. However, genetic alterations of other subunits are generally not found in tumor tissues, which suggest that dysregulation of NF-κB activity plays a more important role in its oncogenic potential. Indeed, CYLD is a tumor suppressor that negatively regulates NF-κB at the level of TRAF2 and IKK. Its mutation in familial cylindromatosis, a disease of dramatic benign growth of skin appendages, results in upregulation of NF-κB.

Overactivation of NF-κB could promote tumor growth through several mechanisms. First, NF-κB can stimulate cell proliferation, for example, by upregulating cyclin D1 which mediates the G1 to S checkpoint. Likewise, by virtue of its antiapoptotic properties, NF-κB could contribute to neoplastic cell survival, for example, by resisting apoptosis normally induced by the immune surveillance provided by cytotoxic T lymphocytes and natural killer cells. Several oncogenic viruses, especially EBV (via LMP-1), HTLV-1 (via Tax), KSHV (via Pak-1), activate NF-κB and thereby implicate it in mediating oncogenic transformation. Additionally, NF-κB may promote tumor growth by upregulating VEGF needed for angiogenesis and promote metastasis by upregulating adhesion molecules like ICAM-1 needed for attachment to and subsequent penetration of the vasculature. With such a diverse array of potentially tumor supportive functions, it is not surprising that a large number of cancers display constitutive activation of NF-κB.

Exciting new genetic experiments from several laboratories indicate that NF-κB is a critical molecule in linking inflammation to cancer. One group used mice deficient in MyD88, TLR2, or TLR4 to demonstrate that under physiological conditions TLR signaling is required to protect the intestinal epithelium from injury. Since TLR2 and TLR4 signal primarily through NF-κB, this indicates a role for NF-κB in the survival of intestinal epithelium. An accompanying paper by another group demonstrated in a mouse model of ulcerative colitis–associated colon cancer that knocking out IKKβ in myeloid cells led to decreased tumor growth, whereas knocking out IKKβ in intestinal epithelium had no effect on tumor size but did lead to decreased tumor incidence due to increased apoptosis. A parallel study in a mouse model of

liver cancer showed that inhibition of NF-κB by either TNFα-neutralizing antibody treatment or induction of nondegradable "super-repressor" IκBα caused apoptosis of transformed hepatocytes. These studies together paint a picture in which NF-κB is involved in cancer progression and not initiation, in contrast to earlier ideas discussed previously. Specifically, this model of cancer progression involves NF-κB on two levels. First, NF-κB is required in immune cells (especially macrophage lineage) to produce cytokines in response to chronic inflammatory insult. Second, NF-κB is required in transformed epithelial cells to allow those cytokines to signal against apoptosis. While such antiapoptotic function has a normal physiologic role, it appears that it is errantly active during the period in which transformed cells develop into more aggressive forms. If true, this would seem to have clear implications for treatments that could halt the development of inflammation-associated cancers. If this model holds up to further scrutiny, it will be interesting to see what other cancers progress in a similar fashion.

7.2 Pharmacologic Inhibition of NF-κB

Keeping in mind potential side effects, there is ample evidence that downregulating NF-κB could be useful in treating numerous cancers and diseases with a chronic inflammatory component. Thus, finding specific and effective inhibitors of the NF-κB pathways is of intense interest, and indeed, the list of known inhibitory compounds/substances – perhaps even more impressive than the lists of known activators and target genes – numbers nearly 500. Here, we briefly review the major classes of pharmacologic inhibitors that have been applied against NF-κB.

Naturally, at least some anti-inflammatory compounds can be assumed to have negative effects on NF-κB activity. Indeed, glucocorticoids may exert their effects via several possible mechanisms, including upregulation of IκBα expression, competition for coactivators between NF-κB and glucocorticoid receptor, or by repressive crosstalk between the two pathways. The specific points of inhibition of the NF-κB pathway by several other immunosuppressive drugs, like cyclosporine A, FK506, thalidomide, and plant flavonoids are presently not precisely known. On the other hand, NSAIDs (nonsteroidal anti-inflammatory drugs) have more specific roles in the NF-κB pathway regulation, namely, by inhibiting IKK. Aspirin and sodium salicylate specifically inhibit IKKβ by antagonizing its ability to bind ATP; however, these molecules can exert anti-inflammatory effects via other mechanisms as well. Sulfasalazine, used as an NSAID to treat inflammatory bowel disease, inhibits both IKKα and IKKβ, also by reducing ATP binding. Finally, sulindac, an NSAID employed against rheumatic diseases, specifically inhibits IKKβ, but it is not known whether it exerts effects through ATP.

Since NSAIDs also have effects beyond IKK and because nearly all NF-κB-activating stimuli signal through IKK, IKK is an attractive target for further drug development. Specifically, IKKβ inhibitors are extremely sought after since it is the critical IKK complex component in the canonical pathway and much more is known about its role in diseases than IKKα. No fewer than 15 compounds have been isolated or synthesized with micromolar or better IKK binding constants. The very recent demonstration of successful small

interfering RNA (siRNA) treatment of hypercholesterolemia in mice also opens the door to siRNA-targeting of IKK proteins or other NF-κB targets. All of these compounds are in preclinical testing, and if any one of these are eventually approved for human use, the clinical impact could be enormous.

Another strategy for inhibiting NF-κB is by preventing IκB degradation. One successful strategy is inhibition of the 26S proteasome. Bortezomib (Velcade, Millennium Pharmaceutical, Inc.) is such a drug, and was approved in May 2003 for the treatment of refractory multiple myeloma. Work continues to see if bortezomib may have some other antitumor activity that would be useful in treating solid tumors. Four other 26S proteasome inhibitors are also in preclinical testing. It is a bit odd that inhibiting the proteasome, which degrades all polyubiquitinated proteins, would have specific activity against NF-κB. However, potentially more specific inhibitors of the $SCF^{\beta-TrCP}$ ubiquitin ligase complex have not been reported.

Last, but not least, receptor-level inhibitors are an important class of anti-NF-κB drugs. The anti-TNFR antibody etanercept (Enbrel, Immunex Corp.) and the anti-TNFα antibodies infliximab (Remicade, Centocor Inc.) and adulimumab (Humira, Abbott Laboratories) have been recently approved for treatment of rheumatoid arthritis. There is good potential for these drugs to have benefits in other rheumatologic diseases; however, these drugs, especially infliximab, are also associated with possibly fatal sepsis. Anakinra (Kineret, Amgen Inc.), a recombinant form of IL-R1a, was also approved in 2001 for treatment of refractory rheumatoid arthritis, and combination therapy with anti-TNF agents may have synergistic clinical effects. Finally, a rationally designed dominant-negative form of TNF is in preclinical testing, but it remains to be shown what advantages, if any, it has over the already approved drugs.

7.3 Atypical Roles of NF-κB: Example of Learning

In almost every context, NF-κB is thought to exert its effects in the context of inflammation, apoptosis, or stress response. This is also true in the nervous system, where NF-κB plays important roles in multiple sclerosis, excitotoxic neuronal death, and neuronal oxidative stress. Interestingly, however, NF-κB may have additional physiologic functions with implications for learning and memory as discussed below.

Although NF-κB was known to be involved in the functioning of neurons soon after the discovery of NF-κB itself, increased attention to its possible role in learning did not begin until much later, with the discovery that NF-κB is localized in the synapses of many neurons and that it could be induced at physiologic levels of synaptic stimulation. The significance of this discovery is that NF-κB could mediate memory (i.e. long-term potentiation, LTP) by acting as a bridge between short-term stimulation and long-term changes due to alterations in gene expression patterns. Later animal studies hinted that this was indeed the case, as fear memory formation in the amygdala was impaired by the NF-κB inhibitor thalidomide and by κB decoy DNA, whereas memory formation was enhanced by NF-κB-activating histone deacetylase (HDAC) inhibitors. LTP in the hippocampus is likewise dependent on NF-κB activity.

Some parts of the signaling pathway have been identified. The current model of synaptic plasticity (i.e. long-term changes

in a synapse) is that a prolonged glutaminergic stimulation leads to the opening of the synaptic calcium channel NMDA, followed by intracellular calcium initiating a signal transduction cascade that leads to gene expression or modulation. Consistent with this model, both the calcium/calmodulin-dependent kinase CaMKII and the calcium-dependent protease calpain have been implicated in the activation of synaptic NF-κB, which can then travel retrograde to the nucleus and modulate gene transcription. In either case, the mechanism of IκB degradation is unknown. It is also currently unclear which genes NF-κB upregulates to mediate synaptic plasticity, but NF-κB activity is associated with changes in glutaminergic synaptic currents. Additionally, NF-κB's role in LTP is probably limited to specific cell types in the brain since many neurons exhibit constitutive NF-κB activity. Nonetheless, evidence is strong that NF-κB mediates formation of some memories, and many open questions remain about this function. This example gives a flavor of various aspects of NF-κB function yet to be discovered despite nearly 20 years of intense investigation.

Acknowledgment

The authors wish to thank Alexander Hoffmann for useful discussions and NIH for support of this work.

Keywords

Electroporation
A process utilizing a series of short electrical pulses to permeate cell membranes, thereby permitting the entry of DNA molecules into animal or plant cells.

Polymerase Chain Reaction (PCR)
An *in vitro* method for the enzymatic synthesis of a specific DNA sequence, using two oligonucleotide primers hybridizing to opposite strands and flanking the region of interest in the target DNA.

Transgene
A piece of nonself origin gene or noncoding DNA fragment that is introduced into plants or animals for the production of transgenic species.

Transgenic Fish
Fish into which a foreign gene or noncoding DNA fragment has been introduced and stably integrated into its genome.

F_1 Transgenic Fish
Transgenic progeny derived from a cross between a P_1 transgenic individual and a nontransgenic individual or between two P_1 transgenic individuals.

P_1 Transgenic Fish
Transgenic fish developed from embryos that received foreign gene transfer.

Fish into which foreign DNA is artificially introduced and integrated in their genomes are called *transgenic fish*. Since the development of the first transgenic fish in 1985, techniques to produce transgenic fish have improved tremendously, resulting in the production of genetically modified (GM) fish of many species. In the past few years, the fast booming application of transgenic fish technology has led to many valuable discoveries in different disciplines of the biological sciences, many of which could potentially lead to the next breakthrough in new treatments for human diseases. Transgenic fish technology has also been applied to produce fish with beneficial traits, such as fast growth rate, enhanced disease resistance, and environmental biomonitors, in the hope of improving the quality of both human life and the earth environments.

1 Introduction

Fish into which a foreign gene or noncoding DNA fragment is artificially introduced and integrated in their genomes are called *transgenic fish*. Since 1985, a wide range of transgenic fish species have been produced mainly by microinjecting or electroporating homologous or heterologous transgenes into newly fertilized or unfertilized eggs and, sometimes, sperm. To produce a desired transgenic fish, several factors should be considered. First, an appropriate fish species must be chosen. This decision would depend on the nature of each study and the availability of the fish holding facility. Second, a specific gene construct must be designed on the basis of the special requirement of each study. For example, the gene construct may contain an open reading frame encoding a gene product of interest and regulatory elements that regulate the expression of the gene in a temporal, spatial, and/or developmental manner. Third, the gene construct has to be introduced into sperm or embryos in order for the transgene to be integrated stably into the genome of the embryonic cells. Fourth, since not all instances of gene transfer are efficient, a screening method must be adopted for identifying transgenic individuals.

Since the development of the first transgenic fish, techniques to produce transgenic fish have improved tremendously, resulting in the production of genetically modified (GM) fish of many species. In recent years, transgenic fish have been established as valuable models for different disciplines of biological research as well as for human disease modeling. The application of transgenic fish technology to produce fish with beneficial traits, such as environmental biomonitors and enhanced disease resistance, is also rising. In this chapter, we will review the progress of the transgenic fish technology and its application in basic research and biotechnological application.

2 Selection of Model Fish Species

Gene transfer studies have been conducted in several different fish species such as salmon, rainbow trout, common carp, goldfish, loach, channel catfish, tilapia, northern pike, walleye, zebrafish, and Japanese medaka. Depending on the

purpose of the transgenic fish studies, the embryos of some fish species prove to be more suitable than others. In selecting a fish species for gene transfer studies, a series of parameters are considered. These parameters are (1) length of the life cycle; (2) year round supply of eggs and sperm; (3) culture conditions; (4) size of the adult at maturity; and (5) availability of background information on genetics, physiology, and endocrinology of the fish species.

2.1 Small-size Fish Model

Japanese medaka (*Oryzias latipes*) and zebrafish (*Danio rerio*) are regarded as ideal fish species for conducting gene transfer studies. Both the fish species have short life cycles (3 months from eggs to mature adults), produce hundreds of eggs on a regular basis without exhibiting a seasonal breeding cycle, and can be maintained easily in the laboratory for two to three years. Their eggs are relatively large, 1.0 to 1.5 mm diameter, and possess very thin and semitransparent chorions. These features allow easy microinjection of DNA into the eggs if appropriate glass needles are used. Furthermore, inbred lines and various morphological mutants of both the fish species are available. These fish species are suitable candidates for producing transgenic fish for (1) studying developmental regulation of gene expression and gene action; (2) identifying regulatory elements that regulate the expression of a gene; (3) measuring the activities of promoters; and (4) producing transgenic models for human diseases and environmental toxicology. However, a major drawback of these two fish species is that their small body size makes them unsuitable for endocrinological or biochemical analysis.

2.2 Medium-size Fish Model

The handicap of using small body–size fish species such as medaka or zebrafish in gene transfer studies can be easily overcome by the use of fish species such as loach, killifish (*Fundulus*), goldfish, and tilapia. The body sizes of these fish species are big enough so that sufficient amounts of tissues can be isolated from individual fish for biochemical and endocrinological studies. Another important attribute of these fish species is their shorter maturation time compared to rainbow trout or salmon. In particular, tilapia is a very appropriate medium-size fish species for gene transfer studies since it requires only about three months to complete its entire life cycle. It is possible to produce three generations of transgenic tilapia in one year. Unfortunately, the lack of a well-defined genetic background and asynchronous reproductive behavior of these fish species present some problems for conducting gene transfer studies.

2.3 Large-size Fish Model

Rainbow trout, salmon, channel catfish, and common carp are commonly used large body–size model fish species for transgenic fish studies. Since the knowledge of endocrinology, reproductive biology, and physiology of these fish species have been well worked out, they are well suited for studies on comparative endocrinology as well as on aquaculture applications. However, the maturation time for each of these fish species is relatively long. For example, rainbow trout and salmon require two to three years to reach reproductive maturity, and common carp or channel catfish about one to two years.

Thus, it will prolong inheritance studies. In addition, since these fish species have a single spawning cycle per year, it restricts the number of gene transfer attempts that can be conducted per year.

3 Types of Transgenes

A transgene is a piece of nonself origin gene or DNA fragment that is introduced into fish for the production of transgenic fish. Transgenes are usually constructed in plasmids that contain appropriate promoter/enhancer elements for proper expression of the transgenes in fish. A variety of promoters from nonfish species have been employed to control the expression of transgenes in fish (Table 1). Additionally, increasing number of fish promoters (Table 1) are available for the purpose of generating ''all-fish'' expression cassettes, among which the carp β-actin promoter has been shown to drive strong expression of transgenes in various fish cell types. Tissue-specific promoters and inducible promoters such as zebrafish *heat shock protein 70* (*hsp70*) have also been used successfully to control the expression of transgene in the desired tissue(s) at the desired time(s). For example, activation of *hsp70*-controlled transgene can be achieved by heat shock and, intriguingly, by focusing a sublethal laser microbeam onto individual cells that carry the transgene. The targeted cells appear normal after the treatment.

Depending on the purpose of the gene transfer studies, transgenes can be grouped into three major types: (1) *gain-of-function*; (2) *reporter-function*; and (3) *loss-of-function*. The basic organization and the function of these transgenes will be discussed below.

3.1 Gain-of-function Transgenes

Gain-of-function transgenes are designed to add new functions to the transgenic

Tab. 1 Examples of promoters used in production of transgenic fish.

	Origin Species	***Promoter***
Nonfish origin:		
	Rat	GAP43[a]
	Chicken	β-actin
	Xenopus	elongation factor 1α
	Cytomegalovirus	CMV intermediate–early
	Moloney murine leukemia virus	MoMLV LTR
Fish origin:		
	Carp	β-actin
	Goldfish	α1tubulin[a]
	Medaka	elongation factor 1α, β-actin
	Zebrafish	H2A.F/Z, α-actin[a], heat shock protein 70[b]

[a]tissue-specific promoters- GAP43: nervous system; α1 tubulin: nervous system; α-actin: muscle (see able 3 for more examples).
[b]Inducible promoters; LTR: long terminal repeat; H2A.F/Z: histone H2A.F/Z.

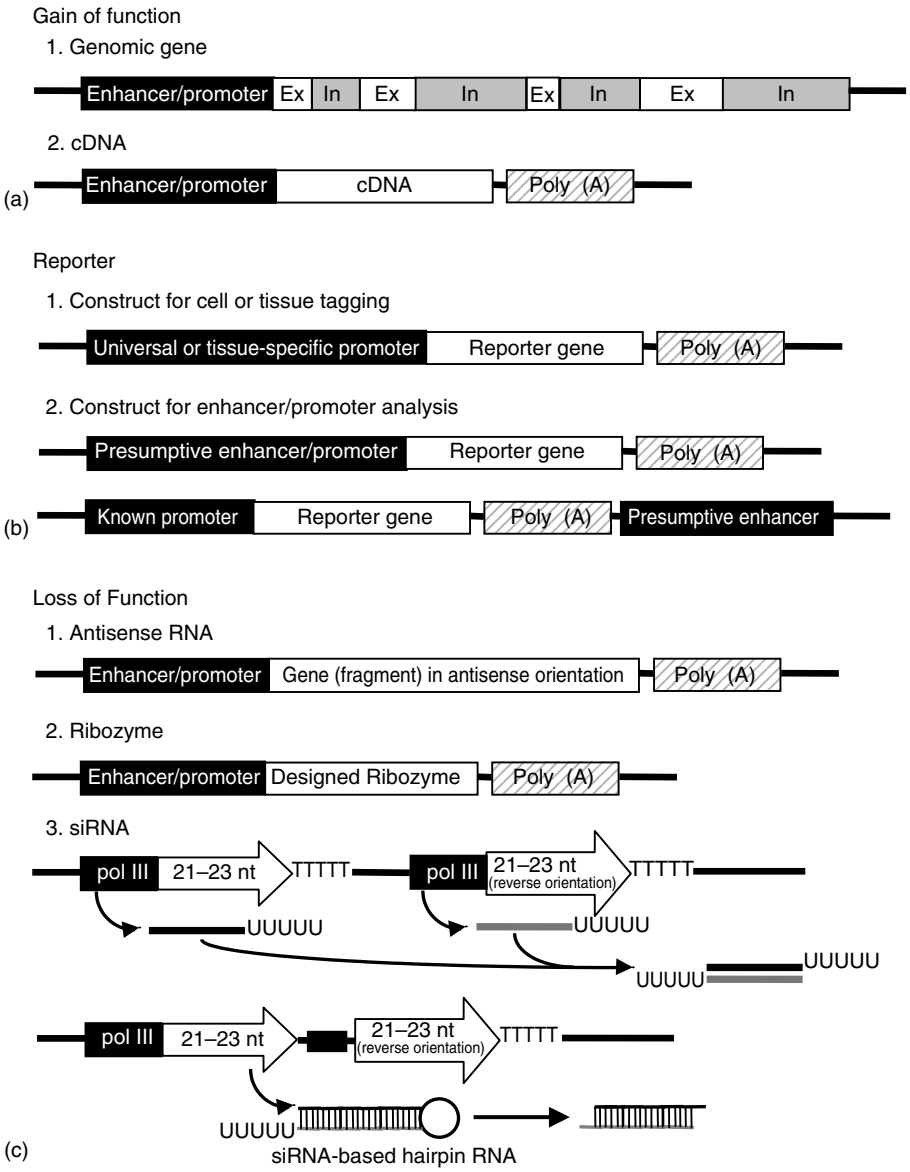

Fig. 1 Prototypes of transgenes for fish transgenesis. Depending on the experimental purpose, the promoter used in the transgene construct can be either constitutive or an inducible one. Ex: exon; in: intron; pol III: RNA polymerase III promoters.

individuals or to facilitate the identification of the transgenic individuals if the genes are expressed properly in the transgenic individuals. The coding regions of the transgenes are usually homologous or heterologous genomic or cDNA sequences, which encode polypeptide products (Fig. 1a). The expression

of the transgenes is usually driven by promoter/enhancer sequences of homologous or heterologous sources. If the transgenes contain functional signal peptide sequences, the gene products will be secreted out of cells once they are synthesized. Transgenes containing the structural gene of mammalian or fish growth hormones (GH) or the respective cDNA fused to a functional promoter/enhancer of chicken or fish β-actin gene are examples of the gain-of-function transgene constructs. Expression of such transgenes in transgenic individuals has been shown to result in growth enhancement. Winter flounder antifreeze protein gene and chicken δ-crystalline gene with their own promoter/enhancer sequences are other commonly used *gain-of-function* transgenes used in various gene transfer studies.

Another type of commonly used *gain-of-function* transgenes are the "reporter-function transgenes," which are discussed in the next section.

3.2 Reporter-function Transgenes

Genes such as *bacterial chloramphenicol acetyltransferase* (*CAT*), *β-galactosidase* (*β-gal*), *neomycin phosphotransferase* II (*neo*^{R}), *luciferase*, and *green fluorescent protein* (*GFP*), are frequently used as reporters. These reporter genes serve as a convenient marker for indicating the success of gene transfer into the target cells since the translational products of these genes can be easily monitored. Furthermore, because these gene products can be measured quantitatively, they are also routinely adopted for identifying the sequence of an undefined promoter/enhancer or for measuring the relative activity of a promoter/enhancer element in question. A less frequently used reporter type is the one with target-specificity. One such example is cameleon, a fluorescent calcium sensor, which was originally used to detect calcium transients in culture cells and pharyngeal muscle of *Caenorhabditis elegans*. Recently, *cameleon* and several other indicator genes have been used to establish transgenic zebrafish for monitoring neuronal activity. The prototypes of a *reporter-function* transgene are shown in Fig. 1b.

Among the commonly used reporters, the jellyfish (*Aequorea victoria*) GFP and its variants have become the choice markers for transgenic fish because the detection of GFP signal is direct and easy, requiring no exogenous substrate. There are numerous GFP variants available, including those producing green, blue, and yellow fluorescence light. Together with the red fluorescence protein (RFP), these reporters can be easily detected in live transgenic fish such as zebrafish and medaka whose embryos and body are transparent, without the need to sacrifice the fish. Additionally, these reporters can be used to study multiple transgenes simultaneously in the same fish. Since the first GFP transgenic fish in 1995, GFP-tagged transgenic embryos and fish have become the most convenient and widely used tools in basic biological research, particularly in the regulation of gene expression and morphogenetic movements during embryonic development (see Sect. 6.1). In many cases, similar applications can be achieved with the other reporter genes mentioned above. However, the detection of these reporters is indirect and involves additional steps such as enzymatic reaction with substrate and immunohistochemical staining with specific antibody to the reporter.

3.3 Loss-of-function Transgenes

The *loss-of-function* transgenes are constructed for interfering with the expression of host genes at the transcriptional or translational level. Mechanistically, there are at least three groups of ''loss-of-function'' transgenes. The transgenes might encode antisense RNAs or oligonucleotides that selectively hybridize to a target endogenous mRNA, resulting in degradation of the mRNA with RNase H or interference with translation of the mRNAs via preventing the binding of ribosomes. A variation of the antisense RNA approach is to introduce a group of chemically modified oligonucleotides known as morpholino phosphorodiamidate oligonucleotides (MOs) into fish embryos. In contrast to ordinary antisense molecules, MOs exhibit long-term stability with less toxicity to living cells and appear to function through translation blockage only. The second group of ''loss-of-function'' transgenes is catalytic RNA (ribozymes) that can cleave specific target mRNAs at a specific site and thereby ''knock down'' the normal gene expression. The most recent development of the *loss-of-function* transgenes is to introduce a group of small RNAs known as small (short) interfering RNAs (siRNAs) into cells. siRNA will guide a ribonuclease known as RISC (the RNA-induced silencing complex) to recognize mRNA containing a sequence homologous to the siRNA, resulting in degradation of the mRNA by the ribonuclease. The prototype of *loss-of-function* transgenes is shown in Fig. 1c. Although there is currently no report of stable lines of transgenic fish carrying this type of transgenes, the feasibility of this approach in silencing genes has been demonstrated in numerous fish cell lines *in vitro*. Moreover, many recent studies also prove that MOs and siRNA molecules can silence their targets specifically and effectively when introduced into fish embryos, such as zebrafish, medaka, and rainbow trout.

4 Methods of Gene Transfer

Techniques such as calcium phosphate precipitation, direct microinjection, retrovirus infection, electroporation, and particle gun bombardment have been widely used to introduce foreign DNA into animal cells, plant cells, and germ lines of mammals and other vertebrates. Among these methods, direct microinjection and electroporation of DNA into newly fertilized eggs have proven to be the most reliable methods of gene transfer in fish systems.

4.1 Microinjection of DNA into Embryos or Unfertilized Eggs

Microinjection of foreign DNA into newly fertilized eggs was first developed for the production of transgenic mice in the early 1980s. Since then, the technique of microinjection has been adopted for introducing transgenes into Atlantic salmon, common carp, catfish, goldfish, loach, medaka, rainbow trout, tilapia, and zebrafish. The gene constructs that were used in these studies include human or rat growth hormone gene, rainbow trout or salmon GH cDNA, chicken δ-crystalline protein gene, winter flounder antifreeze protein gene, *E. coli* β-galactosidase gene, and *E. coli* hygromycin resistance gene. In general, gene transfer in fish by direct microinjection is conducted as follows. The parameters for microinjection are summarized in Table 2. Eggs and sperm are collected in separate, dry containers.

Tab. 2 Parameters of fish transgenesis by microinjection and electroporation.

Parameters	*Gene Transfer Method*	
	Microinjection	*Electroporation*
Developmental stage	1 to 2 cells	1 to 2 cells
DNA size	<10 Kb	<10 Kb
DNA concentration	10^{6-7} molecules/embryo	100 µg ml^{-1}
DNA topology	Linear	Linear
Chorion barrier	Dechorionated/micropyle	Intact chorion
Electrical field strength	N/A[a]	500 to 3000 v
Pulse shape	N/A[a]	exponential/square
Pulse duration	N/A[a]	ms[c] to s
Temperature	RT[b]	RT[b]
Medium	PBS/saline[d]	PBS/saline

[a] N/A, not applicable.
[b] RT, room temperature (25 °C).
[c] ms, millisecond.
[d] PBS/saline: phosphate-buffered saline.

Fertilization is initiated by mixing sperm and eggs, then adding water, with gentle stirring to enhance fertilization. Eggs are microinjected within the first few hours after fertilization. The injection apparatus consists of a dissecting stereomicroscope and two micromanipulators, one with a micro-glass-needle for injection and the other with a micropipette for holding fish embryos in place. Routinely, about 10^6 to 10^8 molecules of a linearized transgene are injected into the egg cytoplasm. Following injection, the embryos are incubated in water until hatching. Since natural spawning in zebrafish or medaka can be induced by adjusting photoperiod and water temperature, precisely staged newly fertilized eggs can be collected from the aquaria for gene transfer. If the medaka eggs are maintained at 4 °C immediately after fertilization, the micropyle on the fertilized eggs will remain visible for two hours. The DNA solution can be delivered into the embryos by injecting through this opening during this time period.

Depending on the species, the survival rate of injected fish embryos ranges from 35 to 80% while the rate of DNA integration ranges from 10 to 70% in the survivors. The tough chorions of the fertilized eggs in some fish species, for example, rainbow trout and Atlantic salmon, can make insertion of glass needles difficult. This difficulty has been overcome by any one of the following methods: (1) inserting the injection needles through the micropyle; (2) making an opening on the egg chorions by microsurgery; (3) removing the chorion by mechanical or enzymatic means; (4) preventing chorion hardening by initiating fertilization in a solution containing 1 mM glutathione; or (5) injecting the unfertilized eggs directly.

4.2 Electroporation of DNA into Embryos or Sperm

Electroporation is a successful method for transferring foreign DNA into bacteria, yeast, and plant and animal cells in culture.

In the past years, this method has become popular for transferring foreign genes into fish embryos or sperm. Electroporation utilizes a series of short electrical pulses to permeate cell membranes, thereby permitting the entry of DNA molecules into embryos or sperm. The patterns of electrical pulses can be emitted in a single pulse of exponential decay form (i.e. exponential decay generator) or high-frequency multiple peaks of square waves (i.e. square-wave generator). The basic parameters are summarized in Table 2. Studies conducted in our laboratory and those of others have shown that the rate of DNA integration in electroporated embryos is on the order of 20% or higher in the survivors. Although the overall rate of DNA integration in transgenic fish produced by electroporation was equal to or slightly higher than that of microinjection, the actual amount of time required for handling a large number of embryos by electroporation is orders of magnitude less than that required for microinjection. Several reports have also appeared in the literature describing successful transfer of transgenes into fish by electroporating sperm instead of embryos. With the success seen in sperm electroporating, electroporation can therefore be considered as an efficient and versatile mass gene transfer technology.

4.3 Infection with Replication-defective Pantropic Retroviral Vectors

By microinjection or electroporation, plasmid-encoded transgenes can be introduced at a satisfactory efficiency into many fish species to produce transgenic offspring. However, the resulting P_1 transgenic individuals are almost always mosaics as a result of delayed transgene integration. Furthermore, both methods are not efficient or applicable in transferring foreign DNA into embryos of live-bearing fish, marine fish, and invertebrates because of the restrictions imposed by the unique spawning behavior or anatomical structure of these species. Modification of transgenes has been adopted to increase the efficiency of gene transfer by microinjection or electroporation. Hsiao et al. and Thermes et al. have taken the following approaches: (1) using the inverted terminal repeat DNA from adeno-associated virus to increase the stability of transgene integration; and (2) employing *I-SceI* meganuclease to mediate high transportation efficiency of the transgene into the nucleus. Despite the improvement, these modified approaches cannot be applied to the mentioned species, whose transgenic offspring can not be produced by either microinjection or electroporation. Instead, transformation of mature or immature germ cells by infection with transgene-encoded retroviral vectors may be an effective approach for transgenesis in these fish.

A replication-defective pantropic retroviral vector containing the long terminal repeat (LTR) sequence of Moloney murine leukemia virus (MoMLV) and transgenes in a viral envelop with the G-protein of vesicular stomatitis virus (VSV), was developed by Burns et al. Since entry of VSV into host cells is mediated by interaction of the VSV-G protein with a phospholipid component of the host cell membrane, this pseudotyped retroviral vector has a very broad host range and is able to transfer transgene into many different cell types. Using the pantropic pseudotyped defective retrovirus as a gene transfer vector, transgenes containing neo^R or β-galactosidase were transferred into zebrafish, medaka, and dwarf surf clams.

More recently, Sarmasik et al. and Chen et al. also used the pantropic retroviral vector to transfer genes into the immature gonads of crayfish, desert guppy, and shrimp, respectively. They found that, by using the pantropic retroviral vector as a gene transfer vector, the problem of transgene mosaicism in P_1 transgenic fish is eliminated as the transgenes are introduced into immature male gonads by the pantropic retroviral vector.

4.4 Emerging New Methodology

Nuclear transplantation is a key technique in animal cloning. This method involves the transfer of nuclei from donor cells to enucleated eggs, stimulating eggs into cleavage and early phase of embryonic development, and in the case of mammals, the developing embryos are transferred into pseudopregnant females to complete the final stages of development. The first successful cloning of animals by nuclear transplantation was established for Northern Leopard Frog (*Rana pipiens*) by Briggs and King in 1952. However, Dolly, the lamb, is the first mammal successfully cloned by the nuclear transplantation technique, and since then, many laboratories throughout the world have adopted this technique to clone other mammals and farm animals. To date, production of diploid and fertile fish by the nuclear transplantation technique have been achieved in two small laboratory fish species, medaka and zebrafish. Three types of donor cells have been used for nuclear transfer: sperm, long-term cultured somatic cells, and embryonic cells.

In the study reported by Wakamatsu et al., embryonic cells from two transgenic medaka lines were used as donor cells to generate transgenic medaka. Blastoderm cells from the donor embryos in the mid-blastula stage were collected and dissociated into single cells. These were subsequently transplanted into the cytoplasm of the recipient enucleated eggs at the animal pole through the micropyle. In this study, 1 out of 588 eggs transplanted with the first donor and 5 out of 298 eggs transplanted with the second donor developed successfully to adulthood. The transgene of the donor nuclei was also transmitted to the F_1 and F_2 offspring in a Mendelian fashion.

Two versions of nuclear transfer technique have been established for zebrafish recently. Jesuthasan and Subburaju reported the use of sperm nuclei as donor for nuclear transfer. Sperm collected from mature males were demembranated by treatment with lysolecithin, digitonin, or by freeze-thawing. The demembranated sperm were then incubated with transgene DNA at room temperature prior to microinjecting into the animal pole region of the unfertilized egg. This method could produce nonmosaic expression of transgene in all cells of the embryos if incubation of the demembranated sperm with DNA was prolonged to 20 min. Few of the treated eggs however developed into fertile adults and the transgene was shown to be transmitted through the germ line. In the report by Lee et al., embryonic fibroblast cells from disaggregated embryos were used as donor cells. These cells were first modified by retroviral insertions expressing GFP as a reporter and were cultured for at least 12 weeks before their nuclei were transplanted into enucleated, unfertilized eggs. The method resulted in 2% of the transplants developing into fertile, diploid offspring. This study clearly demonstrated that nuclei from slowly dividing cultured fish somatic cells could be reprogrammed to support rapid embryonic development

and used as donor cells for nuclear transfer in fish. Moreover, the promising use of modified somatic cells provides an alternative choice of vehicle for gene targeting and fish cloning since fish ES cells are still unavailable. Overall, these studies have demonstrated the feasibility of using germinal and somatic cells from fish as donors for conducting nuclear transfer studies in different important fish species for both basic research and application purposes. In addition, the problem of transgene mosaicism in P_1 transgenic fish can be overcome by the nuclear transplantation method.

5
Characterization of Transgenic Fish

5.1
Identification of Transgenic Fish

Identification of transgenic individuals is the most time-consuming step in the production of transgenic fish. Traditionally, dot blot and Southern blot hybridization of genomic DNA were common methods used to determine the presence of transgenes in the presumptive transgenic individuals. These methods involve isolation of genomic DNA from tissues of presumptive transgenic individuals, digestion of DNA samples with restriction enzymes, and Southern blot hybridization of the digested DNA products. Although this method is expensive, laborious, and insensitive, it offers a definitive answer as to whether a transgene has been integrated into the host genome. Furthermore, it also reveals the pattern of transgene integration if appropriate restriction enzymes are employed in the Southern blot hybridization analysis. In order to handle a large number of samples efficiently and economically, a polymerase chain reaction (PCR) based assay has been adopted. The strategy of the assay involves the isolation of genomic DNA from a very small piece of fin tissue, PCR amplification of the transgene sequence, and Southern blot analysis of the amplified products. Although this method does not differentiate whether the transgene is integrated in the host genome or exists as an extrachromosomal unit, it serves as a rapid and sensitive screening method for identifying individuals that contain the transgene at the time of analysis. This method has been used in our laboratory as a routine preliminary screen for the presence of transgenes in thousands of presumptive transgenic fish.

5.2
Pattern of Transgene Integration

Studies conducted in many fish species have shown that following injection of linear or circular transgene constructs into fish embryos, the transgenes are maintained as an extrachromosomal unit through many rounds of DNA replication in the early phase of the embryonic development. At a later stage of embryonic development, some of the transgenes are randomly integrated into the host genome while others are degraded, resulting in the production of mosaic transgenic fish. To determine the pattern of transgene integration, genomic DNA from PCR positive fish is digested with a series of restriction endonucleases and the resulting products resolved in agarose gels for Southern blot analysis. In many fish species studied to date, it is found that multiple copies of transgenes are integrated in a head-to-head, head-to-tail or tail-to-tail form, except in transgenic common carp and channel catfish where a single copy of transgene

was integrated at multiple sites on the host chromosomes.

5.3 Inheritance of Transgenes

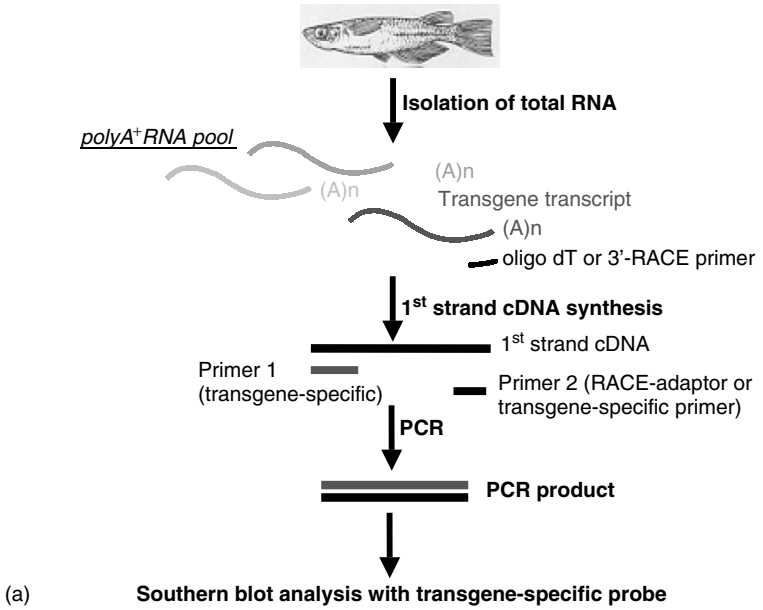
Stable integration of transgenes is an absolute requirement for continuous vertical transmission to subsequent generations and establishment of a transgenic fish line. To determine whether the transgene is transmitted to subsequent generations, P_1 transgenic individuals are mated to nontransgenic individuals and the progeny are assayed for the presence of transgene by the PCR assay method described earlier. Although it has been shown that the transgene may persist in the F_1 generation of transgenic zebrafish as extrachromosomal DNA, detailed analysis of the rate of transmission of transgenes to F_1 and F_2 generations in many transgenic fish species indicates true and stable incorporation of gene constructs into the host genome. If the entire germ line of the P_1 transgenic fish is transformed with at least one copy of the transgene per haploid genome, at least 50% of the F_1 transgenic progeny will be expected in a backcross involving a P_1 transgenic with a nontransgenic control. In many such crosses, only about 20% of the progeny are transgenic. When the F_1 transgenic is backcrossed with a nontransgenic control, however, at least 50% of the F_2 progeny are transgenics. These results clearly suggest that the germ lines of the P_1 transgenic fish are mosaic as a result of delayed transgene integration during embryonic development.

5.4 Expression of Transgenes

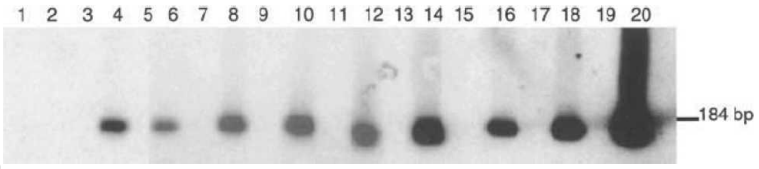
An important aspect of gene transfer studies is the detection of transgene expression. Depending on the levels of transgene products in the transgenic individuals, the following listed methods are commonly used to detect transgene expression: (1) RNA northern or dot blot hybridization; (2) RNase protection assay; (3) reverse transcription-polymerase chain reaction (RT-PCR); (4) immunoblotting assay; and (5) other biochemical assays for determining the presence of the transgene protein products. Among these assays, RT-PCR is the most sensitive method and only requires a small amount of sample. The strategy of this assay is summarized in Fig. 2. Briefly, it involves the isolation of total RNA from a small piece of tissue, synthesis of single-stranded cDNA by reverse transcription, and PCR amplification of the transgene cDNA by employing a pair of oligonucleotide specific to the transgene product as amplification primers. The resulting products are resolved on agarose gels and analyzed by Southern blot hybridization using a radiolabeled transgene as a hybridization probe. Transgene expression can also be quantified by a quantitative RT-PCR method or a quantitative real-time RT-PCR.

6 Application of Transgenic Fish

As techniques of producing various species of transgenic fish have become available in the last two decades, there has been a rapid boom in applying transgenic fish strategy to different disciplines of basic research and biotechnological applications. In this section, we will discuss recent advances in applying the transgenic fish technology in basic research as well as in producing transgenic fish with beneficial traits such as enhanced growth and disease resistance for aquaculture.



(a)



(b)

Fig. 2 Determination of transgene expression by RT-PCR or RACE-PCR. (a) Strategy of RT-PCR and RACE-PCR. (b) An example of detecting cecropin transgene in transgenic medaka. Total RNA was isolated from fin tissues of F_2 transgenic medaka. Expression of cecropin transgene was detected by reverse transcribing poly A^+ RNA into complementary cDNA and PCR amplification of the cecropin cDNA by using cecropin-specific primers. The amplified product was further confirmed by Southern hybridization using a cecropin-specific probe. RT-PCR was conducted with mRNA from transgenic fish without prior reverse transcription (lanes 5, 7, 9, 11, 13, 15, 17, 19) or with first cDNA transcribed from mRNA isolated from the transgenic fish (lanes 4, 6, 8, 10, 12, 14, 16, 18). Lane 1: RT-PCR with no mRNA input; lane 2: RT-PCR with mRNA from negative control fish (c-mRNA); lane 3: PCR with c-mRNA without prior reverse transcription; lane 20: PCR with control plasmid containing cecropin gene. 6.1 Transgenic Fish in Basic Research

Teleost fish serve as extremely valuable models for basic research in vertebrate biology as they are functionally similar to mammalian species, and because they are sufficiently evolutionarily distant to mammals, they are well suited for comparative genomics. Transgenic fish

can be easily and economically produced and reared in large quantities, granting them superiority over the transgenic mouse model, especially in studies requiring a large number of animals. In recent years, transgenic fish tagged with GFP have emerged as important tools in studies of vertebrate developmental biology, basic molecular and cell biology, and human disease modeling. Additionally, gene misexpression and knockdown are also widely used in these studies.

6.1.1 Vertebrate Developmental Biology

Transgenic zebrafish and medaka and their embryos are ideal models for studying the complex developmental mechanisms that transform a single-cell zygote into a multicellular organism with diverse functions. Both the fish species provide the following advantages: (1) short generation time (about 3 months); (2) constantly available and easily reared; and (3) most importantly, transparent embryos granting clear visualization of all stages of embryonic development. Additionally, there are mutant zebrafish and medaka whose transparent bodies consist of less interfering pigmentation. Although most of the developmental studies have so far been conducted in zebrafish, medaka embryos provide a larger window for observation at smaller developmental intervals because of their longer embryonic developmental time (2 days versus 10 days).

As shown in Table 3, researchers have established many lines of transgenic reporter zebrafish that express GFP in specific cells or tissues, including germ cells, blood, lymphoid cells, epithelia, muscle, heart (Fig. 4a), pancreas, liver, intestine (Fig. 4b), vasculature, and the nervous system. This is achieved by introducing a GFP, enhanced green fluorescence protein (EGFP), or RFP reporter that is placed under control of tissue- or cell-specific promoter/enhancer. Because the same fluorescence-tagged cells can be followed over time, these transgenic fish have been successfully used in the study of morphogenesis and gene regulation during embryonic development. For example, transgenic zebrafish with GFP-tagged blood vessels have been used to study the blood vessels assembly during development. Zebrafish *fli1* promoter is able to drive expression of GFP in all blood vessels throughout embryogenesis. By coupling this feature with high-resolution dynamic imaging techniques, confocal microangiography has clearly illustrated the anatomical architecture of the vasculature of zebrafish and show that blood vessels undergoing angiogenesis display pathfinding

behavior similar to that of neuronal growth cones.

Application of fish transgenesis on developmental biology can also be achieved by gene misexpression or knockdown. So far, such an approach has been carried out exclusively in fish embryos. For example, zebrafish embryos have been used to study the role of Sema3D protein in guiding retinal ganglion cell (RGC) axons during embryonic development. Sema3D belongs to the semaphorin family, many members of which are known to repel or attract specific growth cones. Sema3D may participate in guiding RGC axons along the dorsoventral axis of the tectum, as indicated by the differentially higher expression of the protein in the ventral versus dorsal tectum. To understand the function of Sema3D, homozygous zebrafish embryos have been established from stable transgenic zebrafish fish carrying the *sema3D* gene under control of the zebrafish *heat shock protein 70* (*hsp70*) promoter. Ubiquitous misexpression (overexpression) of Sema3D in the embryos can be achieved by heat shock and has been found to inhibit ventral but not dorsal RGC axon growth. Additionally, mosaic Sema3D misexpression can be induced by heat shock in the embryos microinjected with the *hsp70*-controlled *sema3D* transgene. In these embryos, ventral RGC axons have been found to avoid or stop at individual cells misexpressing Sema3D along their pathway. Furthermore, knockdown of Sema3D with morpholino antisense causes errors in retinotectal mapping along the dorsoventral axis. These analyses suggest that Sema3D in the ventral tectum directs the correct innervation of ventral RGCs to dorsal tectum by inhibiting them from extending into ventral tectum. A similar approach has been employed to study the function of Sema4E protein in embryonic development.

6.1.2 Functional Analysis of Promoter/Enhancer Elements

Transgenic zebrafish and medaka have become popular tools in the identification and functional analysis of promoter/enhancer elements of vertebrates. The fast-growing genomic information of zebrafish and medaka facilitates the identification of evolutionarily conserved promoter/enhancer elements via cross-species comparison of genome sequences among fish, mouse, and human. Transgenic GFP-tagged zebrafish and medaka have been applied to define the essential regions of promoter/enhancer elements as well as to unmask the regulatory functions of these elements. For example, transgenic medaka and zebrafish have been used to characterize promoters of carp rhodopsin gene (cRh) and zebrafish *myf-5* gene (myf-5), respectively. In these studies, transgenic fish were designed to carry EGFP gene fused with different lengths of the upstream fragments of the presumed promoter/enhancer regulatory sequences. The role of motifs, enhancers, and minimal cis-regulatory elements involved in tissue-specific expression or the translocation of progenitor muscle cells have been identified by monitoring the expression of the EGFP reporter.

Another example of this approach is the investigation of the regulatory function of the LTRs of human ERV-9 endogenous retrovirus. The LTRs of endogenous ERV-9 retrovirus are conserved during primate evolution, but their function in the primate genomes is unknown. In human, the solitary LTRs of ERV-9 are identified as middle repetitive DNAs associated with up to 4000 human gene

loci including the β-globin gene locus where the ERV-9 LTR is juxtaposed to the locus control region (β-LCR) far upstream of the globin genes. The regulatory function of ERV-9 LTRs in the human genome has recently been demonstrated via using transgenic zebrafish carrying the β-globin ERV-9 LTR coupled to the GFP gene. The analysis suggests a regulatory role of ERV-9 LTR enhancers, during oogenesis, in the synthesis of maternal mRNAs that are required for early embryogenesis. Alternatively, the ERV-9 LTR enhancers could transcriptionally potentiate and preset chromatin structure of the cis-linked gene loci in oocytes and adult stem/progenitor cells.

6.1.3 Signaling Pathways

In addition to traditional cell-culture system, transgenic fish and their embryos have become an important tool for studying different signaling pathways in recent years. So far, most of the transgenic fish studies are conducted in zebrafish, thanks to the abundant genetic information of the species. Several achievements by the new approach are described here. Perz-Edwards et al. have identified specific regions within a whole developing zebrafish embryo where cellular transcription are responsive to retinoic acid signaling, which has been shown to be critical in normal vertebrate development. Lawson et al. have identified the downstream factors of receptor tyrosine kinase signaling that are necessary during *in vivo* blood vessel formation and arterial development. Additionally, Delta-Notch signaling in oligodendrocyte specification and the regulatory function of chemokine signaling in sensory cell migration have also been investigated by using transgenic zebrafish system. In a non-zebrafish system, Petrausch et al., by using transgenic goldfish, have identified the effects of several trophic factors converging on a purine-sensitive signaling mechanism that controls axonal outgrowth and the expression of multiple growth-associated proteins.

Despite the valuable discoveries achieved by using cell culture systems in studying signaling pathways in the last two decades, there are limitations to the use of cell culture, mainly being an artificial system that is isolated from the physiological environment of the animal. On the contrary, the most significant advantage of using transgenic fish for signaling pathway study is that transgenic fish provide an easy and representative system to dissect out signaling pathways and their biological implications with relevance to time and space in an animal. For example, while in many vertebrate species Wnt/b-catenin signaling is known to be involved in the development of neural crest cells and the specification of pigment cells derived from them at later stage, it is unclear which Wnts are involved, and when they are required. To address these issues, Lewis et al. established a transgenic zebrafish line that carried an inducible dominant-negative repressor of Wnt/β-catenin signaling, T-cell Factor 3 (Tcf-3a). The N-terminus of zebrafish Tcf-3a was conjugated with GFP as a reporter and was placed under the control of the zebrafish *hsp70* promoter. By activating the repressor to inhibit endogenous Wnt/b-catenin signaling at discrete times in development, a critical period for Wnt signaling in the initial induction of neural crest was defined. Wnt/b-catenin signaling is crucial for neural crest induction from the end of gastrulation through the 3-somite stage, and the cells lose sensitivity to transgene activation between the 3- and 6-somite stages despite the later requirement of the signaling for the pigment cell lineage. Researchers have also identified

a specific Wnt, Wnt8, and demonstrated its crucial role in initial neural crest induction, by blocking Wnt8 with antisense morpholino oligonucleotides. As demonstrated by these examples, transgenic fish is an excellent system to study a common scenario for many signaling pathways, such as BMP and Notch, in which the same signaling pathways are used in different places and at different times throughout development.

6.1.4 Human Disease Modeling

By providing a general proof of principle or reproducing specific aspects of the human diseases, animal models may be used to identify disease-associated factors or genes and to screen for new treatments for these diseases. In addition to murine models, fish have been used to study human diseases for decades, particularly in cancer research. In recent years, transgenic zebrafish and other species are emerging as valuable tools for modeling human diseases, especially in the domains of neurodegenerative diseases and cancers.

Among the neurodegenerative diseases, transgenic fish have been used for studies of Alzheimer's and Parkinson's diseases, two devastating diseases that affect tens of millions of people worldwide. The formation of neurofibrillary tangles (NFT), along with the β-amyloid plaques, are two central events in the development of Alzheimer's disease (AD). A microtubule-associated protein, tau, is critical in the process of NFT formation, in which tau protein is compromised in its normal association with microtubules, leading to the formation of paired helical filaments. Hyperphosphorylation of tau protein and mutations in the genes encoding the protein have been implicated in the pathogenesis of AD and a variety of hereditary dementias, collectively termed *frontotemporal dementia* with parkinsonism linked to chromosome 17 (FTDP-17).

The cellular consequence of NFT *in vivo* was first illustrated in a fish model by Hall et al. In this model, the giant neurons (anterior bulbar cells [ABCs]) of the central nervous system in the sea lamprey (*Petromyzon marinus*) were used to study the cytopathological changes caused by chronical overexpression of human tau protein. The unique advantages of this system include the already established morphological and cellular characterization of ABCs in detail, and most importantly, the ready accessibility of the neurons for manipulation by microinjection. This system demonstrates the association of filamentous tau deposits with stereotyped cytopathological changes, including the loss of dendritic microtubules and synapses, plasma membrane degeneration, and eventually the formation of extracellular tau deposits and cell death. Furthermore, this sequence of change is spatiotemporally correlated with the AD-related hyperphosphorylation of tau protein. By using this system, a lipid-soluble, low-molecular-weight proprietary compound has been shown to significantly retard the progressive degeneration of ABCs that express human tau protein, suggesting that development of tau-inhibitors may be a promising approach for AD treatment.

A transgenic zebrafish embryo model has also been established to study the functional consequence of FTDP-related mutations of tau protein in neurodegeneration. Zebrafish embryos at the 1–2 cell stage were microinjected with *tau* mutants under control of the neural specific GATA-2 promoter. An FTDP-17 mutant form of human tau has been shown to produce a cytoskeletal disruption that closely resembled the NFT in human disease.

This model system is therefore useful in the study of other mutant taus in vertebrate neurons *in vivo* and in the study of other molecules that are involved in the pathogenesis of human neurodegenerative diseases.

Parkinson's disease (PD) is characterized by the degeneration of mesencephalic dopaminergic neurons (MDNs) in the substantia nigra (SN). One of the most important functions of MDNs is the control of voluntary movement; loss of MDNs will eventually lead to a loss of dopamines, its metabolites, and the dopamine transporter. One of the most promising approaches to develop treatments for PD is to study the normal development of MDNs, in the hope that an understanding of their development will lead to means that can replenish damaged MDNs. Zebrafish have been used to screen for mutations that affect MDN development, and fish transgenesis can further assist in the understanding of the roles of these mutated genes in MDN development. Currently, a transgenic zebrafish model has been established to study the *ubiquitin C-terminal hydrolase L1* (*uch-L1*), a gene associated with the inherited form of PD. Zebrafish embryos were microinjected with *in vitro* synthesized zebrafish *uch-L1* mRNA or a plasmid construct containing GFP reporter under control of the *uch-L1* promoter. Together, these assays demonstrate the preferential activity of uch-L1 promoter in neurons and the spatiotemporal expression of the *uch-L1* in the ventral diencephalons, a functionally homologous region to the SN in human. The transgenic zebrafish system has thus provided further evidence for the connection of *uch-L1* in the development and degeneration of neural cells and can be further used to characterize other genes involved in neurodegenerative diseases.

In cancer research, stable lines of transgenic tumor-bearing zebrafish have been established to study the conserved cancer pathways involved in oncogene-induced lymphoblastic leukemia. In this model, zebrafish embryos at one-cell stage were injected with mouse oncogene *c-myc* (*mMyc*) and chimerical EGFP-*mMyc* transgenes under control of the zebrafish *Rag2* promoter, a lymphocyte specific promoter. In the resultant P_1 founder fish, the *myc*-induced clonally derived T-cell acute lymphoblastic leukemia was observed in almost 100% of the fish expressing green fluorescence. By tracing migration of the EGFP-tagged cells and confirming by RNA *in situ* hybridization, the leukemic T cells were clearly shown to arise in the thymus. The cells then spread to the gills and eyes and finally disseminate to the skeletal muscle and abdominal organs. The homing of leukemic T cells back to thymus was also illustrated in irradiated fish transplanted with GFP-tagged leukemic lymphoblasts. To establish stable lines of *mMyc*-transgenic fish, an *in vitro* fertilization technique was adopted because of the prompt onset of leukemia in the F_1 transgenic fish after germ-line transmission. By fertilizing the eggs collected from normal females with the sperm from 90-day-old leukemic males, the resultant transgene-positive progeny were shown to exhibit expansion of GFP-positive leukemic T cells from the thymus by one month of age. This transgenic zebrafish model can serve as a very powerful tool in the "forward-genetic" screening for modifier genes that are associated with the *myc*-induced leukemia or other types of cancers. The model can also be applied to large-scale screen for new drugs to treat or prevent human leukemia in the future.

In addition to the examples mentioned above, transgenic fish model can be applied in the studies of many other types of human diseases. We expect to see a plethora of such studies in the near future.

6.2 Growth Hormone Transgenic Fish

The initial drive of transgenic fish research came from attempts to increase production of economically important fish for human consumption. The worldwide supply of fishery products has traditionally depended upon commercial harvest of finfish, shellfish, and crustaceans from freshwater and marine-water sources. In recent years, while the worldwide commercial catch of fish experienced a sharp reduction, the worldwide demand of fish products has risen steeply. In order to cope with the demand of fish products, many countries have turned to aquaculture. Although aquaculture has the potential to meet the world demand for fish products, innovative strategies are required to improve its efficiency. What can transgenic fish technology offer in this regard?

There are three aspects of fish growth characteristics that could be improved for aquaculture: (1) increasing the initial growth rate of fry for an early head start; (2) enhancing somatic growth rate in adults to provide larger market body size; and (3) improving feed conversion efficiency of fish to achieve effective utilization of feeds. Among these three, enhanced somatic growth rates via manipulation of the GH gene shows considerable promise. Studies conducted by Agellon et al. and Paynter et al. showed that treatment of yearling rainbow trout and oysters with recombinant rainbow trout growth hormone resulted in significant growth enhancement. Similar results of growth enhancement in fish treated with recombinant GH have been reported by many investigators. These results point to the possibility of improving the somatic growth rate fish by manipulating fish GH or its gene.

Zhu et al. reported the first successful transfer of a human GH gene fused to a mouse metallothionein (MT) gene promoter into goldfish and loach. The F_1 offspring of these transgenic fish grew to be twice as large as their nontransgenic siblings. Since then, similar enhanced growth effect has been observed in the GH-transgenic fish of many other species, such as tilapia, carp, catfish, sea bream, and salmon. These studies have shown that the expression of a foreign human or fish GH gene could result in significant growth enhancement in the P_1, F_1, and F_2 transgenic fish. Additionally, Dunham et al. have demonstrated that transgenic common carp carrying rainbow trout GH transgene display, consistently in two consecutive generations, a favorable body shape, better dress-out yield, and better quality of flesh compared with controls. These studies have demonstrated that the application of GH-transgenic fish could be beneficial to the worldwide aquaculture, and hence could help to alleviate the starvation in many economically poor countries by providing more efficient, cheaper and yet high-quality protein sources.

6.3 Transgenic Fish with Enhanced Resistance to Pathogen Infection

Disease is one of the most severe bottlenecks in aquaculture. For the past few decades, efforts to control infectious diseases in commercially important teleosts have primarily focused on the development of suitable vaccines for fish and

selection of fish strains with robust resistance to infectious pathogens. Although effective vaccines have been developed for several important fish pathogens, the current vaccination practice is expensive, laborious, and time consuming. Genetic selection based on traditional crossbreeding techniques is time consuming and the outcome is frequently unpredictable, and sometimes unachievable because of the lack of desired genetic traits. More effective approaches for controlling fish disease in aquaculture are highly desirable.

Transgenic fish technology can facilitate the genetic selection process by directly modifying the undesirable genetic traits that confer vulnerability to pathogens or by introducing specific genes that are related to disease resistance into fish. The introduced transgenes can be fish-originated or characterized genes from other species. We have recently demonstrated the feasibility of introducing the antimicrobial peptide genes, cecropin B and cecropin P1, into fish to enhance disease resistance. Cecropins, first identified in *Cecropia* moth, are members of the antimicrobial peptide family that are evolutionarily conserved in species from insects to mammals. These peptides possess activities against a broad range of microorganisms, including bacteria, yeasts, and even viruses. *In vitro* studies conducted by Sarmasik et al. showed that recombinant cecropin B inhibited the propagation of common fish pathogens such as *Pseudomonas fluorescens, Aeromonas hydrophila, and Vibrio anguillarum*. Furthermore, Chiou et al. showed that cecropin and a designed analog, CF-17 peptide, effectively inhibited the replication of fish viruses such as infectious hematopoietic necrosis virus (IHNV), viral hemorrhagic septicemia virus (VHSV), snakehead rhabdovirus (SHRV), and infectious pancreatic necrosis virus (IPNV) (Fig. 3). More recently, our laboratory has shown that synthetic peptide CF-17 is also effective in inhibiting the propagation of insect baculovirus. Additionally, Jia et al. demonstrated the enhanced resistance to bacterial infection in fish which were continuously transfused with a cecropin–melittin hybrid peptide, CEME, and pleurocidin amide, a C-terminally amidated form of the natural flounder peptide. These results led to the hypothesis that production of disease-resistant fish strain may be achieved by introducing the known antimicrobial peptide genes into fish through the application of transgenic fish technology.

To test this hypothesis, we introduced gene constructs containing prepro-cecropin, procecropin, mature cecropin B, and cecropin P1 into medaka embryos by electroporation. The resulting F_2 transgenic medaka were subjected to bacterial challenges at a LD_{50} dose with *Pseudomonas fluorescens* and *Vibrio anguillarum*, respectively. The resulting relative percent survival (RPS) of the tested transgenic F_2 fish ranged from 72 to 100% against *P. fluorescens* and 25 to 75% against *V. anguillarum* (Table 4). These results clearly demonstrate the potential application of transgenic fish technology in producing fish with more robust resistance to infectious pathogens.

6.4 Transgenic Fish with Different Body Color

There are two main motives in producing fish with altered body color: (1) to generate novel varieties of ornamental fish with rare colors for the purpose of rearing as pets, and (2) to use the change of body color as indicators of environmental changes. GFP and several GFP variants are the most used genes for such purposes.

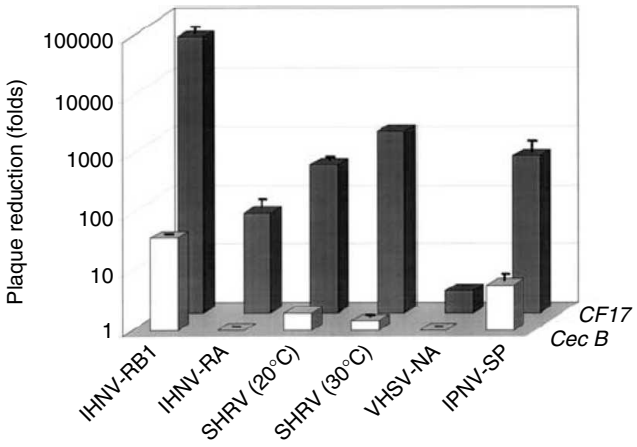

Fig. 3 Effect of peptides cecropin and CF-17 on inhibition of fish virus propagation *in vitro*. The antiviral activity of the peptides cecropin B (Cec B) and CF17 was evaluated against one nonenveloped birnavirus, the SP isolate of infectious pancreatic necrosis virus (IPNV), and three enveloped rhabdoviruses: the RB1 (type2) and RA (type 1) isolates of infectious hematopoietic necrosis virus (IHNV), snakehead rhabdovirus (SHRV), and an avirulent North America isolate (NA) of viral hemorrhagic septicemia virus (VHSV). Viral infection was carried out in EPC cells for SHRV, and CHSE-214 cells for the rest viruses. From Chiou, P.P., Lin, C.M., Perez, L., Chen, T.T. (2002) Effect of cecropin B and a synthetic analogue on propagation of fish viruses *in vitro, Mar. Biotechnol.* **4**, 294–302, with permission.

Additionally, melanin-concentrating hormone (MCH) isolated from chum salmon has also been exploited to generate transgenic medaka fish with altered body color. So far, researchers have successfully produced several colorful transgenic zebrafish displaying whole-body green, red, yellow, or orange fluorescent colors under daylight, dim light, or UV light. Some of these fish have been sterilized to avoid contaminating the wild population if they should accidentally be released from aquariums to the environments. For research purpose, mutant zebrafish and medaka with less interfering pigmentation for optical observation have also been developed. One such example is a line of ''see-through'' transgenic medaka which are transparent throughout their entire life, thus allowing clear visualization of GFP that is introduced into the fish as a reporter. The application of transgenic fish as biomonitors will be discussed in the next section.

6.5 Transgenic Fish as Environmental Biomonitors

Fish have long been used as models in environmental toxicology studies. Prompted by concerns of human health, tissues of wild-caught fish have been monitored as indicators for the presence of dangerous pollutants such as polycyclic hydrocarbons, oxidants, and heavy metals in the waters or in fish themselves. Different assays

Fig. 4 Examples of transgenic zebrafish that express GFP or RFP reporter in specific tissues. (a) A ''green-heart'' fish. Transgenic zebrafish carrying GFP reporter placed under control of the promoter of zebrafish cardiac myosin light chain 2 gene (*cmlc2*). Green fluorescence was intensively and specifically expressed in the myocardial cells located both around the heart chambers and the atrioventricular canal. The transgenic fish is kindly provided by Dr. Tsai (Huang, C.J., Tu, C.T., Hsiao, C.D., Hsieh, F.J., Tsai, H.J. (2003). Germ-line transmission of a myocardium-specific GFP transgene reveals critical regulatory elements in the cardiac myosin light chain 2 promoter of zebrafish, *Dev. Dyn.* **228**, 30–40). (b) A fish with ''red guts.'' Transgenic zebrafish carrying RFP reporter placed under control of the promoter of zebrafish intestinal fatty acid binding protein gene (*i-fabp*). Homogenous red fluorescent signals are shown in the gut epithelial cells as demonstrated in this transverse section of a transgenic larva. n: notochord. From Her, G.M., Yeh, Y.H., Wu, J.L. (2003) 435-bp liver regulatory sequence in the liver fatty acid binding protein (L-FABP) gene is sufficient to modulate liver regional expression in transgenic zebrafish, *Dev. Dyn.* **227**, 347–356, with permission.

Tab. 4 Relative percent survival (RPS) of F_2 cecropin transgenic medaka challenged with *P. fluorescens* and *V. anguillarum*.

Transgenic lines	***P. fluorescene RPS***[a]	***V. anguillarum RPS***[a]
Preprocecropin B: CMV pre pro cecropin B	100% (1)	50% (1)
Procecropin B: CMV Ig pro cecropin B	72–100% (5)	25–50% (3)
Cecropin B: CMV Ig cecropin B	72–100% (2)	ND
Cecropin P1: CMV Ig cecropin P1	100% (2)	75% (1)

[a]RPS = [1 − %mortality of F_2 transgenic fish/%mortality of F_2 nontransgenic fish] × 100 CMV: cytomegalovirus promoter; Ig: catfish IgG signal peptide; ( ): number of F_2 families tested; ND: nondetermined.

have been employed to measure biological parameters that are impacted by toxic pollutants, including DNA damage, defense enzymes (e.g. glutathione peroxidase and superoxide dismutase), genes inducible by toxic chemicals (e.g. cytochrome P450 1A1 and 1A2), and factors that regulate redox potential (e.g. glutathione and ascorbic acid). Although these assays are very sensitive, they require specialized techniques and equipment, and thus cannot be performed in the field when the samples are collected. In addition, the obtained data from wild-caught fish samples give no indication of the exact time when those fish were exposed to the toxicants.

Transgenic fish can potentially serve as sensitive sentinels for aquatic pollution, with the benefit of avoiding the inconveniences mentioned above. The principle of such biomonitor fish is to introduce into the fish reporters that are easy to observe and are under the control of promoter/enhancer elements responsive to pollutants. GFP and its variants are thus the best reporters of choice for easy optical observation, whereas luciferase is for extreme sensitivity. So far, researchers have made significant progress in establishing transgenic zebrafish carrying luciferase or GFP reporter under control of the aromatic hydrocarbon response elements (AHREs), electrophile response elements (EPREs), or metal response elements (MREs). The specificity of each type of response elements is as follows: AHREs respond to numerous polycyclic hydrocarbons and halogenated coplanar molecules such as 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD) and polychlorinated biphenyls; EPREs respond to quinones and numerous other potent electrophilic oxidants; MREs respond to heavy metal cations such as mercury, copper, nickel, cadmium, and zinc. In the zebrafish cell line ZEM2S, these three types of elements can drive the expression of luciferase reporter in a dose-dependent, chemical-class-specific manner in response to more than 20 environmental pollutants. The expression of GFP transgenes can be detected in the F_1 and, sometimes, in the F_2 generations; however, the transgenes are eventually lost following that. There are still technical obstacles in generating transgenic biomonitor fish, but the problems can be possibly overcome in the near future.

6.6 Other Examples of Transgenic Fish

Other applications include the use of transgenic fish as a model for studying mechanisms of seawater adaptation and generating cold-resistant fish carrying antifreeze proteins (AFPs). AFPs are found in many cold-water fish species, such as the winter flounder, ocean pout, and sea raven. Expression of *afp* genes permit these fish to survive in freezing seawater under as low as $-1.8\,^{\circ}C$. However, AFP transgenic Atlantic salmon does not demonstrate a measurable increase of cold tolerance.

Transgenic fish can potentially serve as bioreactors for producing therapeutic proteins beneficial to human health. The advantages of fish as bioreactors include (1) relatively low cost as compared to mammals such as cows; (2) easy maintenance; (3) producing large quantity of progeny; and (4) most importantly, no known viruses or prions have been reported to infect both human and fish. Successful expression of bioactive human proteins such as coagulation factor VII in fish embryos demonstrate this application of transgenic fish to produce therapeutic chemicals for human in the future.

7 Concerns and Future Perspectives

Transgenic fish serve as very valuable model systems for different disciplines of biological research as well as for human disease modeling. The application of transgenic fish technology to produce fish with beneficial traits, such as environmental biomonitors and GM food, is also on the rise. There has been groundbreaking discoveries made in the past few years based on the transgenic fish models, and such application is expected to continue to thrive in the future. The development of transgenic fish as environmental biomonitors is also encouraging and will continue to expand. The technique to produce transgenic fish has improved tremendously in the last two decades; nonetheless, there are still concerns about low efficiency, mosaic expression, nonfish components of the transgenes, and the long generation time for certain fish species. The following advances would thus be essential in developing the next generation transgenic fish: (1) developing more efficient mass gene transfer technologies; (2) developing targeted gene transfer technology such as embryonic stem cell gene transfer method; (3) identifying more suitable fish-origin promoters to direct the expression of transgenes at optimal levels and desired time; and (4) developing methods to shorten the time required to generate homozygous offspring.

Despite the promising future of transgenic fish as model systems in biological research, there are great concerns about the environmental impacts of such applications of transgenic fish technology to produce GM food or hobby pets. On the basis of mathematical modeling, a ''Trojan Gene Effect'' has been demonstrated in the male transgenic medaka carrying salmon growth hormone gene. Release of such fish into the environments could ultimately lead to the extinction of the wild type population owing to their advantage in mating with the wild type female. The study provides a sound analysis of the potential impact of the accidental release of transgenic fish into the environment, reminding us of the delicate interaction between a newly introduced species and the native population and environment. However, we would reason that the potential environmental impact by transgenic fish is controllable and even avoidable. First of all, the ''Trojan Gene Effect'' might not necessarily exist for other types of transgenes or in other fish species. In practice, transgenic fish can be maintained in confined areas to avoid the escape of fish into the nearby waters. Moreover, as the desirable genetic traits can be introduced into fish, the undesirable behavior traits could be possibly removed from the transgenic population by screening the behavior pattern of each transgenic individual. Ultimately, establishment of sterile transgenic population, such as a sterile triploid all-female strain, can be applied to avoid the spreading of transgenes into the wild population. Ideally, such sterility should be reversible; otherwise it would mean the loss of the goose that lays golden eggs. Finally, from a historical perspective, the concerns on the environmental impacts in the early days of the recombinant DNA technology have not been realized and many lessons can be learned from this experience.

Acceptance of GM fish as food by society is a key factor for the development of transgenic fish as a new source of cheaper and high-quality food. Largely, the concern is due to the public perception that GM food is unsafe to human health. Safety is the ultimate goal of GM fish development and relies on thorough characterization of

the transgenes and safety assessment of the GM fish, resembling the development of new drugs. Unfortunately, it is a fact that there is always a subpopulation of people who are allergic, to different degrees, to many of the existing natural food sources, such as peanuts and shellfish. Therefore, the challenge is great in developing GM fish with absolutely no adverse effect to every single individual in the human population. A thorough evaluation process to fully analyze any health risk of GM fish to human should be established and the information should be clearly delivered to the public and well marked on the food product. Development of ''gene-inactivated'' transgenic fish may be more acceptable by people who are concerned of the safety of the ''new'' genes that are introduced into fish. One candidate of such GM fish is transgenic fish strains with their myostatin gene being inactivated. Inactivation of myostatin gene causes double muscling in animals, resulting in significant increase in mass of skeletal muscle. Natural mutation of myostatin gene has been found in the meaty Belgian Blue and Piedmontes cattles, and the double muscling effect has been observed in mice whose myostatin gene is artificially inactivated. Such ''gene-inactivation'' approach would be very valuable in producing transgenic fish with more flesh and higher food conversion rate, particularly for the economically important aquaculture species.

In summary, the application of transgenic fish has resulted in many valuable discoveries in basic biological science, many of which could lead to the next breakthrough for new cures for human diseases. On the other hand, the potential of GM fish as bioreactors or as new food sources should not be deterred by the environmental and safety concerns but instead it requires more research efforts in the future to develop new GM species with beneficial traits that are also safe to human health and carry no harm to the environment.

Keywords

Autologous
Derived from endogenous sequences.

Binary Model
Mouse model in which gene activity can be switched on and off.

Chimeric Mouse
Mouse derived from donor ES cells and recipient embryo, displaying coat color mosaicism.

Chromosome Substitution
A single full-length chromosome from one inbred strain has been transferred onto the genetic background of a second strain by repeated backcrossing.

Conditional Model
Mouse model in which a modification can be activated on command.

CRE-LoxP
Bacterio phage P1-derived recombination system: the recombinase CRE-mediated recombination between two identical recombinase recognition sites: LoxP.

CRE-MER
Fusion of a CRE recombinase with a mutated ligand-binding domain of the estrogen receptor.

Ectopic Expression
Expression out of place or out of time.

Embryonic Stem Cells
Pluripotent stem cells derived from preimplantation embryos.

Gene Targeting
Modification of endogenous genes through use of replacement vectors.

Gene Trapping
Process by which transcription of a marker gene is coupled to that of an endogenous locus in which the gene trap vector is inserted and transcripts are trapped.

Heterologous
Derived from exogenous sequences.

Inbred Strain
A mouse strain bred to homozygocity for all loci by 20 brother-to-sister back crosses.

Insertional Mutagenesis
Gene modification by insertion of foreign DNA vectors.

Isogenic DNA
DNA derived from the same genetic background.

Knockin
Targeted mutation of an existing locus, mostly replacing endogenous coding sequences with functional sequences

Pluripotent
Unlimited differentiation capacity.

Recombinant Inbred Strain
Recombinant inbred strains are derived from crosses of two inbred strains.

RNA interference
RNA-mediated posttranscriptional gene silencing.

Spatio-temporal Expression Pattern
Gene activity determined in time and location.

Tetraploid
Containing four haploid genome copies.

Transgene
A(n expression) construct that is inserted into the mouse genome.

Genetically modified mouse models have become a crucial tool in present day biomedical research. Modifying genes in mice provides an excellent approach to unravel gene function at the molecular and cellular level, as well as its role in the physiology and pathology of the intact organism. By doing so, numerous models have been developed that reliably replicate diseases in humans, thereby providing insight in disease mechanisms and paving the way toward prevention and therapy. Crucial for these advances has been the ability to modulate gene expression at will. It is possible to increase or decrease gene expression, or eliminate the expression of a gene completely. These alterations can be made cell type–specific and even inducible or reversible. Moreover, it is possible to replace mouse genes with the cognate human gene carrying a specific mutation. This chapter will deal with the essential approaches in transgenic mouse research and its impact on biomedical research.

1
A Brief History of Mice

1.1
Mouse Genetics

The resources directed toward studying the mouse have been exponentially growing. After the completion of the human genome sequence, the mouse was the second mammalian genome for which the complete sequence was determined. There is no mammalian system that comes close to rival the molecular and genetic possibilities that the mouse has to offer to researchers. Many physiological methods that worked fine in larger experimental animals have been miniaturized to make use of the genetic approaches uniquely available to mouse researchers. What makes the mouse so special?

The advantages that come to mind first are obvious: for biomedical researchers, mammals are highly preferred model systems, because the physiology of man and most mammals is very similar and the pathology of most diseases is reproduced well in animal models. The mouse stands out from the other mammals as being the smallest. Mouse husbandry is therefore easy and economical; its requirements for food are modest, and mice are excellent breeders with a short generation time, allowing around four successive generations each year. Upon completion of the human and mouse genome sequence, the usefulness of the mouse as a model animal for the human has been further reinforced. The number of genes in both species is around 30 000. With the exception of about 200 genes, which were shown unique to mouse or man, the vast majority of genes is conserved between mouse and man. These combined properties make the mouse an excellent animal model to study gene function and extrapolate the outcome to human disease.

Second, the mouse has advantages that may be less obvious, but which relate to the long tradition of mouse research starting in the early 1900s. Up until then, hobbyist mouse keepers had already been breeding mice for their coat color variation. By making use of these mice, it was possible to demonstrate that this variation followed the laws of Mendelian inheritance. Soon, it was also realized that there was a need for

genetically homogeneous mouse strains and the most widely used *inbred strains* such as BALB/c and C57BL6 originate from that period. An excellent historical overview on mouse genetics is provided by Dr. Silver.

At present, hundreds of inbred strains have been generated (see Sect. 6). This resource is the key to the success of mouse research. Inbred strains ensure that experiments can be carried out in the absence of inter-individual genetic variation, because mice within an inbred strain are all *genetically identical* to each other and *homozygous* throughout the genome. Moreover, each strain has one or more unique and, often, well-established properties that make the strain particularly useful for a specific area of research. For instance, some mouse strains appeared susceptible to cancer or cardiovascular diseases, while others are better suitable for behavioral research. The genetics of such complex diseases and biological processes is very difficult to study in man. This is mainly due to the fact that multiple genes are involved and that the genetic basis for susceptibility to, for instance, cancer will vary from person to person. In the mouse, it is possible to crossbreed a susceptible and a resistant strain. As a result, the susceptibility to cancer will vary in the progeny. Genetic variation in these mice is confined to the differences between the two parental strains, and every given locus will only have two different alleles. Hence, the genetics is confined to a maximum of two alleles per locus, which greatly simplifies genetic analysis. These properties allowed generating specific resources to study complex diseases, including *recombinant inbred* (RI) strains (http://jaxmice.jax.org/info/recombinbred.html). These RI strains combine a specific genetic contribution of one mouse strain with the genetic background of another strain. Along these lines, a very powerful resource has been developed recently, consisting of a panel of inbred mouse strains carrying only a single chromosome from the other strain (http://jaxmice.jax.org/library/notes/493c.html). These *chromosome substitution* strains are very similar to recombinant inbred strains, but offer a less costly strategy to move from a susceptibility locus toward the gene proper. The principles of mouse genetics are crucial when working with transgenic animals, because it is vital to control the genetic background in the experiments (see below): the interaction between the transgene and the genetic background will ultimately determine the phenotype; for example, changing the genetic background on a given genetic trait may prevent an early death of a particular mouse model.

While mouse genetics has a major impact on our understanding of the mechanisms underlying complex diseases, a constant influx of mice carrying single gene mutations greatly stimulates mouse research. These mutations have either occurred spontaneously in mouse breeding programs or originated from research on the gene toxicity of radiation and chemical compounds. The latter approach has been rejuvenated upon the availability of better technology to identify the causative mutations (see below). A good example of a spontaneous mutation is the leptin gene mutation that occurred in the C57BL6 mouse. The mutation was named *ob*, after obese, because the mice have no control over their feeding behavior and become overwhelmingly obese. Hence, the phenotype could be discovered easily. The subsequent discovery of the causative gene marks one of the most dramatic discoveries in this research field.

1.2
Molecular Mouse Genetics

Despite all the possibilities for the basic biomedical research offered by "traditional" mouse genetics and the discoveries of relevant mutations through random mutagenesis, the true breakthrough for the mouse as the animal of choice came with the accomplishment of (1) transgenesis through injecting DNA in fertilized oocytes and (2) gene targeting via homologous recombination in embryonic stem cells. The latter mice are commonly

(b)

known as *knockout* mouse models. This combination of technologies offers the possibility to design models with ''gain of function'' and ''loss of function,'' which is an ideal situation for a (mouse) geneticist (Fig. 1a).

Notably, these technological breakthroughs were facilitated by the availability of inbred mouse strains. Transgenesis works most efficient when the donor eggs are produced by first generation (F1) hybrids between C57Bl6 and BALB/c. In the case of the gene-targeting approach using embryonic stem cells, it is critical to make use of the appropriate strain combinations when injecting the cells into blastocysts and propagating the embryos in foster strains. This dependence on the genetic background provides the ability to choose the optimal strain and may be one of the reasons why, mice are, as of yet, the only mammalian species suitable for gene targeting (see Sect. 3). The goal of altering the gene function through transgenesis is to generate animal models in which the role(s) of the gene of interest either in normal (e.g. development) or abnormal biological processes (e.g. disease) is revealed. Other important applications in fundamental science include the study of mammalian gene expression regulation. Currently, genetic modification is carried out in a wide range of invertebrate and vertebrate species, including mammals such as mice, rats, rabbits, and livestock such as sheep, pigs, cattle, and recently even primates. The choice of the models is primarily determined by its objective (e.g. improvement of economical value or development of pharmaceutical proteins). Although fundamental biological processes can be well studied in relatively simple organisms such as the nematode *Caenorhabditis elegans*, or the fruitfly *Drosophila melanogaster*, for experimental biomedical research the laboratory mouse is by far the most used animal model. Below, we will briefly outline the emergence of the two technologies and sketch the initial experimental strategies that caused great excitement within the scientific community.

1.2.1 Brief Overview of Developments in Transgenesis

By classical definition, a *transgenic* organism carries extra, often foreign (i.e. from a different organism) DNA in its genome, called a *transgene*. Transgenesis literally crosses (*trans*) species barriers. One of the most obvious conceptual characteristics is that a transgene integrates at random in the recipient host genome, whereas gene targeting, by homologous recombination, selectively alters an existent locus. A number of milestone achievements,

Fig. 1 Genetically modified mouse models in biomedical science. (a) A rough estimation of published scientific output using genetically modified mouse models. The blue line represents reports on transgenic models and the red line on gene targeting. Note: with the advent of conditional gene targeting, which utilizes transgenesis in conjunction with targeted mutagenesis, a strict separation of transgenesis and gene targeting into the twentieth century is difficult. (b) Milestones in mouse molecular genetics. The first report on germ-line transmission of integrated retroviruses (via infection) dates back to the mid-1970s. Subsequently, pronuclear microinjection of fertilized oocytes and subsequent proof of transgene integration, expression, and germ-line transmission, were pioneered in different laboratories. Similarly, breakthroughs in the use of embryonic stem (ES) cell technology are listed. Many other excellent laboratories have since contributed to refinement of technologies and strategies; these are listed throughout this chapter (see color plate p. xxvi).

which were pivotal for the development of modern-day mouse molecular genetics, are summarized in Fig. 1(b).

In the mid 1970, robust technology to clone genes and manipulate genes was still about five years away. Subsequently, as the structure of eukaryotic genes was revealed and recombinant DNA technology developed, gene constructs could be generated comprising an eukaryotic promoter fused to the full-length coding sequence of the gene of interest (consisting of a DNA copy (cDNA) of the mRNA molecule). Generating mice with a strong promoter driving an extra copy of the gene resulted in mouse models with high-level expression of the gene of interest. Interesting phenotypes did occur when the gene was markedly overexpressed. In addition, however, genes would become expressed in the wrong tissue or at the wrong place. This *ectopic* expression was also a powerful way to obtain phenotypic information. Initially, researchers were often confronted with a high failure rate: gene constructs would be integrated in high-copy head-to-tail arrays (see Sect. 2), but would not show a corresponding increase in expression level, or transgene expression would diminish in consecutive generations. A much-improved understanding of eukaryotic gene regulation in the mid-1980s provided the insight, leading to improved construct design. For instance, DNA elements located tens of kilobases outside of the β-globin gene were shown to control high-level tissue-specific gene expression through interaction with DNA sequences immediately 5′-prime of the gene. Also, sequence elements were discovered that isolate a specific gene from influences of flanking DNA. In addition, evidence was obtained for a role of splicing in mRNA stability. These advances led to the use of much larger constructs harboring the complete intron–exon structure of the genes, and including large up- and downstream DNA segments. Such fragments were obtained through cloning in cosmids, bacterial artificial chromosomes and yeast artificial chromosomes, allowing handling DNA fragments in the range from 40 up to 1000 kb.

1.2.2 Brief Overview of Developments in Gene Targeting

The development of gene targeting by homologous recombination in embryonic stem cells (ES) can be attributed to two crucial technological advances that ultimately compounded. One line of research involves ES research. Initially, ES cells were used to study cellular differentiation and cancer, because when injected subcutaneously into nude mice, teratomas would develop. Figure 1(b) itemizes a number of crucial advances in ES cell technology that helped develop ES cell technology to its current status. Improved culturing conditions ensured sustenance of pluripotence, a property of ES cells crucial for their application as vehicles to introduce germ-line mutations. Soon after the first mouse was made that showed germ-line transmission of genes introduced through genetic modification of ES cells *in vitro*, evidence was obtained that an endogenous locus could be exchanged for a mutated sequence by homologous recombination *in vitro* (see Sect. 3). These strategies targeted the murine *HPRT* gene and were based on the fact that HPRT is an excellent selectable marker expressed in the genome on the X chromosome of male cells. Spurred by success, the question arose whether gene targeting would also be feasible for nonselectable autosomal genes; this was proven possible shortly after.

Sections 2 and 3 will elaborate on the conventional transgenesis and gene-targeting technology. Noteworthy, with the introduction of novel concepts in molecular genetics, our ability to manipulate gene expression in the mouse currently knows few limitations. Sections 4, 5, and 7 of this chapter will elaborate on some of the more recent technological advances such as binary systems (see Sect. 4), random mutagenesis (see Sect. 5), and RNA interference (see Sect. 7).

2 Transgenesis; Basics and Technology

2.1 Transgene Design

Shortly after its introduction in the early 1980s, the main scientific applications of transgenesis in the mouse could be roughly divided in two areas: (1) studies of gene promoter activity (and/or other regulatory elements) and (2) studies of the effect(s) of gene overexpression (or a mutated form thereof; Fig. 2a). Gene activity is, simply put, controlled by a *promoter*. A promoter is a stretch of DNA sequence, which usually precedes the coding part of a gene. A promoters' task is to regulate gene expression: it controls the ''when (at which time point) and where'' (in what cells, tissues) of gene activity. Eukaryotic genes also carry a termination element. In order to function properly in a eukaryotic genome, a transgene minimally meets these requirements: it carries a promoter, a coding part, and a stop signal. The easiest way to read out promoter activity in cell or a developing animal is by placing a so-called *reporter gene* downstream of it. Reporter genes encode proteins, often found in lower organisms such as yeast, fireflies, or jellyfish, which reveal their presence by a microscopically or macroscopically clearly visible mark (Fig. 2a, b). This approach is standardly used to examine *spatio-temporal* gene expression patterns and/or tissue specificity of native promoter sequences *in vivo* (Fig. 2b).

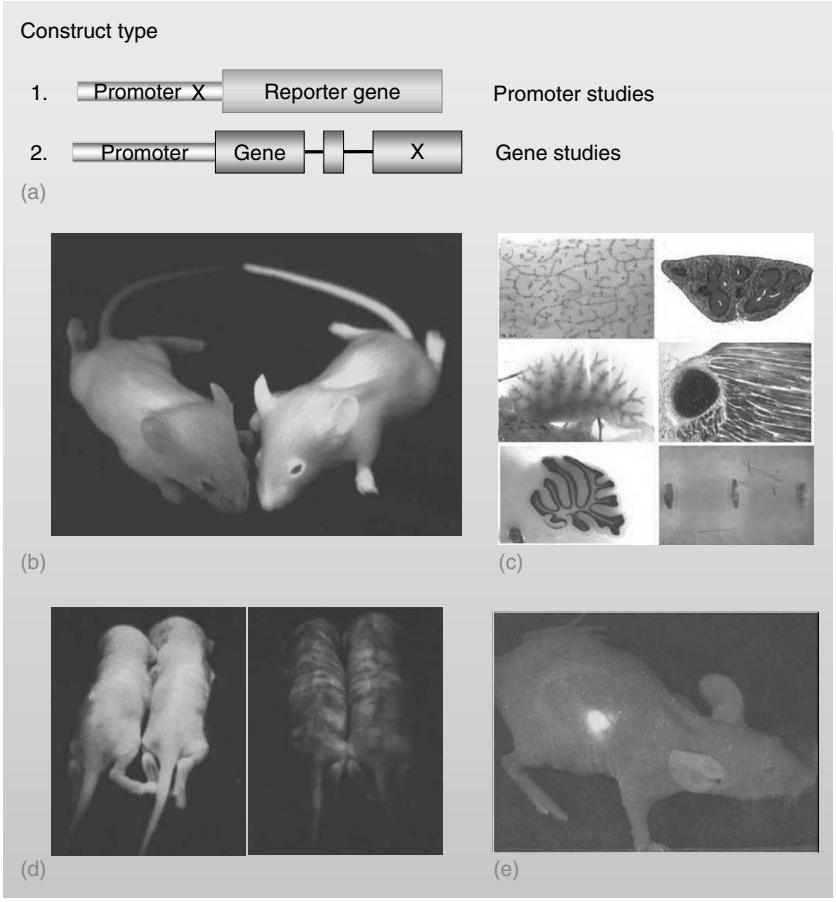
By far, transgenesis is used to achieve and/or study the effects of overexpression (higher gene activity than normal) or *ectopic* expression (gene activity in different cell types than normal) of a gene of interest, or of a mutated form thereof. The common denominator of these studies is the analysis of the resulting altered phenotype. This can be abnormal development, altered physiology or behavior, development of disease, and so on. The choice of regulatory sequences (see below) determines whether the expression of a transgene follows the expression pattern of its endogenous counterpart or is limited to distinct cell types or particular developmental stages.

2.1.1 Origin and Structure of the Transgene

The origin of a transgene, or elements therein, may range from prokaryotes or from lower (e.g. reporter genes) to higher eukaryotes, like mice or men. In experimental biomedical research, human transgenes offer several advantages. Importantly, many known genetic disorders in humans have been extensively characterized at the molecular genetic level: mutations or deletions are charted and such ''diseased alleles'' are readily available. In addition, most genes and proteins are well conserved between mouse and man. This, of course, is important when the biological activity of a gene product depends on proper interaction with other cellular proteins. Finally, the sequence

divergence between mouse (transgene recipient) and human (transgene donor) of a given gene can be used to determine whether a mouse is transgenic or not, what its copy number is (number of transgene integrations), and whether a transgene is actively expressed, since it allows for discrimination between transgene and the endogenous gene. Figure 3 gives an example of such an analysis.

Most eukaryotic genes display a typical intron/exon structure, with only exon sequences represented in mRNA. Transgenes, in general, are more reliably expressed if the intron/exon boundaries are preserved in a transgene construct. Solely cDNA-based expression vectors (i.e. exons sequences only) frequently show low expression levels and are often silenced. Since many integrating DNA or RNA viruses do not carry the eukaryotic intron/exon structures, an expressed genetic sequence without such boundaries may be recognized as foreign and potentially harmful by the eukaryotic host cell and will be inactivated (silenced) by cellular defense mechanisms. The native intron/exon structure of a gene need not be preserved in its entirety: indeed, inclusion of only one intron in a transgene has been shown



to augment transgene expression. Many successful transgene constructs include both genomic and cDNA sequences derived form the same gene (Fig. 4a).

2.1.2 **Regulatory Elements**

Any transgene comprises a number of essential elements that control gene expression (Fig. 4b). The most basic and essential elements are the promoter and termination signals for transcription (RNA synthesis). A promoter controls gene expression by providing binding sites for proteins (RNA polymerase transcriptional machinery, cell type–specific transcription factors) that regulate gene transcription (i.e. activation). The real-life situation is often much more complicated than this; many more regulatory elements exist that all play a role in establishing stable and faithful gene expression patterns. Among these are enhancers, which typically act in an orientation-independent manner, Matrix attachment regions (MARs), scaffold attachment regions (SARs), Locus control regions (LCR), chromosomal insulators, and antirepressor elements. Some of these elements are involved in subnuclear localization of genes to areas of active transcription and/or insulate gene expression from influences of surrounding chromatin. Some of these autologous (i.e. endogenous) regulatory elements may actually be many thousands of base pairs removed from the coding sequences of a gene. Indeed, if the purpose of a study is to examine faithful gene expression patterns, for instance throughout embryonic development, a transgene should include such endogenous elements. The exact location of such elements within a locus is often not known and hence there is an obvious advantage in using large DNA segments as transgenes. The development of molecular vectors, which can harbor large pieces of DNA, such as so-called artificial

Fig. 2 Transgenesis; concepts. (a) Original scientific applications of transgenesis in the mouse were roughly divided in two areas: (1) studies of gene promoter activity (and/or other regulatory elements) and (2) studies of the effect(s) of overexpression (or a mutated form) of gene X. Promoter studies typically make use of *reporter* genes (green box) that reveal their presence through specific catalytic activity. Often-used reporter genes include the green fluorescent protein jelly fish (b, d), bacterial beta-galactosidase (c), (also see Fig. 3), and fire fly luciferase (d). (b) Transgene expression is controlled by a keratinocyte-specific promoter (source image: http://www.mshri.on.ca/nagy/cre.htm; Maatman, R., Gertsenstein, M., de Meijer, E., Nagy, A. et al. (2003) Aggregation of embryos and embryonic stem cells, *Methods Mol. Biol.* **209**, 201–230). (c) Differential expression of beta-galactosidase (upper left to lower right): Lymphatic vessels (intestinal surface), marginal zones between red and white pulp (spleen), bronchial epithelium (lungs), Large skeletal muscles (limb), granule cell layer (cerebellum), Intervertebral discs (source images: Valenzuela, D.M., Murphy, A.J., Frendewey, D., Gale, N.W. et al. (2003) High-throughput engineering of the mouse genome coupled with high-resolution expression analysis, *Nat. Biotechnol.* **21**, 652–659). (d) Fluorescent images of an X-linked enhanced green fluorescent protein (EGFP) transgene; transgenic male offspring (left) of a mating between an X-linked EGFP transgenic female and a nontransgenic male have ubiquitous green fluorescence in the skin owing to the presence of a single active X chromosome. Transgenic female pups (right) have mosaic (tortoiseshell) green fluorescence in the skin owing to random inactivation of one X chromosome (source image: Hadjantonakis, A.K., Dickinson, M.E., Fraser, S.E., Papaioannou, V.E. (2003) Technicolour transgenics: imaging tools for functional genomics in the mouse, *Nat. Rev. Genet.* **4**, 613–625). (e) An external image of adenovirus-encoded GFP gene expression acquired from a nude mouse in the light box 72 h after portal vein injection (see color plate p. xxviii).

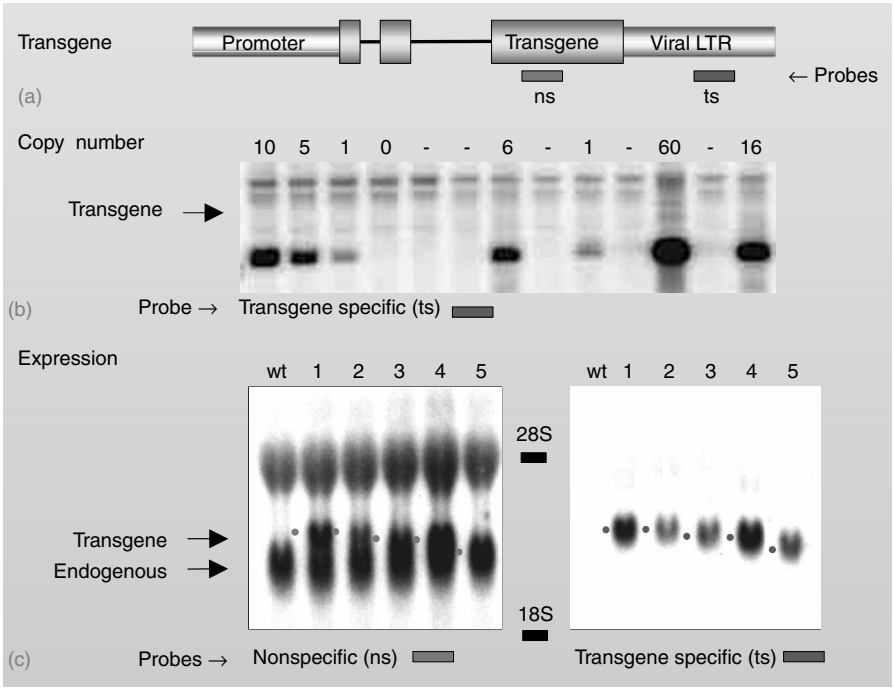


Fig. 3 Transgene construction and detection. (a) Schematic representation of a hypothetical transgene. The transgene is derived from mouse genomic sequences (brown). Transgene expression is under control of a general promoter and terminates in a retroviral long terminal repeat (LTR) element. Probes used for detection of transgene DNA or RNA are depicted as a brown box (nonspecific (ns) probe, which detects both the endogenous gene and the transgene) or a blue box (a transgene-specific (ts) probe, which only detects the transgene). (b) Copy number determination by Southern blot analysis with a ts probe. Bold print above image represent DNA samples with known copy numbers, resp. 10, 5, 1, and no transgene copies inserted; the remaining lanes show four founders with varying copy numbers (image adapted from:(http://www.healthsystem.virginia.edu/internet/transgenic-mouse/southerndesign.cfm)) (c) Detection of transgene expression by Northern blot hybridization clearly demonstrates the need for transgene specific probes (right panel). Left panel: expression signal of endogenous gene masks transgene expression (see color plate p. xxix).

chromosomes that can be propagated in yeast (YACs), phages P1 (bacterial viruses; PACs), or bacteria (BACs) has been imperative for the cloning and expression of such transgenic constructs. Exceedingly large constructs (>500 000 bp) are first transferred into embryonic stem cells (see Sect. 3), which are then used to generate transgenic mice.

Regulatory elements need not necessarily be autologous in nature, they may be *heterologous*. For instance, when overexpression or ectopic expression is required, general type heterologous promoters (e.g. viral promoters) and/or enhancers are widely used. The use of heterologous and autologous regulatory elements is often combined. The first published transgenic mouse model displaying a specific phenotype made use of the general-type metallothionein promoter (pMT). The MT promoter is inducible *in vitro* and *in*

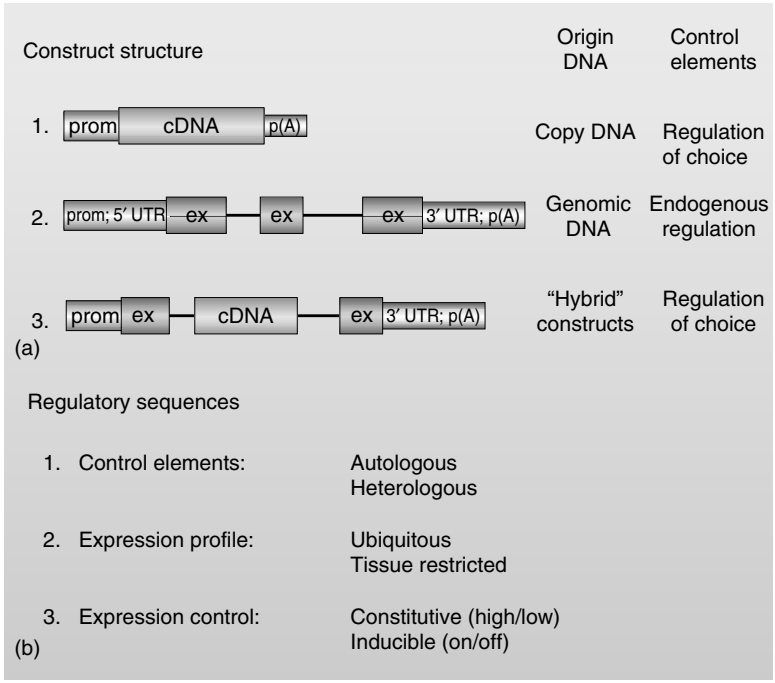

Fig. 4 Transgene structure and regulation. (a) Schematic overview of basic transgenic construct design. For all constructs (1,2,3), eukaryotic coding sequence is the starting material. Regulatory sequences are cloned separately into the construct, which is entirely cDNA based (1). Endogenous regulatory sequences may be included when genomic DNA is used (2). A transgene can be tailored to specific requirements. The hybrid genomic/cDNA construct depicted (3) combines intro-exon boundary inclusion with facile cloning options: the use of cDNA may reduce the size of a vector considerably. prom: promoter sequences, ex: exon, cDNA: copy DNA, 3′ UTR: 3-prime untranslated region, p(A): polyadenylation signal. (b) Regulatory sequences in transgene design. Depending on the specific purpose of the model, many different systems are available to control transgene expression. As indicated, regulatory element can be autologous (i.e. derived from an endogenous locus) or heterologous in nature (1). The required transgene expression profile may need to be ubiquitous, or cell type specific. This determines the choice of promoter (2). Finally, the model may require controlled expression; instead of constitutive expression, inducible expression would be preferred (3). (Figures adapted from: Voncken, J.W. (2003b) Transgene design, *Methods Mol. Biol.* **209**, 51–67).

vivo with glucocorticoids, heavy metals, or bacterial endotoxin (LPS). Heterologous promoters and other regulatory elements are applied widely, and as indicated before, their incorporation into constructs is determined primarily by the aim of the animal model (see Fig. 2). Not only general-type promoters, like the ones driving housekeeping genes (e.g. *phosphoglycerate kinase PGK*) or other genes that are widely expressed throughout eukaryotic cell types (e.g. *histones, ß-actin*), but also

viral promoters are often used to ensure high and ubiquitous transgene expression. LCRs are included in transgenic constructs to both enhance transgene expression and to achieve position-independent and copy number–dependent expression of a transgene, often with cell lineage–specific enhancer activity. Finally, promoter choice is often dictated by whether expression of a transgene is deleterious to the mouse or not. For example, many oncogenes play an important role in embryonic development, interfering with their normal expression (pattern) results in embryonic lethality. To bypass this problem, either tissue-specific or inducible promoters (or combinations of such regulatory systems are used (see Sect. 4)).

Taken together, the origin of DNA, structure and choice of regulatory elements for a transgene are largely determined by the scientific aim of the experimental model itself. For biomedical studies employing the laboratory mouse as a model system, the use of human transgenes is often preferred.

2.2 Pronuclear Injection

Transgenes can be introduced into living cells in many different ways. Among the most standard procedures *in vitro* (''in the test tube'') are transfection methods either using calcium phosphate/DNA precipitates or liposomes (small DNA-containing vesicles surrounded by a lipid membrane), which are taken up by cells, electroporation (electroshock), viral vectors (e.g. adenovirus, retrovirus, which carry the transgene), particle bombardment, and microinjection. Some of these methods, however, cannot be used in combination with mouse oocytes. The very first proof-of-principle report on germ-line transmission of a foreign DNA sequence in the mouse was achieved through retroviral transduction. As indicated above, viruses of this class are often inactivated in eukaryotic cells. Although recent technological developments in the field of transgenesis again make use of retroviral constructs (see Sect. 7), pronuclear injection has been the golden standard for generating transgenic animals over the last two decades.

The principle of pronuclear injection is simple: a sterile DNA solution is prepared, which contains a very low concentration of the transgene (nanograms (10e-12 kg)/microliter (10e-15 l)). A very fine glass needle containing the transgene DNA solution is inserted into one of the pronuclei and DNA solution is expelled into the nucleoplasma (Fig. 5a, 6a). The amount of DNA injected is extremely low (femtograms (10e-18 kg)/picoliters (10e-12 l)). Injected transgene DNA in the nucleus tends to integrate at random into the genome. Often, this occurs in head-to-tail tandem arrays called *concatamers*. (Fig. 5b). The repetitive nature of such concatamers may lead to transgene inactivation, as does the random character of the insertion: it often causes transgenes to land in inactive heterochromatin, which constitutes most of a eukaryote cells' DNA. The use of insulator elements (see Sect. 2.1) or targeted transgenesis (see Sect. 4) provides solutions to these problems.

2.3 Biotechnological Procedures

Figure 6 gives an overview of the biotechnological procedures involved in the production of transgenic mice. Because generating transgenic mice by pronuclear injection is a rather inefficient process, a relatively large number of fertilized oocytes

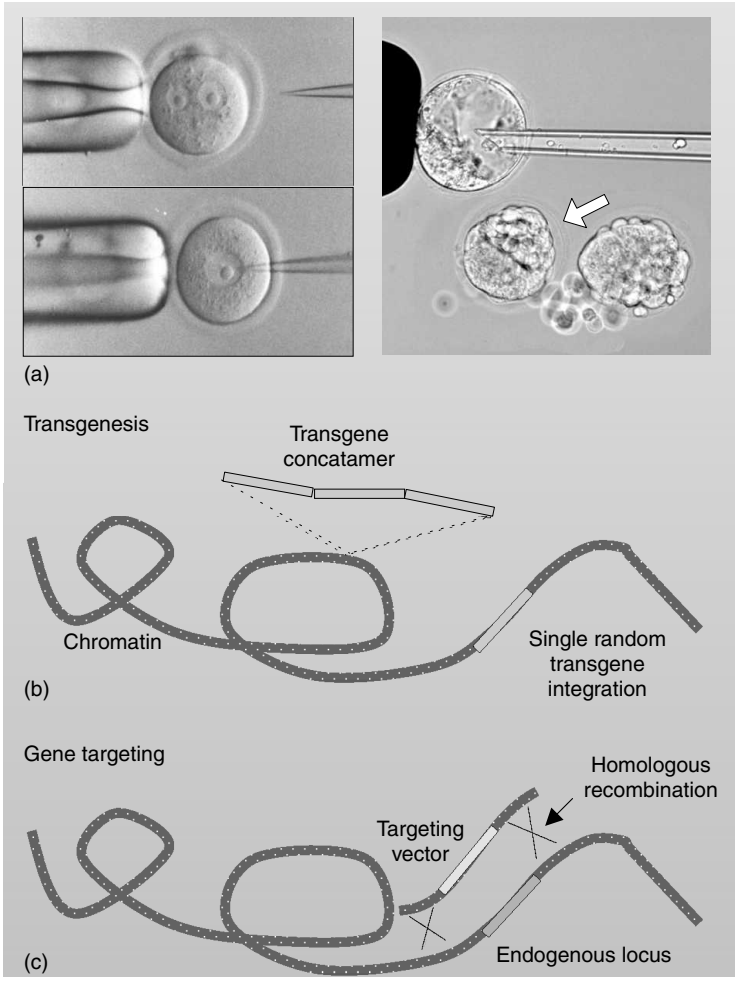

Fig. 5 Microinjection. (a) Pronuclear injection of DNA into a fertilized one-cell-stage embryo. In the early stages following fertilization, two pronuclei are visible in the zygote: one from the oocyte and one from the sperm cell; these will eventually fuse to form a diploid nucleus. Both prefusion pronuclei are clearly visible in the cytoplasm (the male pronucleus is mostly used for injection, since it is the largest) (left panel; source image: Hogan, B., Beddington, R., Costantini, F., Lacey, E. (1994) *Manipulating the Mouse Embryo. A Laboratory Manual*, 2nd edition, Cold Spring Harbor Laboratory Press, Cold Spring Harbor, New York). Microinjection of genetically modified ES cells into blastocysts; arrow indicates collapsed, injected blastocysts; ES cells are clearly visible in the blastocoel (right panel). (b) Schematic representation of random integration of transgenesis in the mouse genome: transgene either integrated single or as concatameric head-to-tail arrays. (c) Gene targeting is homology-driven: a targeting vector will exchange with an endogenous locus by homologous recombination.

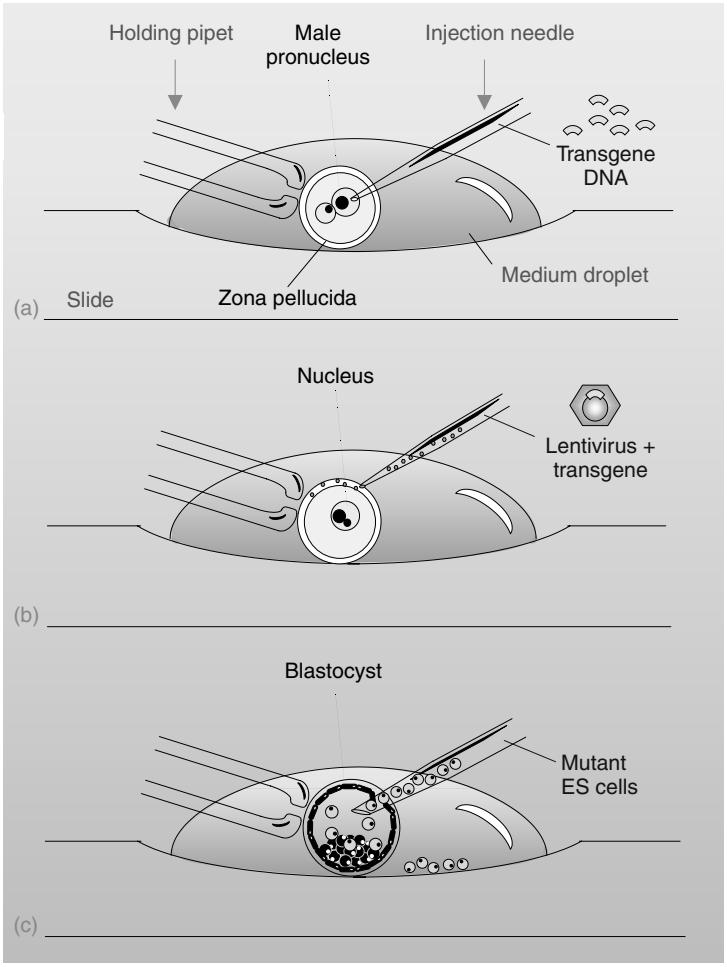

Fig. 6 Schematic representation of a number of techniques to generate genetically modified mouse models. (a) Pronuclear injection of transgene DNA. (b) Injection of infectious viral particle in the perivitellin space; the advantages of using lentiviral shuttle vector are significant: it obviates potentially harmful procedures otherwise used to introduce transgenes into a cell (pronuclear microinjection, electroporation) and offers some degree of control over transgene copy numbers. Lentiviral vectors are also used to generate transgenic lines through infection of ES cells. One of the few restrictions on recombinant lentiviral vector use is the size limitation on the transgene inserts. (c) Microinjection of pluripotent, genetically modified ES cells into blastocysts.

needs to be injected to obtain the so-called founder mice: transgenic founders developed *in utero* from successfully injected zygotes that carry an integrated transgene in their genome. A typical transgenic study uses at least three expressing transgenic founders to establish independent transgenic mouse lines from.

Convenient numbers of fertilized eggs are obtained by superovulation, much the same as way as in humans for *in vitro* fertilization purposes: exogenous hormones (follicle-stimulating hormone and luteinizing hormone analogs) are injected at a 48-h interval to achieve multiple ovulations per donor female, which are subsequently mated to fertile males. Simultaneously, recipient females, the so-called foster females, are endocrinologically primed for pregnancy by copulation to vasectomized males (see Fig. 7). Microsurgery is carried out under aseptic conditions and general anesthesia. A number of different mouse strains are useful for biotechnological procedures, many of which have their own advantages and specific traits (see Sect. 1). Detailed descriptions of the technology, useful strains, and husbandry are to be found in a number of media.

3 Gene Targeting; Basics and Technology

First established in the late 1980s and early 1990s of the last century, gene targeting is now a well-established technology for generating genetically modified mouse models. Gene targeting allows for germ-line manipulation at predetermined genomic loci by a process called *homologous recombination*: part of an endogenous allele is replaced or mutated by vector sequences that carry flanking sequences homologous to the endogenous gene (Sect. 3.1). It is in this aspect where gene targeting fundamentally differs from conventional transgenic technology: the possibility to change existing genes offers a very important and powerful extension of the molecular genetic tools to create experimental animal models in biomedical research. Whereas transgenesis asks for genes and their phenotypes to be dominant in nature (e.g. expression of (mutated) oncogenes), gene targeting now permits study of recessive gene function (e.g. tumor suppressor genes). The concept of gene targeting is simple: eradication of a gene may reveal its function by a resultant phenotype. Current applications range from conventional *null mutation* of a given gene, the so-called gene knockouts, to replacement of endogenous alleles with mutated alleles and even inducible (*conditional;* see Sect. 4.3) genetic modifications.

3.1 Targeting Vector Design

Generally speaking, two types of vectors exist by which genes can be mutated.

1. Replacement vectors
2. Random insertion vectors

All classical *replacement type vectors* have in common that they carry stretches of DNA, which are highly homologous or identical to the gene, which is to be targeted. The mechanism by which gene replacement is accomplished, *homologous recombination*, uses these identical or very similar sequences of DNA: homologous recombination is a sequence homology-initiated and driven process (Fig. 5c, 8a). It appears to be a highly selective process, which only takes place between relatively large (several kilobase pairs) DNA segments. In fact, it is important that the constructs used for homologous recombination are being derived from the exact same genetic background (*isogenic*) as the cell line used for gene targeting. This requirement implies that a sequence divergence of around 1 in 100 bp will cause a marked drop in

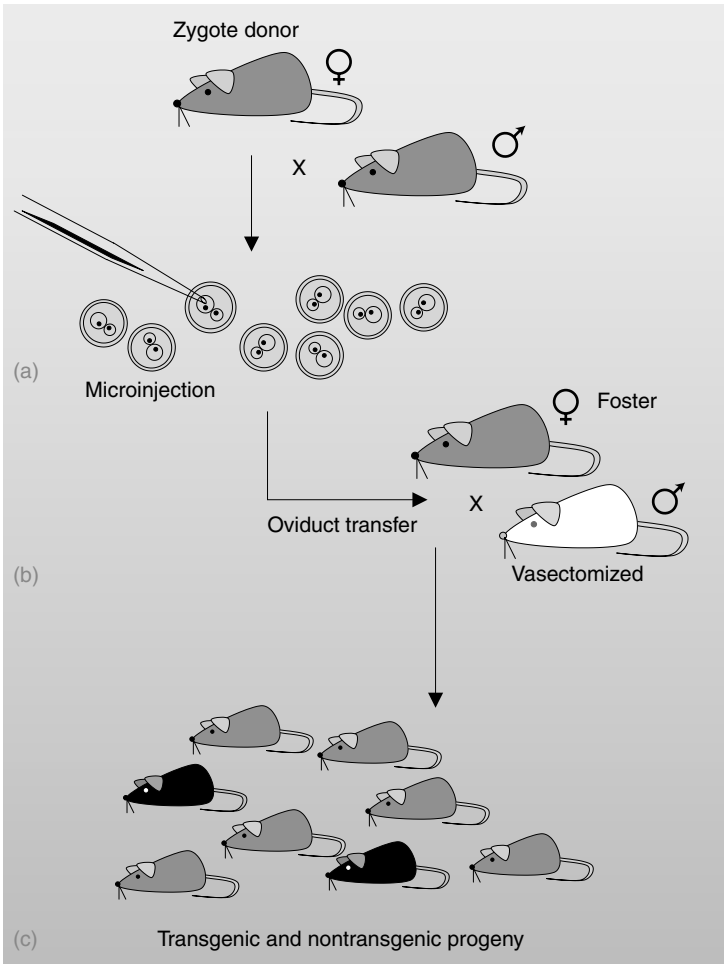

Fig. 7 Biotechnological procedures in conventional transgenesis. (a) Hybrid F1 animals are used for superovulation and mating to generate sufficient zygotes for injection. (b) Upon microinjection, the embryos are transferred into the oviduct of a pseudopregnant female; *pseudo-pregnancy*, is achieved by mating to a vasectomized male and exists for a maximum of 3 days; the surgical transfer of microinjected one- or two-cell-stage embryos directly into the fallopian tube at 0.5 day *post coitum* ensures sustenance of the pregnant state. (c) Offspring will manifest coat colors of both strains (e.g. C57Bl6 and CBA) used to generate the F1 hybrids (e.g. B6CBA/F1). Roughly, 10% of the offspring will carry an integrated transgene, and will be further examined for transgene expression and transmission. Such an animal is referred to as a *transgenic founder*. In addition, these media provide comprehensive information on historical and genetic backgrounds of in- and outbred strains on mouse embryology and dissection of specific developmental stages.

the frequency of homologous recombination. Conventional gene-targeting constructs mostly harbor a selection marker (neomycin, hygromycin, or puromycin resistance gene), which serves a number of purposes: it replaces endogenous gene sequences, thereby interrupting the gene and rendering it nonfunctional (Fig. 8a). In addition, the marker is used to positively select for embryonal stem cells that have integrated the targeting vector. A second feature often included in a replacement

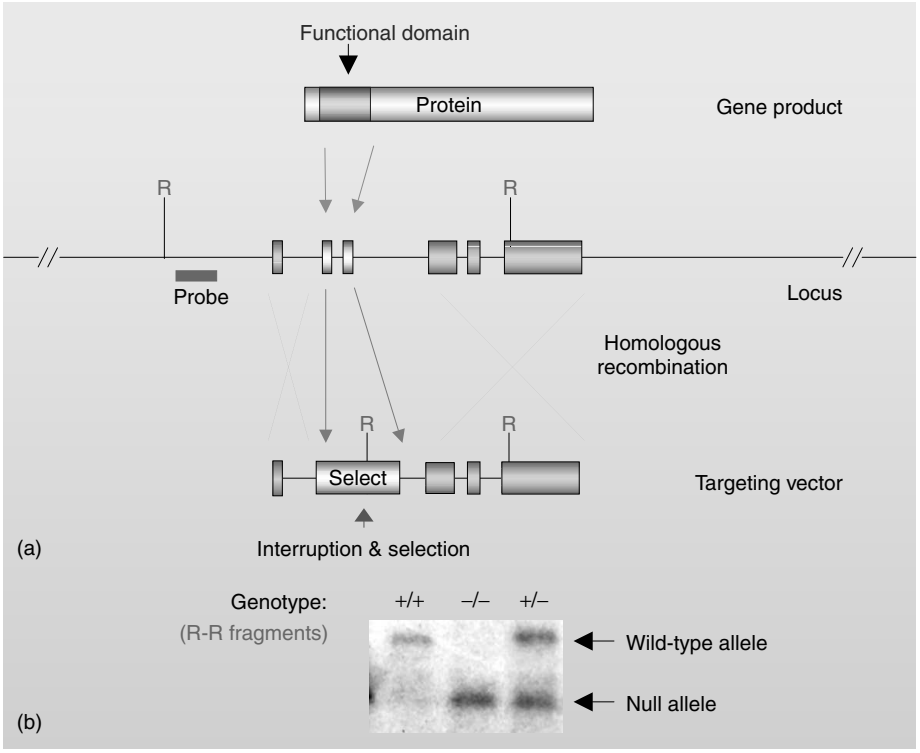

Fig. 8 Basic design of a conventional targeting vector. (a) The targeting vector duplicates part of the locus to be mutated (homologous sequences), but is interrupted by a positive selection marker (*select*), for instance, an antibiotic resistance gene. Many conventional targeting vectors also contain a negative selection marker. The herpes simplex virus Thymidine Kinase gene is often included: the TK gene product converts a harmless compound, for instance, Ganciclovir, into a cytotoxic substance. The positioning of the TK cassette at one of the ends of a targeting vector results in exclusion of TK from the genome upon homologous recombination, whereas TK is cointegrated in case of random integration of a targeting vector. (b) The vector is designed such that by means of an ''external probe'' (blue-grey box: *probe*; from within the to be targeted locus, but outside the homology regions used in the targeting construct) and strategically chosen restriction endonuclease sites (R) a shift is detected upon homologous recombination. The figure shows the three possible genotypes; two wild-type (+/+) alleles, two knockout (−/−) alleles (homozygous knockout), and a combination of both in the heterozygous (+/−) condition (see also Fig. 10). Mutagenesis vectors may be introduced into ES cells via several means; the most commonly used method is electroporation (electroshock) by which the cellular membrane is damaged, allowing uptake of DNA in cells (see color plate p. xxvii).

vector is a negative selection marker, for example, the *Herpes simplex virus* thymidine kinase (HSV-TK). Upon positive (negative) selection, a number of separately isolated ES cell clones are ''genotyped'' to ensure proper recombination on both ends of the targeting vector. Typically, these cells carry a monoallelic mutation, that is, only one of two alleles in the ES clone is replaced by the targeting vector (Fig. 8b).

Random insertion type vectors insert at will in the genome and, therefore, do not rely on sequence homology with target genes (see Sect. 5.1). Integration of a vector in a locus may, however, cause inactivation of a gene. The best-known application of insertion type vectors is *gene trapping* (see Sect. 4 and 5). Gene trap vectors are constructed such that they either trap promoter activity or trap a polyadenylation signal from an endogenous locus (Fig. 15). In this manner, not only actively transcribed but also inactive genes can be trapped (with promoter-trap or poly(A)-trap vector respectively). Variations on this concept are described in Sect. 5.

3.2 Embryonic Stem (ES) Cells

In contrast to classical transgenesis, where mutagenesis is done directly in the embryo, gene targeting is done in *embryonic stem cells* (ES cells) (Fig. 9a). These are very early stem cells isolated from preimplantation embryos (*blastocysts*). ES cells are *pluripotent*, that is, they are fully undifferentiated and, in essence, have the capacity to participate in mouse embryogenesis and become any cell type in the animal. The first steps in a gene targeting experiment are carried out *in vitro*. ES cell culturing conditions are aimed at maintaining their pluripotency. ES cells are either cultured on a layer of supporting feeder cells (mouse embryo fibroblasts (MEFs)) in the presence of factors that block differentiation of stem cells in general (like *Leukemia Inhibitory Factor*,) or are ''feeder-independent.'' It is their pluripotency that is ultimately called upon: when generating targeted mutations in the mouse, male mutant ES cells are reintroduced into preimplantation embryos and made to participate in embryogenesis and spermatogenesis in particular. If the latter occurs, the targeted mutation can be stably transmitted via the germline to offspring and bred to homozygocity.

3.3 Genesis of Mosaic Embryos

ES cells may be used in a number of ways to generate genetically mosaic embryos. The most commonly used procedure is *blastocyst injection*: preimplantation blastocysts are used to introduce ES cell into (Fig. 5a). The donor mouse line (i.e. of which ES cells are derived) and the recipient line (i.e. of which blastocysts are procured) differ in coat color genetics. Typically, an inbred strain such as *C57blk* (black coat color) is used for blastocyst production to inject *129Sv* or a *129Ola* (sand-colored coat), some of the most commonly used ES cell lines, into. The procedure described above is schematically represented in Fig. 6c.

Alternatively, ES cells can be fused to morula stage embryos in a procedure termed *morula aggregation*. Embryos in the morula stage typically comprise 8 to 16 blastomeres (individual embryonic cells) surrounded by a protective layer called the *zona pellucida*. In order to achieve aggregation, this zone is first removed and the embryos together with a small number of ES cells are cocultured in a small depression, in which gravity forces them to

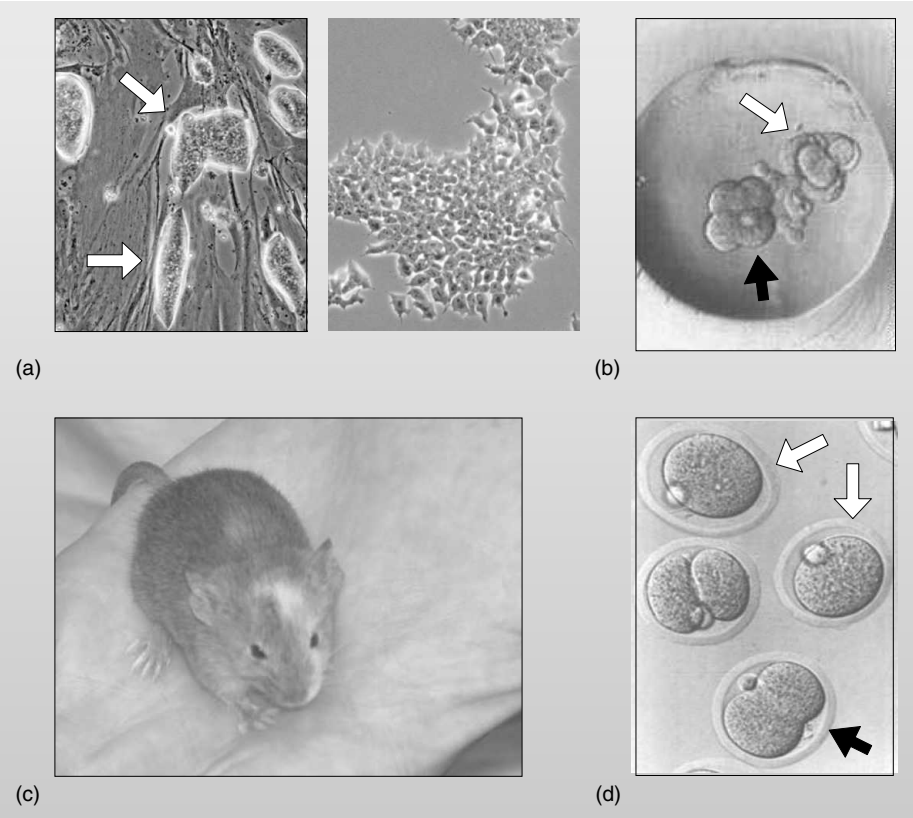

Fig. 9 Embryonic stem cells, embryos, and chimeric mice. (a) Left panel: ES cells grown on mouse embryonic fibroblasts (MEFs); white arrows point at colonies of tightly coherent ES cells; right panel: feeder-free ES cells. (b) Aggregation of 8-cell-stage morulas (black arrow) with genetically modified ES cells (white arrow). (c) Chimeric mice beautifully displaying the coat color mosaicism resulting from contribution of ES cells of two different genetic backgrounds to the developing embryo the mix of, in this case, C57Bl (recipient blastocyst – black) and 129Ola (donor ES cells – sand) becomes manifest as Agouti, patches of purely 129Ola-derived tissue is sand colored (e.g. over left eye). (d) Electrofusion of two-cell-stage embryos (middle left) results in fusion and formation of one-cell-stage tetraploid embryos (white arrows). Tetraploidy does not hamper placenta formation, but does not permit normal embryogenesis. Tetraploid blastocysts injected with diploid ES cells will support fully ES cell–derived embryonic development (source image: (http://www.mshri.on.ca/nagy/cre.htm)) (see color plate p. xxxi).

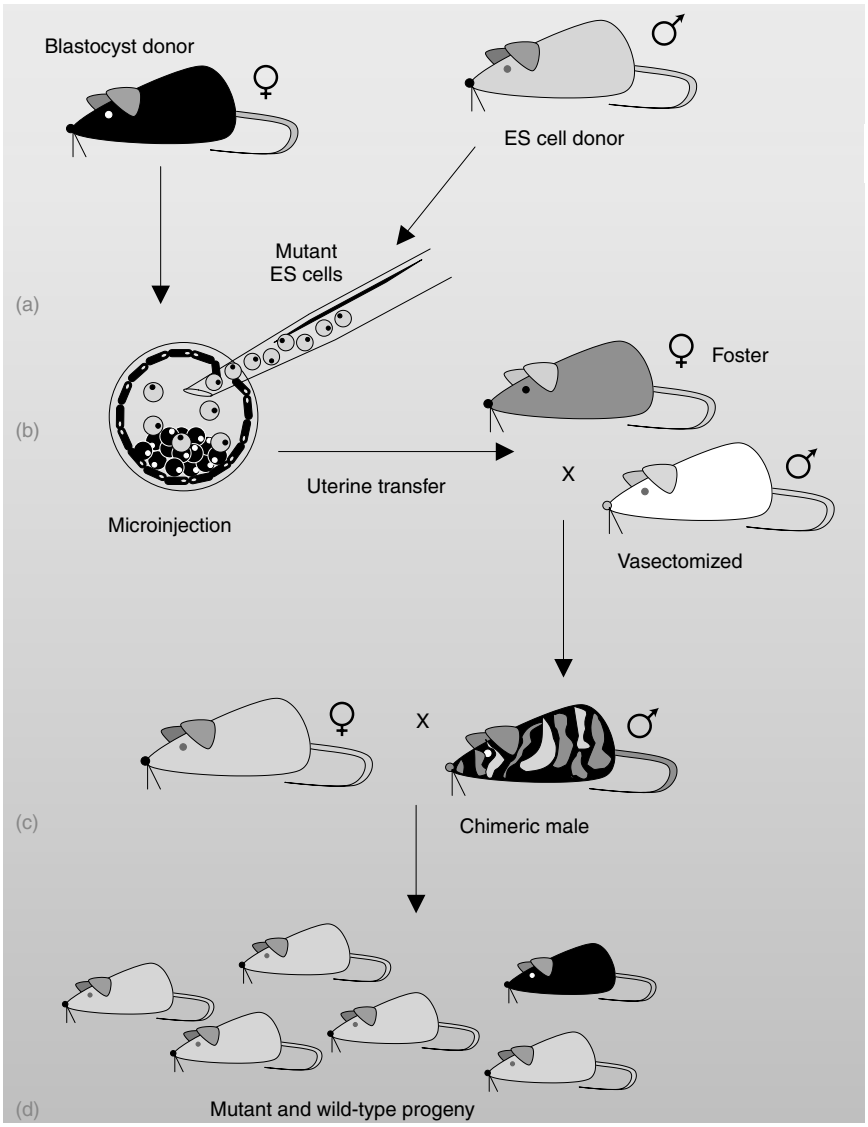
be in close contact with each other (Fig. 9b; http://www.mshri.on.ca/nagy/cre.htm).

Both methods yield the typical mosaic coat (e.g. a mixture of different coat colors, like black and sand). The mice that display the coat color mosaicism are referred to as *chimeric mice* (Fig. 9c). Chimeric males are bred to wild-type mice to generate a mouse that is heterozygous for the mutant allele in all its cells; the subsequent mating of two

heterozygous animals allows the mutation to be bred into a homozygous state.

3.4 Biotechnological Procedures

In contrast to transgenic technology, preimplantation embryos are isolated at the blastocyst stage. Microinjected embryos are transferred directly into the uterus of a 2.5-day pseudopregnant female, where they develop into chimeric embryos (Fig. 9b, 10). A typical targeting experiment uses at least two independent mutant embryonic stem cell lines for microinjection to verify and confirm the phenotype



in two independently established homozygous knockout animals.

4 Refinements to the Models

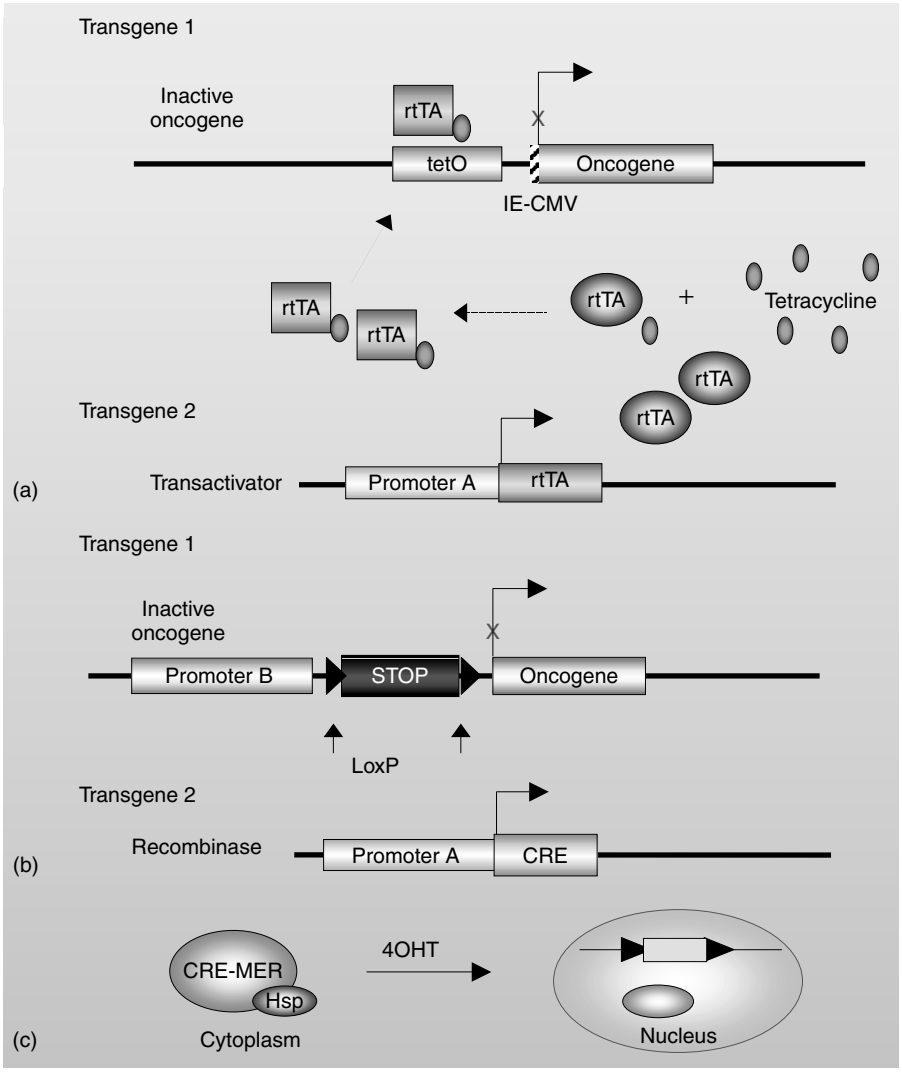
Transgenes or gene knockouts may cause unexpected embryonic or neonatal lethality, either by interfering with embryo development or placentation. If the aim of an animal model is to, for example, study the effect of a transgene or a gene knockout on adult physiology or development of a disease, embryonic lethality limits the usefulness of such a model. To circumvent this problem, animal molecular geneticists have sought to refine animal models. The resulting mouse models often combine aspects of transgenesis and gene targeting and may include a molecular switch, by which null mutation of a gene now is rendered *conditional*. Such on/off models are referred to as *binary models*. The most pivotal advantages of such molecular switches are gain in accuracy and specificity of the model and an important concomitant reduction of disease burden for the animals. Some exciting models and applications that have been developed over the last decade are described below.

4.1 Fully ES Cell–derived Embryos

The placenta is one of the first organ systems to develop during early embryogenesis. It provides an essential means by which the developing embryo and the mother animal exchange essential factors such as nutrients and oxygen. A surprisingly large number of null mutations result in defective placentation. Defective placentation in a conventional genetic approach thwarts all possibilities to uncover a gene function during early embryogenesis. J. Rossant and coworkers developed an elegant solution to this problem during the early 1990s: tetraploid embryos were used to reintroduce diploid ES cells into. The concept is elegantly simple: tetraploid cells will contribute to placentation (polyploidy is a normal feature within the developing placenta); they will, however, not contribute to the development of the embryo itself. It was shown that in this approach, reintroduced normal diploid wild-type ES cells were fully capable of supporting normal embryonic development. The data demonstrated that with this technology

Fig. 10 Biotechnological procedures in conventional gene targeting. (a) Inbred strains are used for superovulation and mating to generate sufficient blastocysts for injection. The procedures in use to obtain sufficient blastocysts for microinjection are natural matings or superovulation. Breeding properties of some inbred strains are relatively poor, hence, natural mating often require large numbers of mating pairs. Super ovulation is often not very efficient in inbred strains either, but will usually yield adequate embryo numbers for injection. (b) Upon microinjection, the embryos are transferred into the oviduct of a pseudopregnant female (see also legend to Fig. 7). (c) Since male ES cells are used, researchers look for a gender bias among chimeric offspring: a potent male (XY) ES cell line forces even female recipient blastocysts (XX) into a male sex phenotype. As a general rule is considered: the higher the coat color mosaicism, the more likely it is that the ES cells participate in spermatogenesis, the higher the chance for germ-line transmission of the mutation; (d)–Germ-line transmission is revealed by the coat color of the donor (ES cell; sand-colored in the figure; several ES cell lines are in use) strain; 50% of the sand-colored offspring will be heterozygous for the germ-line mutation (see color plate p. xxx).

the study of genetically manipulated ES cells in all fetal lineages was possible, while, at the same time, potential negative effects of a null mutation on placental development were circumvented. Tetraploid recipient embryos were generated by electrofusion: normal diploid two-cell-stage embryos were subjected to a defined electroshock that results in fusion of the cells to form one tetraploid one-cell-stage embryo (Fig. 9d). This tetraploid early embryo is allowed to further develop *in vitro*, to be used at a later stage for aggregation or microinjection (see Sect. 3.3). It should be noted that although the role of a gene can now be studied independent of placentation, specific lethality as a result of gene mutation is not prevented. To bypass



these problems, inducible or binary models are used.

4.2 Conditional Transgenesis

Conditional transgenesis is employed to have better control over (trans)gene expression in a given model. This may be advantageous for a number of reasons, for instance, to circumvent lethality during embryonic development caused by toxic or teratogenic properties of transgenes or to study the onset of disease from its earliest stages onward.

In its simplest form, conditionality is integrated in an animal model by means of tissue-specific promoters and/or control element usage (see Sect. 2.1). Transgene expression is confined to a defined target tissue or select cells within a tissue, for instance, epithelial lung cells (surfactant protein promoter) or anterior pituitary cells (POMC, pro-opiomelanocortin promoter). Several tens to hundreds of models have been created and used in this fashion to successfully study the specific effect(s) of transgene expression in development or disease.

Truly conditional transgenesis, in which the investigator not only determines where a transgene is turned on but also when and how strong, can be achieved with binary models. Binary models incorporate a switching mechanism. Several molecular switches exist to turn on or off transgenes. Figure 11 lists examples of these methods. Most binary switches are reversible. Two main concepts are

Fig. 11 Binary models. (a) The Tet-system requires two independently generated transgenic lines, which are combined by interbreeding. Transgene 1 carries a minimal (''enhancer-less'') Cytomegalovirus immediate early (IE–CMV) promoter fused to heptamerized prokaryotic tetO regulatory sequences. Transgene 1 is transcriptionally silent until the transactivator line (transgene 2) provides transactivator protein. In the original Tet-system, transgene 2 expressed a tetracycline (Tc)-controlled transcriptional activator, tTA. tTA is a fusion between the Tet-repressor of the *Tn10* Tc resistance operon of *E. coli* and a C-terminal part of the herpes simplex transactivator protein VP16. tTA will induce transcription from the tetO-controlled transgene up to five orders of magnitude, but is inhibited by Tc. The example depicts rtTA (red ovals), a reverse Tc-controlled transactivator, which is a mutant form of tTA and needs Tc-derivatives to bind tetO (yellow squares). So rather than an inhibitable model, rtTA is an inducible model. Refinements on the Tet-system include choice of regulatory sequences (promoter A) in transgene 2 (cell type–specific, general promoter). In addition, several derivatives of Tc exist, among which Doxocyclin (Dox) has better tissue penetration and pharmacokinetic properties than Tc itself and very high and selective affinity for TetR. (b) The use of bacteriophage P1 CRE-LoxP recombination–dependent removal of a strong transcriptional block (STOP) in a transgene construct may be helpful in defining the molecular events at the onset of tumorigenesis and in addition circumvents possible embryonic lethal effects of the transgene. The choice of regulatory sequences (promoter A) in transgene 2 is determined by the model. Although the excision of a transcriptional block is, in principle, reversible, for practical reasons this system is rarely used as a binary switch, since it would entail obligatory screening for genetic modifications (insertions) in target cells: this obviously compromises the usefulness of the models in terms of precision and rapidity. (c) Fusion of CRE to the mutant forms of the ligand-binding domain of nuclear hormone receptors, such as the estrogen receptor (MER), has generated a recombinase CRE-MER that can be ''induced'' at the posttranslation level: CRE-MER is retained cytoplasmic through interaction with heatshock proteins (Hsp) such as HSsp90; upon addition of 4-hydroxytamoxifen (4OHT), a synthetic steroid, the Hsp-binding is released, and the recombinase shuttles to the nucleus to excise floxed sequences (also see Fig. 12) (see color plate p. xxxii).

used: (1) a combination of nonmammalian promoters and transcription factors and (2) integration of transcriptional interruptions that are removed by recombination. The use of inducible transcription by means of nonmammalian, for example, regulatory elements borrowed from bacteria or lower eukaryotes, like the fruit fly (*D. melanogaster*), allows transgenes to be activated and silenced "on command." The system that utilizes removal of a strong transcriptional block by means of recombination, although in principal reversible, is, for practical reasons, mostly used one-way.

Several binary switches are itemized below:

- *Tetracycline-controlled transgene expression: the Tet-system*. The transgene of interest is placed under the control of a Tetracycline resistance operon from *Escherichia coli*, the tet-operator (*tetO*). A second, independent transgenic line expressing a derivative of TetR, a transcriptional regulator of tetO, confers Tetracycline (Tc)-inducibility or repressiveness to the transgene of interest (see Fig. 11a). Transcription factors with regulatory activity toward the tetO are absent in eukaryotic cells, which means that theoretically the system cannot be leaky for transcription and pleiotropic effects are therefore not expected.
- *Insect hormone–controlled transgene expression*. The system uses the molting steroid hormone *ecdysone* for transgene induction. It requires a heterodimeric receptor and an ecdysone responsive element, which is incorporated as a regulatory element in the transgene of interest. Administration of *ecdysone* (or a derivative *muristerone A*) rapidly and selectively induces transgene expression. Upon withdrawal of the steroid hormone, expression is silenced. Again, since mammalian cells lack insect hormone receptors, the binary system theoretically works as an on/off system, much like the Tet-system. Ecdysone nor its derivatives are toxic or teratogenic. Owing to excellent pharmacokinetic properties, the method is ideally suited for very precise conditional control over gene expression.
- *Transgene induction by removal of a transcriptional block*. The system makes use of a recombination process derived from bacteriophage P1: phages (bacterial viruses) use a site-specific recombinase (CRE) to integrate their DNA into the genome of their bacterial host. An essential second component of this process is a recombinase recognition site, called an *LoxP site*: two LoxP sites are recognized and recombined by CRE (Fig. 12a). The two essential components, LoxP and CRE, also work in eukaryotic systems, and are commonly maintained on two separate transgenic lines. Flanking a sequence with two similarly oriented LoxP sites will lead to its excision in the presence of CRE. Hence, an on/off transgenic system employs a silenced transgene, in which a strong transcriptional block is bracketed by two similarly oriented LoxP sites; a second independent transgenic line, which expresses the CRE recombinase, may be driven off a general, tissue-specific or inducible promoter, depending on the objective of the study (Fig. 11b). More details on this recombination-based switching mechanism will be discussed in Sect. 4.3.

4.3 Conditional Gene Targeting

Gene targeting is widely used to study gene function in the mouse. Hundreds

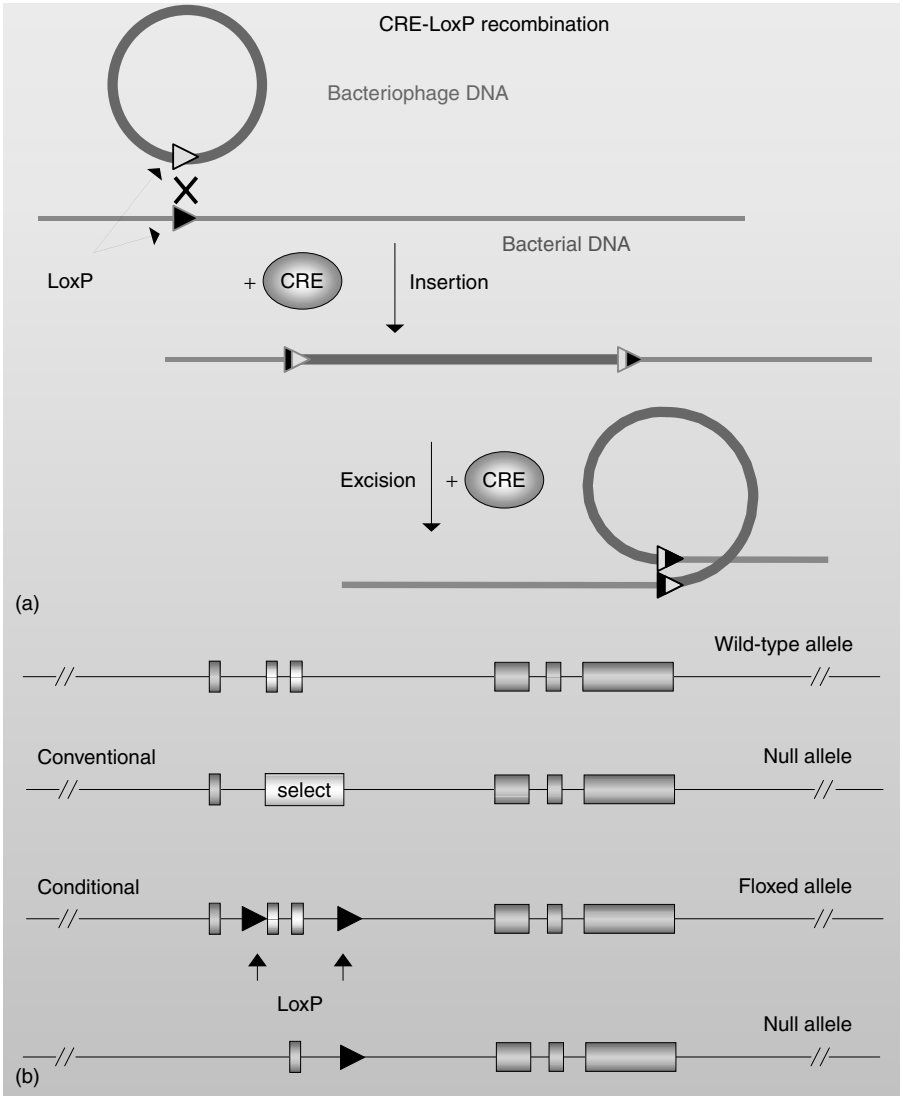


Fig. 12 (a) CRE-LoxP system: LoxP sites are short sequences harboring inverted 13 nucleotide repeats separated by an 8-nucleotide asymmetric spacer. The LoxP are recognition sites for the recombinase CRE. CRE drives site-specific recombination of two identical LoxP sites, for clarity depicted as a yellow and a black triangle. Two similarly oriented LoxP sites on one contiguous DNA strand will be recombined by CRE and the sequence in between the LoxP sites is excised. (b) This recombination principle is used in conditional gene-targeting vectors: a crucial coding region (two blue exons) is ''floxed'' (i.e. flanked by LoxP sites) in ES cells and excised *in vivo*. The LoxP sites in the ''floxed'' allele are assumed not to interfere with wild-type gene expression. The figure compares the structure of a conventional and a conditional knockout allele. A variation on this theme is the FLP-*frt* system, which is derived from yeast. The FLP gene product, like CRE, is a site-specific recombinase; *frt* (FLP recognition target) represents the small inverted repeats, analogous to LoxP, recognized by the recombinase (see color plate p. xxxiv).

of genes have been "knocked out" in the conventional approach, in which the null mutation is transmitted through the germline, as discussed in Sect. 3.1. An estimated one in three null mutations results in embryonic or early postpartum lethality. Therefore, germ-line mutations may be appropriate models to recapitulate human congenital genetic disorders. They may, however, not be the best tools to study gene function in adult mice, since this is hampered by often unexpected and unexplained lethality. K. Rajewsky and coworkers were among the first to develop a conditional gene-targeting strategy that allows inactivation of a gene in a defined *spatio-temporal* setting: the null mutation can, for instance, be confined to selected cell types or to a specific stage during development.

Conditional gene targeting makes use of the CRE-LoxP principle, as described in Sect. 4.2. Briefly, LoxP sites flank a genomic sequence in a targeting vector, which will be deleted *in vivo*; this allele is referred to as a *floxed* allele (Fig. 12b). This final "floxed" wild-type allele only carries recombinase recognition sites at positions within the locus where they are presumed inert, for example, introns: up until the moment of recombination-driven excision *in vivo*, the allele should function as a wild-type allele. Since the CRE-LoxP system is applied more widely than the FLP-*frt* system *in vivo*, further descriptions of conditional gene targeting will focus mainly on the CRE-LoxP system.

The current standard experimental conditional approach requires two separate mouse lines:

1. the "floxed" line (as described above)
2. the "deleter" line, expressing CRE.

The transcriptional control directing CRE expression determines the specificity and degree of regulation of the conditional knockout. CRE-transgene expression is controlled either by constitutively cell type–specific or inducible regulatory elements (also see Sect. 2.1 and 4.2). Deleter strains are most often generated by conventional transgenic technology. Alternatively, the CRE-cDNA can be inserted via targeted mutagenesis to a locus of interest, under control of the endogenous promoter. Although the latter method does not require a thorough knowledge of the regulatory elements controlling the locus at hand, the approach is not as straightforward as conventional transgenesis. Drawbacks of the former method comprise all known problems linked to conventional transgenesis: transgene expression is dependent on integration site and copy number. Consequently, a number of independent founders will have to be generated to select a useful strain. A substantial collection of tissue-specific CRE mouse lines is currently available.

Inducible CRE expression allows for a high level of control (see Sect. 4.2). Again, it should be noted that conditional gene targeting is mainly used unidirectionally, that is, once a gene of interest is inactivated through CRE-mediated recombination, reversion of the genotype is not easily accomplished.

4.3.1 Controlled CRE Expression

Inducibility can be conferred by rather simple measures such as CRE expression through infectious viral particles. Such viruses can be locally administered or systemically. In addition, their tropism (i.e. host-cell range) can be manipulated.

Inducible mammalian promoters have been used, as well as the Tet-system (see Sect. 4.2). Besides the induction of CRE

transcription and translation, CRE induction has also been achieved at the post-translational level. This was accomplished by fusing CRE-encoding sequences in frame to the ligand-binding domain (LBD) of nuclear steroid hormone receptors, such as the estrogen or progesterone receptor (ER, PR respectively). Ligand binding transfers the CRE-ER fusion product into the nucleus, where the recombinase exerts its catalytic activity toward LoxP sites. Mutation of the ER moiety, has generated *CRE-MER* (mutated estrogen receptors) fusions, which are only induced by synthetic hormones and not by their natural ligands (Fig. 11c). Ongoing improvements of these and alike inducible systems clearly generate a highly sensitive and specific means to control transgene expression and enable the study of gene ablation and overexpression that, without such tools, were impossible. An increasing number of published models employing CRE-MER variants attest to the feasibility of the approach *in vivo*.

4.4 Knockins: Humanized Mice

Many studies in human disease have uncovered mutations that are relevant to the etiology of the pathological condition. Examples of these are large congenital chromosomal duplications or deletions in inborn genetic disease, specific dominant mutations in oncogenes, recessive mutations in tumorsuppressor genes, or polymorphisms in genes involved in lipid metabolism linked to atherosclerosis. In order to understand the exact molecular mechanism underlying the development of disease, such mutations need to be exactly recreated in the mouse. Clearly, conventional and conditional genomic manipulations are not specific enough to address such issues. CRE-mediated recombination has provided possibilities and strategies to manipulate the genome beyond conditional gene knockouts or transgenesis. As illustrated in Fig. 13 and 14, the CRE-LoxP system can be used to manipulate the genome in various manners:

- *Gene knockin* or *gene exchange strategies* apply CRE-LoxP-mediated recombination to exchange endogenous coding regions for exogenous or mutated sequences in a locus (Fig. 13a). Especially, the latter application is of significant interest to the scientific community, since it permits the development of animal models, which reflect human genetic disorders more closely than models applying overexpression or ablation of a gene. Initial approaches inserted reporter genes into an endogenous locus; this simple variation on conventional gene targeting achieves the same purpose as a transgene harboring a reporter preceded by endogenous regulatory sequences (see Sect. 2.1). The main difference, of course, is that this strategy obviates the handling of large DNA fragments with potentially unidentified regulatory elements needed to achieve faithful expression patterns, since these elements are provided by the targeting into the endogenous locus. Recently developed strategies take knockin significantly further and allow for specific introduction of (point) mutations and repeated exchange of genetic sequences: recombination-mediated cassette exchange (RMCE) applies strategically positioned pairs of wt and mutated LoxP sites or LoxP and *frt* sites to achieve stepwise and directional replacement of genomic sequences with other of mutated sequences (Fig. 13b).

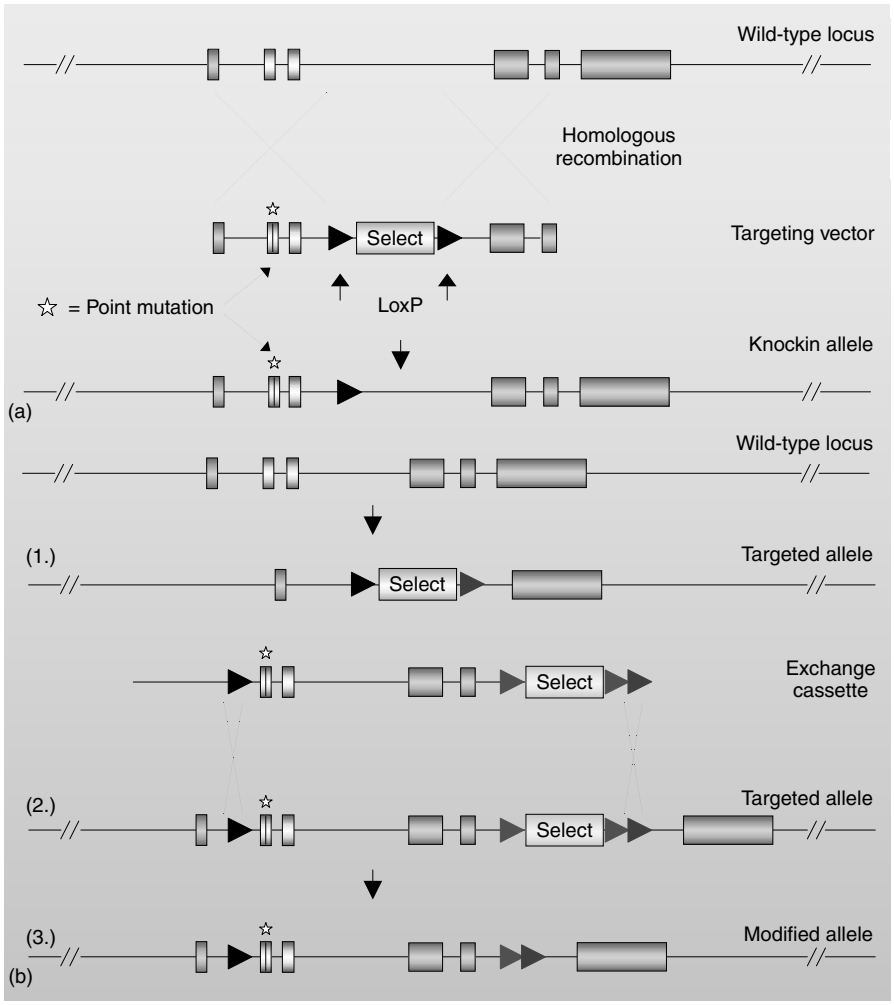

Fig. 13 Applications of site-directed recombination in molecular mouse genetics. (a) A conditional targeting construct usually harbors an antibiotic resistance gene (select) flanked by recombinase recognition sites (either LoxP or *frt*; see legend to Fig. 12). Prior to microinjection into blastocysts or aggregation with morulas, the selection marker is excised in ES cells by recombination (by transient expression of either CRE or FLP). The targeting construct depicted contains a specific point mutation (asterix) in one of its exons. Homologous recombination results in introduction of the mutation in the endogenous locus. (b) The use of multiple nonidentical LoxP and or *frt* sites (black, red, and blue triangles) creates the possibility to repeatedly exchange sequences between vectors and a locus via site-specific recombination. The procedure is referred to as *recombination-mediated cassette exchange (RCME)*. First, a locus is targeted and an asymmetrically ''floxed'' selection marker is introduced (1). Using the same LoxP variants, an exchange cassette is introduced (2) upon which the selection marker is removed by recombinase-mediated excision (3). The exchange procedure can be repeated multiple times, since the position of the most peripheral recombinase recognition sites (black and red triangles) is maintained (see color plate p. xxxv).

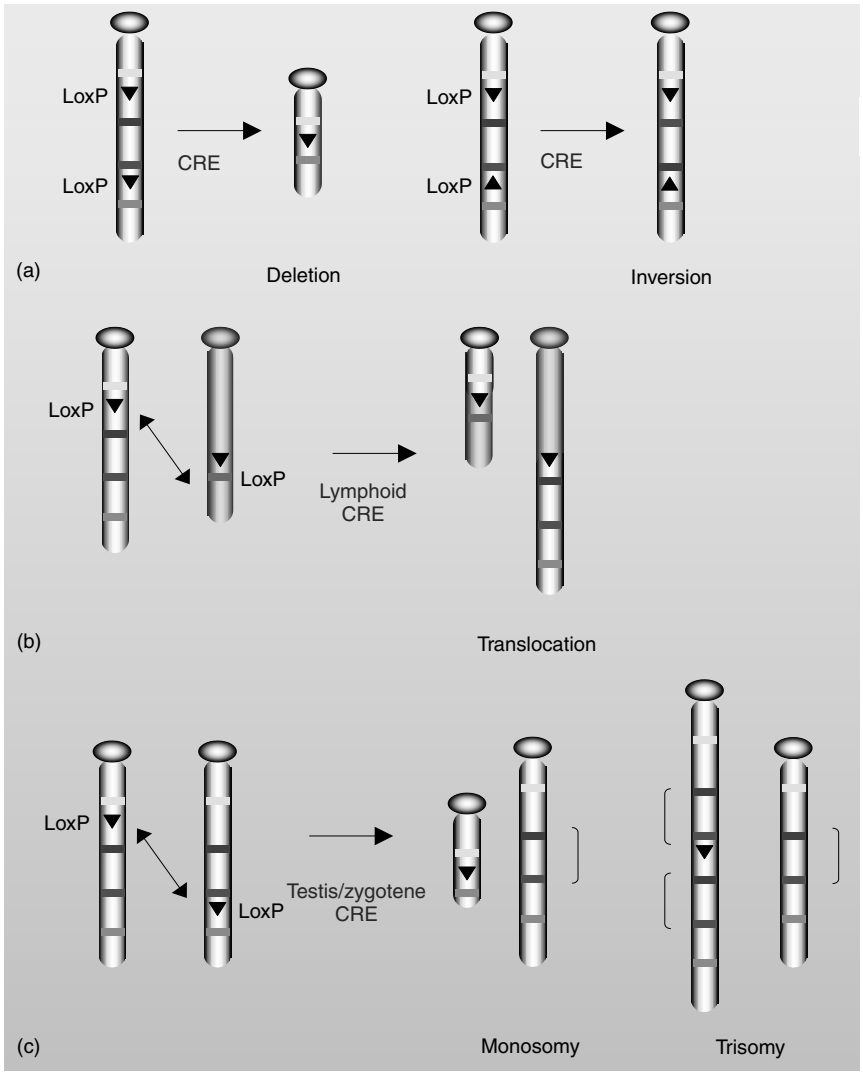

Fig. 14 CRE-LoxP applications in chromosome engineering. (a) Chromosome engineering is an important tool that facilitates functional analysis of large chromosomal regions: large segments of DNA can be either deleted or inversed, depending on the orientation of the LoxP sites in respect to each other. Series of overlapping deletions can be generated by combined use of one targeted LoxP site and retrovirus-mediated random insertion of additional LoxP sites. CRE-LoxP recombination may be used to generate balancer chromosomes to maintain lethal recessive mutations and has the potential to facilitate large-scale mutagenesis screens. Deletion or inversion carriers can be used to uncover and instantly map, for example, ENU-induced recessive phenotypes to deleted or inversed chromosomal regions. (b) Interchromosomal recombination by positioning LoxP sites on nonhomologous chromosomes will recreate translocations, which occur in human disease. (c) The use of CRE-mediated recombination to create defined autosomal trisomies in the mouse, for example, through meiosis-/zygotene-specific CRE-deleter strains that are solely active in testis.

- *Chromosomal deletions, inversions, translocations.* Simultaneous specific positioning of LoxP sites on one chromosome allows for gene inversions or complete deletions, depending on the orientation of the recombinase recognition sites relative to each other (Fig. 14). Positioning of such recombinase recognition sites on nonhomologous chromosomes has proven to be a feasible strategy to achieve chromosomal translocation, alike translocations that are implicated in some leukemias.
- *Targeted integration of transgenes* to loci, which are known to be "open," that is, not embedded in heterochromatin. The gain of this approach is a high probability of transgene expression. An often-used target locus is the *ROSA26* locus, an ubiquitously transcribed locus that does not encode a protein, but which is active in many different cell types throughout development and adult life. Transgenes are flanked by DNA sequences homologous to the *ROSA26* locus and targeted via conventional methods (see Sect. 3).
- A substantial number of other applications for site-directed recombination has been reported on in the scientific literature. Since the principal mechanism remains the same in all instances, a few of these applications are listed here, but not worked out in detail: *selection marker recycling, exchange of reporter genes, removal of reporter genes, or selection markers* (as in the generation of floxed alleles).

5 Random Mutagenesis in ES Cells

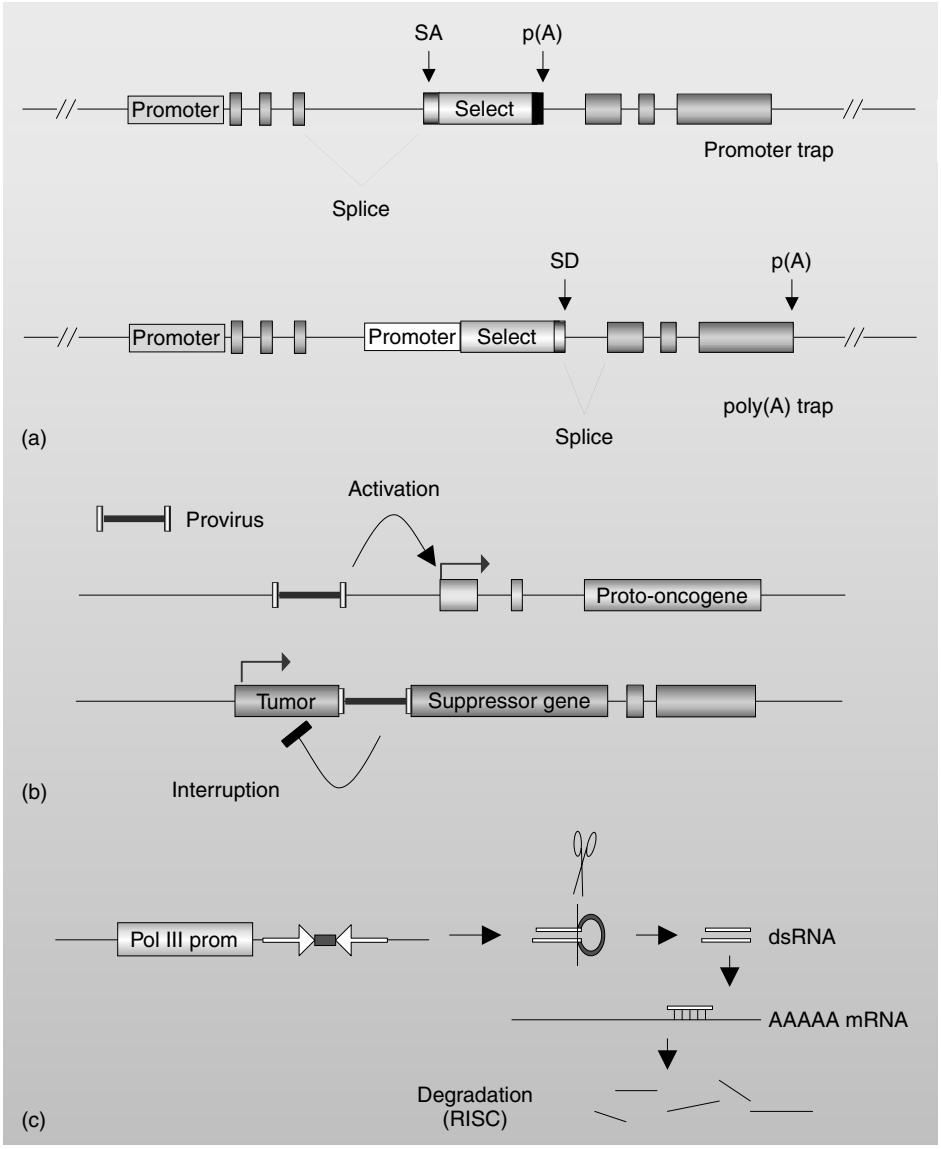
The completion of the mouse and human genome sequences has sparked renewed interest in developing tools for genome-wide mutagenesis in the mouse. Among the main molecular genetic technologies currently pursued are targeted mutagenesis (see Sect. 3 and 4), *insertional mutagenesis,* by insertion of gene trap vectors or viral or transposable sequences, and chemical mutagenesis. These technologies all represent random mutagenesis protocols, which, in principle, can be applied to mouse ES cells. The important advantage of random mutagenesis is that new mutations can be generated in mice at

Fig. 15 Random mutagenesis strategies. (a) Promoter-trap and poly(A)-trap vectors, respectively, catch or induce transcriptional activity and have the potential to identify most, if not all, of the active and inactive genes in the genome, including alternatively spliced forms and low-abundance transcripts, and is thus an important tool in genome annotation. (b) Gene mutation through random insertion of retroviral vectors (or transposable elements; see Sect. 5.2). Shown is an oncogene, which is activated by a nearby proviral insert, and a tumorsuppressor gene, which is inactivated proviral insertion into the gene. Inserted elements are engineered such that they simultaneously function as sequencing tags to identify the surrounding genomic DNA. (c) Stable or inducible RNA interference as an alternative to targeted mutagenesis to study gene function in mice: a short double-strand RNA (ds) stem-loop-stem structure (white arrows, blue loop) is produced from a RNA polymerase III-promoted vector. The loop is enzymatically removed inside the cell; the resulting short interfering RNAs will bind their complementary mRNA, upon which the target mRNA is degraded by a complex called *RISC (RNA-induced silencing complex)*. RNA interference–mediated gene silencing does not require targeted mutagenesis of a gene, and may therefore represent a more efficient and rapid method to assess gene function (see color plate p. xxxvi).

a rate far exceeding conventional gene targeting. In addition, it is possible to identify and maintain recessive lethal phenotypes at any developmental stage, which, for instance, is not possible with chemical mutagenesis (see Sect. 5.3).

5.1 Gene Trap Mutagenesis

Gene trapping provides a method to mutate genes in the genome through random insertion throughout the genome.



Essentially, all currently designed gene trap vectors insert a selectable marker or reporter gene lacking essential regulatory sequences into an endogenous gene. Through marker insertion the gene is interrupted, while marker expression is complemented by endogenous regulatory elements (Fig. 15a). In this manner, transcriptionally active as well as inactive loci can be trapped. Recent reports provided proof that gene trapping can also be used to selectively mutagenize genes that share certain properties, in this case, the fact that their gene products are all transmembrane proteins. A ''secretory'' trap vector was constructed such that it captured signal sequences in preceding exons by means of including a ''capturing'' transmembrane domain in the gene trap construct. These and other approaches collectively demonstrate the power and versatility of gene trapping in genome-wide functional analysis of molecular mechanisms important in development and physiology. A collective gene trap database has recently been initiated by a number of consortia (http://www.igtc.ca/index.html – http://www.escells.ca/ – http://www.mmrrc.org/ – http://tikus.gsf.de/project/web_new/index.html – http://www.sanger.ac.uk/PostGenomics/genetrap/ – http://baygenomics.ucsf.edu/overview/welcome.html).

5.2 Retroviruses and Transposable Elements in Random Mutagenesis

The use of *retroviruses* in random mutagenesis is adapted from applications in which proviruses are used to screen for collaborating oncogenes in leukemogenesis. Slow transforming retroviruses such as Moloney Murine Leukemia Virus (MoMuLV) cause transformation by integration into the genome. Proviral integration may activate oncogenes or interrupt tumor suppressor genes (Fig. 15b). This is an extremely useful asset in random mutagenesis, since the integrated proviruses now serve as a *molecular tag* for cancer genes: it can be used to identify the locus at which it is integrated by sequencing the flanking integration site. Retroviral vectors have been adapted for use in mouse embryos and ES cells as well, and now permits germ-line mutagenesis.

In analogy to random proviral insertion, also *transposable elements* from yeast, insects, fish, and mammals, among other organisms, can be used for functional genomic analyses. Transposable elements (TEs) are a heterogeneous class of genetic elements that have the capacity to move from one site on a chromosome to another: they ''jump.'' TEs are very efficient at integrating into DNA, and some elements can carry extra DNA. TEs are therefore useful vectors for transferring new genetic material into genomes and for random insertional mutagenesis. By way of example, among the properties that make the Tc*1*/*mariner* superfamily of TEs useful for molecular genetic research are the facts that they are easy to work with, their efficient and stable integration, and persistent, long-term transgene expression following transposon-mediated gene transfer. Importantly, such TEs ''jump'' in species other than their original hosts, which underscores the need for further development and use of these and alike molecular tools for functional genomics in the mouse. Several reports on germline induced TE transposition and germline attest to the mutagenic potential of the approach.

5.3 Random Enu Mutation

For many years, mutant mouse models were obtained largely as a ''spin-off'' from research on the mutagenic properties of chemical compounds and radiation. With the recent advent of more genome resources, it has become possible to identify such induced mutations more rapidly. Initially, substantial efforts were undertaken, involving collaborations of many laboratories, each with their own phenotyping expertise. At present, robust technology is in place to mutagenize mice. One of the *caveats* remained however, because, although screens for recessive mutations are the most promising ones, such screens are exceedingly difficult and expensive. Recently, it was shown that a narrowly focused screening system for recessive mutations can be highly productive, while the expenses remained acceptable. Moreover, M. Justice, A. Bradley, and colleagues made use of a set of strains carrying engineered coat color markers and a chromosomal inversion (see Fig. 14a), enabling to further reduce costs by focusing the screen on a predefined chromosomal segment. Given the large number of loci controlling complex genetic disorders, this strategy permits an ordered approach to finding disease genes. The strategy is highly suitable to focus on some synthenic regions in the mouse genome, which are known to be associated with disease susceptibility in man.

6 Phenotype Analysis

Genetically engineered mouse models serve to study genotype–phenotype relationships and can show an impressive variety of phenotypes, ranging from embryonic lethality to increased susceptibility to chronic diseases such as cardiovascular disease and cancer. The models allow defining primary gene functions as well as the role of a particular gene mutation in disease.

Once mouse models have been generated, it is important to carry out an in-depth analysis of the pathology of the entire mouse and not restrict the analysis to the target organs that are the main subject of the intended study. A detailed strategy is outlined elsewhere. Often, one will find that the dramatic alterations in the gene expression pattern will show unexpected effects on the phenotype. For instance, in the case of a study on apolipoprotein C1, the expected perturbation of lipid metabolism was accompanied by a dramatic and progressive hair loss of the mice with the highest level of expression of the transgene. The most common problem encountered, however, in studies using genetically modified mouse models is a lack of phenotype, even when a unique and evolutionarily conserved gene has been altered for which there are no obvious functionally redundant homologs present in the mouse genome. The main cause of this is the large difference in environmental stress experienced by wild mice as opposed to inbred laboratory mice. Often, phenotypes need to be evoked by either increasing the environmental stress (i.e. high-fat diets, mutagens) or increasing the genetic stress using a second transgenic strain with a mutation in a related pathway. A good example is provided by the use of mouse strains in cardiovascular research. Wild-type laboratory mice are resistant to develop atherosclerosis because of its highly antiatherogenic lipoprotein profile. By knocking out genes controlling lipoprotein metabolism, such as the

apolipoprotein E gene, the mice become sensitized. Upon feeding a moderated high-fat diet, such mice will develop complex lesions in the aorta within 2 months. Many gene alterations will have no effect on atherogenesis when studied separately. However, when these mice are crossed with apolipoprotein E–deficient mice, it is now possible to study the role of such genes. Thus, the apolipoprotein E–deficient mouse serves as a sensitized mouse model that is highly susceptible to the effects of additional genetic changes. Likewise, changing the genetic background of the mice will affect susceptibility to disease; this approach has been used to define novel loci in human disease.

Recent technological advances permit analysis of transgene expression and the biological consequences thereof by noninvasive methods. In vital imaging, very sensitive cameras measure bioluminescence from, for example, tumors or embryos *in utero*, which express luciferase of GFP reporter transgenes in living animals (Fig. 2d). Clearly, the impact of technological developments like these is substantial not only in terms of increased specificity and resolution of the model but also in terms of reduced animal usage.

7 Perspectives

7.1 Partial Transgenesis; Viral Shuttles

Recent technological advances allow more rapid approaches to study gene function without the need for germ-line modification. Remarkably, partial transgenesis can be achieved through local electroporation of transgenic vectors into tissues. Using this approach, local muscle tissue in rats has been specifically modified to study its function. Another example is the study of cell migratory and (trans)differentiation processes during neural tube closure; in these studies, one side of the tube is selectively electroporated with an expression construct, while the other side functions as a control.

The use of viral vectors to deliver transgenes to mammalian cells is another method to achieve partial transgenesis. The use of several classes and combinations of viral vectors is being explored in gene therapeutic applications. Similar vectors are very useful in accomplishing partial transgenesis, restricted to certain tissues such as bone marrow (which is easily harvested and cultured *ex vivo* and reintroduced into a recipient mouse). The latter approach can also be employed to, for instance, study isolated effects of gene knockout in the hematopoietic compartment in combination with bone marrow transplantation. Local and transient transgenesis is currently used to activate conditional floxed transgenes (see Sect. 5), for instance by adenovirus-encoded CRE. This approach was proven useful in, for example, somatic activation of transforming oncogenes in the lung.

Lentiviral vectors, unlike the classical slow replicating retroviruses, harbor the advantage that they are not silenced in embryonic stem cells, which makes expression characteristics of such vectors good. Recombinant lentiviruses were recently used to introduce transgenes into fertilized oocytes and ES cells (Fig. 6b). The advantages of using lentiviral shuttle vector are significant: it obviates potentially harmful procedures otherwise used to introduce transgenes into a cell (pronuclear microinjection, electroporation) and offers some degree of control over transgene copy numbers.

7.2 RNA Interference; Posttranscriptional Gene Silencing

The abundance of biological information that has become available upon completion of the genome sequence of both mouse and human is exciting and overwhelming at the same time. An estimated 10 000 genes have been identified currently, which represents an estimated one-third of the total gene complement in a human or mouse. Of these genes, only a few thousand have been functionally studied. Clearly, one of the remaining challenges in molecular genetics is to analyze the function of novel genes. Gene targeting is beyond any doubt one of the most successful and informative technologies when it comes to elucidating gene function. Despite improvements in cloning technologies that employ recombination in prokaryotes instead of "standard" recombinant DNA technology and that significantly simplify otherwise laborious cloning strategies, gene targeting remains time-consuming and expensive.

Recent scientific and technological advancements may, however, provide faster means to address novel gene function. One of the most exciting developments finds its origin in the realization that gene expression is controlled at a posttranscriptional level by double-strand (ds) RNA-mediated degradation of cytoplasmic RNAs. This process, called *RNA silencing* – or *posttranscriptional gene silencing* – was first discovered in plants as an unexpected gene silencing in transgenic plants: silencing of an endogenous gene often occurred in concert with silencing of the transgene. Transgene-mediated RNA silencing is now recognized as a form of RNA silencing that uses small interfering dsRNAs (siRNA), which serve as a guide for specific target mRNA recognition and its subsequent enzymatic degradation. Investigations by many groups showed that RNA interference (RNAi) is a regulatory process used by many organisms to control gene expression. Many of the protein factors involved in RNAi are conserved, from protozoans to humans. RNAi has recently been developed into a technology by which endogenous gene function can be assessed in many vertebrates, including mammals. One obvious advantage of RNAi-mediated gene silencing is that it does not rely on genetic modification. This makes the technology very rapid compared to (conditional) gene targeting. Proof of principle has been achieved in many vertebrate systems including several human cells lines. RNAi also works in early mouse embryos, and was recently demonstrated to be transmittable via the germline in transgenic mice. Whereas initial strategies in cell lines made use of synthetic dsRNA sequences, a relative costly approach, RNAi, is currently achieved via stable expression. In addition, recent reports show that random siRNA libraries can be generated from cDNA libraries via ingenious cloning strategies. The potential held by this approach is that such libraries are self-selecting, thereby enabling investigators to set-up high-throughput genetic screens. RNAi can be made tissue specific, inducible, and can be delivered to mouse embryos using viral vectors. Such improvements will clearly enhance the application of RNAi in functional genomic research.

Although genetic manipulation is possible in tissue culture, the study of genetic interaction of transgenes with other genes and local or systemic effects of transgene expression in the intact organism provides a much more complete and physiologically relevant picture of a gene's function than can ever be achieved *in vitro*. Genetic modification therefore represents an

important and biologically relevant tool to complement *in vitro* gene expression studies aimed at, for example, delineation of signal transduction pathways or identification of tissue-specific regulatory elements. Refinements to genetically modified mouse models in biomedical research are of importance for a number of reasons. Conditional models recapitulate the pathophysiology as it occurs in humans and permit a high degree of selectivity and resolution, which not only renders studies more specific and focused but also significantly reduces the burden on the laboratory animal. The positive effects thereof are reduced stress on the system and, concurrently, improved specificity.

Keywords

B.t. Toxins
B.t. toxins are proteins produced by the soil bacterium *Bacillus thuringiensis*. The toxin recognizes certain receptors on the surface of insect midgut epithelial cells. A pore complex is formed through the membrane resulting in the loss of potassium ions (necessary for the osmotic balance). The insect will die due to massive water uptake.

Herbicide Resistance
By transferring the respective genes, plants can become tolerant to certain herbicides. Herbicide-resistant plants already on the market are mostly tolerant to the broad-spectrum herbicides glyphosate and glufosinate, which do not discriminate between certain plant species (as do selective herbicides).

Hypersensitive Reaction
Plants possess a natural defense mechanism against pathogens like fungi, bacteria, or viruses. During early infection, infected cells will be triggered to die (programmed cell death). Together with the plant cells, the pathogens die and their spread will be prevented. With the help of gene technology, the hypersensitive reaction shall be accelerated to make plants more resistant to pathogens.

Marker Gene
Marker genes are necessary to select early transformation events since plant transformation is of low efficiency (1–10% transformation success). Mostly, antibiotic resistance genes have been used as marker genes, since bacterial genes are readily available and antibiotics can be easily used as selective agents in culture media.

Transgenic or Genetically Modified Organism
A transgenic or genetically modified organism is an organism in which the genetic material has been modified in a way that does not occur naturally (e.g. by conventional breeding or natural recombination). Genetic modification involves moving, inserting, or deleting genes within or between species.

Here we describe the state of the art of genetically modified plants intended for food use. First, an introduction to the different methods of plant transformation as well as the molecular requirements for the stable introduction and expression of the gene(s) of interest is given. Then, we present an overview on the transgenic plants already on the market or approved for placing on the market worldwide. Finally, examples of new transgenic plants in different stages of development are presented. These comprise of well-established traits like herbicide or insect resistance, being transferred to additional crop species as well as new approaches to enhance the nutritional quality of food crops or to produce pharmaceuticals in transgenic plants.

1 Methods to Establish Transgenic Plants

As an introduction to transgenic or genetically modified plants (GMP), we would first like to describe the transformation methods that are currently used, as well as the molecular requirements for the stable introduction and expression of the gene(s) of interest.

1.1 Transformation Methods

In general, two different approaches to transferring foreign DNA into plant cells can be distinguished: (1) a vector-mediated transformation method (via *Agrobacterium*); and (2) direct gene transfer methods.

1.1.1 Agrobacterium Transformation

In the first case, the natural ability of the bacterial phytopathogen *Agrobacterium* to transfer DNA into plant cells is exploited. *Agrobacterium tumefaciens* and *Agrobacterium rhizogenes* are soil microorganisms that incite crown gall tumors and hairy root disease, respectively, in a wide range of dicotyledonous as well as in some monocotyledonous plants. For plant transformation, mainly *A. tumefaciens* is used, and this bacterium contains a large tumor-inducing plasmid (Ti). During infection, a specific segment of the plasmid DNA referred to as T-DNA (transferred DNA) is inserted into the plant genome. The T-DNA contains genes for phytohormones, which are responsible for cell proliferation and the formation of the crown gall, as well as genes for the formation of special nutrients (opines) in the plant cell. In order to use *Agrobacterium* as a tool in genetic engineering, these genes have been deleted and replaced by the genes of interest. This was possible since only the 25-bp T-DNA border sequences on the right and left border are needed for DNA transfer. A wide

variety of such ''disarmed'' (nontumor-inducing) vectors have been developed. *Agrobacterium*-mediated transformation is the most commonly used method for most dicotyledonous plants. Advantages include the typical insertion of only one or a few copies of the transgene, and the transfer of relatively large segments of DNA with only minimal rearrangements.

1.1.2 Direct Gene Transfer

For many years, *Agrobacterium* could not be used to transform monocotyledonous and other recalcitrant species, so direct gene transfer methods have been developed as an alternative. These include DNA uptake into protoplasts (protoplast transformation) and the shooting of DNA-coated particles into tissues (particle bombardment).

1.1.2.1 **Transformation of protoplasts.** In contrast to animal cells, plant cells possess a solid cell wall, which is the first barrier to overcome when foreign genes are to be transferred into them. One way to circumvent this barrier is to use plant cells in which the cell wall has been digested enzymatically, resulting in the so-called *protoplasts*. DNA uptake into protoplasts can then be stimulated by the use of either polyethylene glycol (PEG-transformation) or electric pulses (electroporation). Where an appropriate protoplast-to-plant regeneration system is available, large numbers of transformed clones can be regenerated to fertile transgenic plants.

In cases where a barrier to gene transfer has not been detected, virtually every protoplast system has proven transformable, though with considerable differences in the efficiency. However, problems can arise from the regeneration of fertile plants from protoplasts as the regeneration is strongly species- and genotype-dependent, and undesired somaclonal variation can occur due to the relatively long tissue culture phase. One advantage of the protoplast transformation method is its great independence from other patented techniques.

1.1.2.2 **Particle bombardment.** The new method of using high-velocity microprojectiles to deliver DNA into plant tissue was developed by Sanford and colleagues in 1987. A particle gun is used to accelerate DNA-coated microprojectiles into cells, past the cell wall and the cell membrane. The microprojectile is small enough ($0.5 - 5\ \mu m$) to enter the plant cell without causing too much damage, yet it is of large enough mass to penetrate the cell wall and carry an appropriate amount of DNA on its surface.

The main advantage of particle bombardment is the absence of biological incompatibilities that are found when using biological vectors. Organelles such as chloroplasts have also been transformed using particle bombardment. Unfortunately, particle bombardment, as well as other direct DNA uptake methods often result in complex insertion loci, which can cause gene silencing.

1.2 Tissue Requirements

The ability to cultivate plant tissue *in vitro* is a prerequisite in almost all current transformation protocols. Transformation requires competent (i.e. transformable) cultured cells that are embryogenic or organogenic. Plant cells suitable for regeneration are either cocultivated with *Agrobacterium* or bombarded. For *Agrobacterium* transformation, mostly leaf discs or immature embryos are used for particle

bombardment in monocotyledonous plant scutellar tissues.

1.3 Molecular Requirements

A typical plant gene consists of a promoter, a coding sequence, a transcription terminator, and a polyadenylation signal. The expression level of the gene is mainly determined by these components, but can also be affected by the surrounding sequences.

1.3.1 Promoter

The promoter is the main determinant of the expression pattern in the transgenic plant. Constitutive promoters direct expression in all or almost all tissues, independently of developmental or environmental signals. The promoter directing the synthesis of the cauliflower mosaic virus 35S RNA is the most frequently used constitutive promoter; other constitutive promoters are derived from agrobacterial T-DNA, such as the nopaline synthase (nos) promoter or the octopine synthase (ocs) promoter. Both are mainly used in dicotyledonous plants.

In monocotyledonous plants, it is mostly promoters from the rice actin 1 gene (*act1*) or the maize ubiquitin 1 gene (*ubi1*) that are used. To enhance expression levels, the first intron of the respective genes has been added to the expression cassettes. In dicotyledonous plants, the addition of introns seems to have less pronounced effects on the expression level. Nevertheless, the insertion of an intron is always necessary when the expression of the gene product in bacteria must be completely avoided (e.g. for genes conferring bacterial resistance; see Sect. 3.1.2).

In cases where transgene expression should be directed to certain tissues or developmental stages, regulated promoters are required. Promoter elements responsible for expression in seeds, tubers, vegetative organs, and leaves have been isolated.

Environmental influences can induce gene expression after wounding, heat- or cold stress, or anaerobiosis. The use of natural inducible promoters has the disadvantage of causing pleiotropic effects, since endogenous genes will also be turned on. Chemically induced promoters are favored for the production of pharmaceuticals in transgenic plants, as production of the desired compound can be restricted to a certain time point.

1.3.2 Codon Usage

Expression of the gene of interest can also be influenced at the level of translation: the codon usage differs between plants and bacteria. Therefore, the removal of rare codons, e.g. codons not frequently used in plant cells, from genes of bacterial origin can enhance expression considerably. This was first described for a modified *B. thuringiensis* toxin gene where expression was enhanced up to 100-fold.

1.3.3 Selectable Marker and Reporter Genes

In plant transformation systems, the efficacy of stable gene transfer is low; hence, systems that allow the selection of the transformed cells are required. A selection system consists of a selective agent (which interferes with the plant metabolism) and a selectable marker gene (which codes for a protein, enabling inactivation or evasion of the selective agent).

The most commonly used selectable marker genes in transgenic plants code for antibiotic or herbicide resistance including the following:

1.3.3.1 **Antibiotic resistance genes.**

- *nptII* gene: The *neo* or *nptII* gene, isolated from transposon Tn5 from *Escherichia coli K*12 codes for the neomycin phosphotransferase (NPTII). This enzyme detoxifies a range of aminoglycoside antibiotics such as neomycin, kanamycin, and geneticin. These antibiotics are added to the culture medium after the transformation procedure. Only transformed cells or tissues will survive and will be regenerated to plants.
- *hpt* gene: The *hpt* gene has been isolated from *E. coli* and codes for hygromycin phosphotransferase, which detoxifies the antibiotic hygromycin B. Most plant tissues show a higher sensitivity to hygromycin B than to kanamycin or geneticin. In particular, cereals that are resistant to kanamycin and geneticin can be selected with hygromycin.
- *bla* gene: The $bla_{\text{TEM-1}}$ gene codes for the TEM-1 β-lactamase, the most encountered ampicillin resistance marker in molecular biology. TEM-1 β-lactamase attacks narrow-spectrum cephalosporins and all the anti-gram-negative-bacterium penicillins, except temocillin. Mostly, the ampicillin resistance in transgenic plants is not used as a selectable marker for plant transformation, but is a reminiscence of the transformation method. With direct gene transfer methods, it is used as a selectable marker during the cloning procedure prior to plant transformation. When present on the plasmid used for transformation, the ampicillin resistance gene is transferred and integrated together with the genes of interest, and remains under the control of its prokaryotic promoters.
- *aadA*: The *aadA* gene confers resistance to streptomycin and spectinomycin. The gene has been found in association with several transposons (Tn7, Tn21, ...) and is ubiquitous among gram-negative bacteria.

1.3.3.2 **Herbicide resistance genes.**

- *bar*/pat gene: the *bar* gene from *Streptomyces hygroscopicus* and the *pat* gene from *Streptomyces viridichromogenes* code for phosphinotricin acetyltransferase (PAT), which confers resistance to the herbicide compound, phosphinotricin. It is an inhibitor of glutamine synthetase, a plant enzyme involved in ammonia assimilation. Besides phosphinotricin, the commercially available nonselective herbicides Basta and bialaphos can be used as selective agents. Selection can be applied in the culture medium or by spraying of regenerated plantlets.
- *EPSPS* gene: The *5-enolpyruvylshikimate-5-phosphate synthase* (EPSPS) gene codes for the enzyme 5-enolpyruvylshikimate-5-phosphate synthase (EPSPS) that is involved in the skimatic acid pathway of the aromatic amino acid biosynthesis. EPSPS is present in all plants, bacteria, and fungi, but not in animals. The nonselective herbicide glyphosate binds to and inactivates EPSPS. By transferring a glyphosate-resistant EPSPS gene from the soil bacterium *Agrobacterium* strain CP4 to plants, glyphosate-resistant crop plants have been obtained. Glyphosate is the active ingredient of the commercially available herbicide Roundup.

1.3.3.3 **Reporter genes.** In contrast to selectable marker genes, reporter genes do not confer resistance to selective agents inhibitory to plant development. Reporter genes code for products that can be detected directly or that catalyze reactions whose products are detectable.

- *gusA* gene: The *gusA* (uidA) gene encodes β-glucuronidase (GUS), which hydrolyzes a wide range of β-glucuronides. Substrates for GUS are available for spectrometric, fluorometric, and histochemical assays. The GUS reporter gene system allows easy quantification with high sensitivity. One disadvantage of this system is its nonviability: examined cells and tissues cannot be regenerated into transgenic plants. Therefore, this system is mainly used to optimize a specific transformation protocol.
- *luc* gene: The *luciferase* reporter gene assay uses bioluminescence reactions with substrate/enzyme combinations, which lead to detectable light emission. The *luc* gene originates from the firefly *Photinus pyralis*, and codes for a luciferase, which decarboxylates beetle luciferin. In contrast to the GUS reporter system, the luciferase reporter gene is nonlethal to plant cells.

1.3.3.4 **Alternative marker and excision systems.** Owing to discussions on the possible risk of a gene transfer of antibiotic resistance genes from transgenic plants to clinically important microorganisms, alternative marker systems have been developed. Additionally, through the use of excision systems the presence of antibiotic or herbicide resistance genes in the final product can be avoided.

Alternative markers Several alternative marker systems have recently been developed. For example, Chua and colleagues successfully selected transgenic plants using an inducible *Agrobacterium* gene encoding for isopentenyltransferase (IPT). This enzyme catalyzes the first step in biosynthesis of cytokinins, a class of phytohormones. Only cells containing this gene are able to form shoots and differentiate into mature plants.

As another alternative selection system, phosphomannose isomerase (PMI) was successfully used in transgenic sugar beet and maize. PMI catalyzes the interconversion of mannose-6-phosphate and fructose-6-phosphate. Except for leguminous plants, PMI is absent from most plants, and therefore, only transgenic plants expressing the *E. coli manA* gene can survive on media containing mannose as a carbon source.

Excision systems Another approach is the use of recombination systems that enable the excision of marker genes in the successfully transformed plant. Four different site-specific recombination systems have been shown to function in plant cells. The best-characterized system in plants is the CRE/lox system of bacteriophage P1: the CRE recombinase enzyme recognizes specifically and catalyzes recombination between two lox sequences. Marker genes flanked by these lox sites can be precisely excised in the presence of the CRE recombinase. One disadvantage of the system was that the CRE protein had to be introduced in the transgenic plant via secondary transformation or sexual crossing with a CRE transformant. When inducible developmental stage promoters or tissue-specific promoters are used, both components of the CRE/lox system can be transferred to one transformant. After selection of the transformants, the promoter will be intentionally induced, resulting in excision of the marker gene. This system is also applicable to vegetatively propagated plants.

A recent publication describes the efficient excision of selectable marker genes that are framed by *attP*-sites without the

induction of a recombinase. The molecular basis of the reaction is still unknown, but presumably it is due to illegitimate recombination. Further experiments are necessary to reveal the underlying mechanism and to verify its general applicability.

2 GM Plants Already on the Market

In Europe, 10 genetically modified (crop) plants have been approved for placing on the market according to 90/220 EEC. These approvals covered different uses as applied for by the applicant: in two cases, the approvals included use as food and feed, namely, Roundup Ready soybean (Monsanto) and insect-resistant maize (Novartis, formerly Ciba-Geigy). Nevertheless, only few commercial plantings are carried out in Europe, and in Germany GMPs are grown only on an experimental scale.

Since 1997, GMPs intended for food or feed use in the EU must be notified or approved according to the "Novel Food Regulation." Since then, refined oil from herbicide-tolerant oil seed rape, refined oil from herbicide-tolerant and insect-resistant cotton, and processed products from herbicide-resistant and insect-resistant maize have been notified (Table 1).

Worldwide, GMPs have been grown on 67.7 million hectares in 2003 according to ISAAA. Since 1996, the global area of transgenic crops increased 40-fold, with an increasing proportion grown by developing countries. The main producers of GMPs are the US (42.8 million hectares), Argentina (13.9 million hectares), Canada (4.4 million hectares), Brazil (3 million hectares), China (2.8 million hectares), and South Africa (0.4 million hectares).

Genetically modified soybeans occupied 41.4 million hectares; GM maize was planted on 15.5 million hectares, transgenic cotton on 7.2 million hectares, and GM oilseed rape on 3.6 million hectares.

Some 73% of the GMPs contain a herbicide resistance gene, followed by 18% carrying insect resistance genes, and 8% both herbicide- and insect-resistance genes (stacked genes).

2.1 Herbicide Resistance in Soybean, Maize, Oilseed Rape, Sugar Beet, Rice, and Cotton

As mentioned above, herbicide resistance is the leading trait in commercialized GMP, with 25 lines having been approved for cultivation and/or food and feed use worldwide (Table 2).

2.2 Insect Resistance in Maize, Potatoes, Tomatoes, and Cotton

Insect resistance is the trait found second most often in approved GMPs. Insect-resistant lines, as well as lines that acquire an insect resistance gene in combination with a herbicide resistance or virus-resistance gene, are listed in Table 3.

2.3 Virus Resistance, Male Sterility, Delayed Fruit Ripening, and Fatty Acid Contents in GMPs

GMPs with virus resistance (potato, squash, and papaya; Table 4), male sterility (oilseed rape, maize, and chicory; Table 5), delayed fruit ripening (tomato; Table 6) as well as modified fatty acid content (soybean, oilseed rape; Table 7) have also been approved in some countries.

Tab. 1 Genetically modified crop plants and products approved in the EU.

Plant (line)	*Trait (gene)*	*Applicant*	*Approved use*	*Year*
Soybean (GTS-40-3-2)	HR (*CP4 EPSPS*)	Monsanto	Import and processing	1996
Maize (Bt 176)	IR (*cryIAb*), HR (*bar*), ABR (*bla*)	Ciba-Geigy	Cultivation; import and processing	1997

3 GM Plants "In the Pipeline"

3.1 Input Traits

In the following chapters, selected examples will be presented of studies being conducted in the genetic engineering of crop plants. First, attempts to reduce the production costs of crop plants are summarized. These studies refer to crop plants with genetically engineered resistance against insects, diseases, abiotic stresses, and improved agronomic properties.

3.1.1 Insect Resistance

The best-characterized insecticidal proteins are the delta-endotoxins of *B. thuringiensis* (*B.t.*-toxins), which have been used as biopesticides in agriculture (also organic farming), forestry, and as a mosquito vector control for many years.

B.t. insecticidal activity is highly specific in that the endotoxins are nontoxic to nontarget insects, birds, and mammals.

Besides the commercially available *B.t.*-maize, -potato, -cotton and -tomato lines (see Table 3), insect-resistant rice (*cryIAb* and *cryIAc*), soybeans (*cryIAc*), oilseed rape (*cryIAc*), and eggplants (*cryIIIB*) have been developed. Field trials have also been performed in the United States with insect-resistant sunflower, lettuce, grapefruit, sugarcane, apple, walnut, grape and peanut.

In order to control corn rootworm infections, Mycogen, and Pioneer Hi-Bred are developing transgenic maize, which contains two novel proteins from *B. thuringiensis* strain PS149B1. These proteins belong to another class of insecticidal proteins with no homology to the delta-endotoxins (Bt PS149B1 toxins).

Another approach to achieve insect-resistant plants is to use plant defense proteins such as proteinase inhibitors, lectins or α-amylase inhibitor. Lectins are thought to confer resistance toward sap-sucking insects (e.g. the rice brown planthopper), which act as vector for virus transmission.

Morton and colleagues transferred the α-amylase inhibitor 1 gene from beans to peas and conducted field trials with the insect-resistant pea plants, and reported high insect mortality in transgenic plants. One advantage of using α-amylase inhibitor genes is the long history of human consumption of beans, and the fact that bean α-amylase has no effect on starch digestion in humans.

In an attempt to confer broad-spectrum resistance to storage pests, maize was transformed with the chicken avidin gene. The mode of action of avidin is to cause a deficiency of the vitamin biotin in insects; hence, a thorough safety testing for human consumption must be carried out before the commercial use of biotin maize.

3.1.2 Virus, Fungal, Bacterial, and Nematode Resistance

3.1.2.1 **Virus resistance.** One strategy to obtain virus-resistant plants is to transfer genes from the pathogen itself into the plant (pathogen-derived resistance). The most widely used approach is to express the virus coat protein in transgenic plants. In theory, the expression of viral genes disrupts viral infection or symptom development. All but one of the commercially available virus-resistant plants contain viral coat proteins (see Table 4), and this technique is extended to other plants such as rice, plum tree, tomato, pea, and peanut. Additionally, field trials have been performed in the United States with coat protein–mediated virus-resistant wheat, soybean, sugarcane, sugar beet, cucumber, sweet potato, grapefruit, pineapple, and papaya.

Another form of pathogen-derived resistance is the use of viral replicase genes (or RNA-dependent RNA polymerase genes), which presumably act via posttranscriptional gene silencing. This technique has been used to confer resistance to potato leafroll virus in potato (see Table 4), to barley yellow dwarf virus in oats, cucumber mosaic virus in tomato, rice tungro spherical virus in rice, and wheat streak mosaic virus in wheat.

Since varying degrees of virus resistance have been obtained with coat protein–mediated resistance, approaches have been formulated to ameliorate resistance against cucumber mosaic virus via satellite RNA, especially in tomato. However, this approach has raised controversy

as a single point mutation in the satellite RNA can transform it into a harmful necrogenic form.

In order to protect plants against more than one virus, ribosome-inactivating proteins (RIPs) have been expressed in transgenic plants. RIPs are strong inhibitors of protein synthesis and, depending on the plant species from which they originate, they show different levels of toxicity against different hosts. Pokeweed antiviral protein (PAP) confers resistance to PVX and PVY in transgenic potatoes, while PAPII confers resistance to TMV, PVX, and fungal infections in tobacco, respectively.

On a more experimental scale are approaches to achieve virus resistance using antibodies against the virus coat protein. Such antibodies are able to neutralize virus infection, presumably by interacting with newly synthesized coat protein and disrupting viral particle formation. Like RIPs, broad-spectrum antibodies might be used to protect plants against a wider range of viruses, as has been demonstrated in the case of potyviruses.

3.1.2.2 **Fungal resistance.** Fungal resistance can be conferred via the activation of specific self-defense mechanisms in the plant. One of the mechanisms is the so-called *hypersensitive response* (HR), which enables plants to enclose the pathogen in the infected area by the formation of necrotic lesions. HR induces many defense-related signal molecules such as salicylic acid, ethylene, and phytoalexin. HR is also characterized by an accumulation of pathogenesis-related (PR) proteins that include fungal cell wall–degrading enzymes, antimicrobial peptides, thionins, lipid transfer proteins, and proteinase inhibitors.

In rice, the introduction of chitinase and thaumatin-like protein, respectively, led to increased resistance to sheath blight (*Rhizoctonia solani*). Enhanced resistance to the rice blast fungus *Magnaporthe grisea* was observed upon constitutive expression of chitinase and defense-related protein genes in transgenic rice.

Pathogenesis-related proteins from plants have been used to confer fungal resistance in alfalfa, cucumber, oilseed rape, tomatoes, wheat, grape vine, and oranges.

Other antifungal genes of plant origin comprise genes for RIPs, genes for phytoalexins, and anthocyanin genes. An example of an antifungal gene from nonplant sources that has been transferred to plants is the human lysozyme gene.

In the United States, field trials have been performed with fungal-resistant wheat, barley, cotton, rice, and bananas using different antifungal proteins.

Individual PR-proteins, however, have a narrow spectrum of antifungal activity, and need to function collectively in order to provide a modest but long-term resistance. Therefore, research is currently focusing on genes from mycoparasitic fungi as a source for improving resistance to fungal pathogens. An endochitinase of the mycoparasitic fungus *Trichoderma harzianum* has been transferred to tobacco and potato, and has been reported to confer a high level and a broad spectrum of resistance.

A similar approach has been taken by transferring an antifungal protein from a virus that persistently infects *Ustilago maydis*, to wheat. Transgenic wheat plants exhibit increased resistance against stinking mut (*Tilletia tritici*).

3.1.2.3 **Bacterial resistance.** Resistance to bacterial infections is not yet as

developed as virus- and fungal resistance, due partly to the fact that bacterial diseases are a major problem in only some crop plants such as potato, tomato, rice, and certain fruit trees.

The most efficient form of protection is genetic resistance, which is based on single dominant or semidominant genes. These R genes usually confer race-specific resistance, and their effectiveness is based on their interaction with complementary pathogen avirulence (AV) genes in the pathogen, the so-called *gene-for-gene interaction*. Resistance to bacterial blight caused by *Xanthomonas oryzae* pv. *oryzae* was achieved by transferring the resistance gene *Xa21* from a wild rice species to the elite indica rice (IR) variety 'IR72'. Accordingly, the resistance gene *Bs2* from pepper was transferred to tomato, which then exhibited resistance to bacterial spot disease.

The tomato disease resistance gene *Pto* specifies race-specific resistance to *Pseudomonas syringae* pv. *tomato* carrying the *avrPto* gene. By overexpressing *Pto,* a race-nonspecific resistance was observed in transgenic tomatoes.

The resistance based on single dominant gene expression always bears the danger of early evolution of counterresistance in the pathogen due to the emergence of strains that no longer express the specific avirulence gene product. Therefore, new resistance genes are being investigated for use in pyramiding strategies (combination of resistance genes against the same pathogen, but with different targets). One example is the *AP1* gene from sweet pepper, which delays the hypersensitive response when expressed in transgenic rice plants, and which can be used in combination with *Xa21* or other resistance genes.

In several plant species, bifunctional enzymes with lysozyme activity have been detected, which are thought to be involved in defense against bacteria. After transfer of the bacteriophage T4 lysozyme gene, transgenic potatoes showed a decreased susceptibility toward *Erwinia carotovora atroseptica* infections.

Insects produce antimicrobial peptides as major defense response to pathogen attack, and these include sarcotoxins, cecropins, and attacins. The latter has been transferred to apples and pears, which have improved resistance to *Erwinia amylovora*, causing fire blight. Similarly, the expression of synthetic antimicrobial peptide chimeras in transgenic tobacco led to broad-spectrum resistance against both bacterial and fungal pathogens. Bacterial resistant grapes, transformed with the antibiotic protein mangainin from toads are being field tested in the United States.

3.1.2.4 **Nematode resistance.** In the United States, field tests are being conducted with nematode-resistant carrots, tomatoes, potatoes, and pineapples. In the case of carrot, tomato, and potato, cysteine proteinase inhibitors from cowpea and rice, respectively, have been expressed in the transgenic plants. Proteinase inhibitors are an important element of natural plant defense strategy. The cowpea trypsin inhibitor (CpTI), a serine proteinase inhibitor, and oryzacystatin (Oc-I), an inhibitor of cysteine proteinase, have been shown to be effective against proteinases of a cyst nematode. In field trials, no detrimental effect on plant growth was observed in transgenic potatoes. When two partial nematode-resistant potato varieties were transformed with the cystatin, full resistance to potato cyst nematode *Globodera* was achieved. Cysteine proteinase inhibitors are of particular interest because they are the only class of proteinase that is not expressed in the digestive system of mammals.

3.1.3 Tolerance Against Abiotic Stress

The effects of weather, erosion, and depleted soils expose plants to a variety of stresses. Genetic engineering has been used to provide plants with additional stress response genes in order to counteract these environmental stresses. These genes can be grouped into two categories: (1) genes that respond directly against a particular stress; and (2) genes that regulate stress gene expression and signal transduction. Transfer or overexpression of both types of genes has been used in transgenic approaches to enhance tolerance against abiotic stresses. In the following section, salt, drought, and cold stress are considered together, as, on a cellular basis, all act as dehydration stress.

3.1.3.1 **Genes conferring dehydration-stress tolerance in transgenic plants.** Plants react to these stresses by displaying complex, quantitative traits that involve the function of many genes. Expression of these genes leads to the accumulation of low molecular weight components such as osmolytes, synthesis of late-embryogenesis-abundant (LEA) proteins, and activation of detoxifying enzymes. In transgenic approaches, genes for the enzymes that are responsible for the production of these compounds have been transferred to nontolerant plants. Most of these studies have been performed in model plants such as *Arabidopsis* or tobacco, but some investigations have been extended to food crops such as rice.

Bajaj and colleagues have summarized the results from these studies in a recent review. After transfer of genes encoding enzymes for osmoprotectants such as glycinebetaine, proline or putrescine, transgenic rice plants exhibited increased tolerance to salt and drought stress. Constitutive overexpression of the oat arginine decarboxylase gene in rice led to severely affected developmental patterns. When the arginine decarboxylase gene was under the control of an ABA-inducible promoter, the transgenic rice plants showed an increase in biomass under salinity-stress conditions.

Transgenic rice plants expressing the arginine decarboxylase gene (*adc*) from *Datura* produced high levels of the polyamine putrescine under stress, protecting the plants from drought.

The expression of a LEA protein in the transgenic rice plants led to increased tolerance to water deficit and salt stress in the transgenic plants. As it is believed that abiotic stress primarily affects plants through oxidative damage, genes for detoxifying enzymes have been transferred to sensitive plants. McKersie et al. showed that transgenic alfalfa overexpressing Mn superoxide dismutase to reduce free radicals was more tolerant of water deficit and freezing, and had better winter survival rates. It is envisaged that the use of stress-inducible promoters and the introduction of multiple genes will improve dehydration-stress tolerance.

3.1.3.2 **Regulatory genes encoding transcription factors.** The other promising approach to confer tolerance to dehydration stress is to transfer regulatory genes. As the products of these genes regulate gene expression and signal transduction under stress conditions, their overexpression can activate the expression of many stress-tolerance genes simultaneously. The overexpression of the transcription factor DREB1A in transgenic *Arabidopsis* led to increased tolerance to drought, salt, and freezing stresses. However, the constitutive overexpression of DREB1A also resulted in severe growth retardation under normal growth conditions.

In contrast, the stress-inducible expression of this gene had minimal effects on plant growth, and provided greater tolerance to stress conditions than genes driven by the 35S promoter. Drought tolerant wheat lines transformed with DREB1A are currently being field tested in Mexico.

Lee and colleagues cloned the functional homolog of the yeast Dbf2 kinase that enhances salt, drought, cold, and heat tolerance upon overexpression in yeast, as well as transgenic plant cells. However, the utilization of this gene to engineer transgenic crops with enhanced stress tolerance has still to be shown.

3.1.3.3 **Additional genes that confer tolerance to salt stress.** The detrimental effects of salt on plants are a consequence of both a water deficit resulting in osmotic stress, and the effects of excess sodium ions on key biochemical processes. To tolerate high levels of salts, plants should be able to use ions for osmotic adjustment and internally to distribute these ions to keep sodium away from the cytosol. The first transgenic approaches introduced genes that modulated cation transport systems. Hence, transgenic tomato plants overexpressing a vacuolar Na^+/H^+ antiport were able to grow, flower, and produce fruits in the presence of 200 mM sodium chloride.

3.1.3.4 **Genes conferring tolerance to low iron.** In arid and semiarid regions of the world, the soils are alkaline in nature and therefore, crop yields are limited by a lack of available iron. Under iron stress, some plants release specific Fe(III)-binding compounds, known as siderophores, which bind the otherwise insoluble Fe(III) and transport it to the root surface. To increase the quantity of siderophores released under conditions of low iron availability, Takahashi et al. transferred two barley genes coding for the enzyme nicotianamine aminotransferase (*naat-A* and *naat-B*) together with the endogenous promoters into rice plants. Transgenic rice plants excreted about 1.8 times more siderophore under iron stress than wild-type rice plants. This relatively small increase allowed transgenic rice plants to withstand iron deprivation remarkably better, resulting in a fourfold increase in grain yield as compared with wild-type plants.

Alternately, increasing the rate-limiting step of Fe(III) chelate reduction, which reduces iron to the more soluble Fe(II) form, might enhance iron uptake in alkaline soils.

3.1.3.5 **Aluminum tolerance.** Aluminum toxicity is one of the major factors limiting crop productivity in acidic soils, which comprise about 40% of the world's arable land. One of the most visible symptoms of aluminum toxicity is the inhibition of root elongation. One possible mechanism of aluminum tolerance is the chelation of aluminum by organic ions like citrate or malate in the rhizosphere or within root cells. Overproduction of citrate was shown to result in aluminum tolerance in transgenic tobacco, papaya, and oilseed rape. Expression of the *ALMT1* gene (aluminum-activated malate transporter (ALMT)) from wheat in transgenic barley plants resulted in high-level aluminum tolerance.

3.1.4 Improved Agronomic Properties

3.1.4.1 **Acceleration of sprouting time in potato.** The ability to control sprouting time in potato tubers is of considerable

economic importance to the potato industry. At present, the potato industry uses a range of chemical treatments in order to obtain the desired control. Using a biotechnological approach, the *pyrophosphatase* gene from *E. coli* under the control of the tuber-specific patatin promoter was transferred into potatoes. The *pyrophosphatase* gene was chosen because of the central role of inorganic phosphate in starch degradation and sucrose biosynthesis. It is believed that starch breakdown and subsequent formation of various metabolites is needed for growth of the sprout.

Transgenic potatoes displayed a significantly accelerated sprouting: the transgenic tubers sprouted on average six to seven weeks faster than did control tubers. In addition, after cold storage the majority of transgenic tubers sprouted within one week, whereas the wild-type tubers needed eight weeks or more.

3.1.4.2 **Reduction of generation time in citrus.** Citrus trees have a long juvenile phase that delays their reproductive development by between 6 and 20 years. With the aim of accelerating flower time, juvenile citrus seedlings were transformed with the *Arabidopsis LEAFY* (*LFY*) and *APETALA* (*AP1*) genes, which promote flower initiation in *Arabidopsis*. Both types of transgenic citrus produced fertile flowers as early as the first year. These traits are submitted to the offspring as dominant traits, generating trees with a generation time of one year from seed to seed. Constitutive expression of *LFY* also promoted flower initiation in transgenic rice.

3.2 Traits Affecting Food Quality

The following sections provide examples of how the nutritional value of food crops can be improved through genetic engineering, though none of these genetically engineered food plants has yet reached the marketplace. In addition to the safety of the GMPs for health and environment, the effectiveness of this approach in comparison to alternative methods must be shown for these traits.

3.2.1 Increased Vitamin Content

One of the most advanced projects to fortify food crops with vitamins is the so-called *golden rice*. To enable provitamin A biosynthesis in the rice endosperm, four additional enzymes are required. Immature rice embryos were cotransformed with two *Agrobacterium* constructs containing the *psy* and the *lcy* gene from daffodil, coding for the phytoene synthase and the lycopene β-cyclase, respectively, as well as the *crtI* gene from *Erwinia uredovora*, coding for a bacterial phytoene desaturase. Ten plants harboring all transferred genes were recovered, and all showed a normal vegetative phenotype and were fertile. In most cases, the transformed endosperms were yellow, indicating carotenoid formation. After transfer of the new trait into locally best-adapted varieties, either by traditional breeding or *de novo* transformation, it is hoped that vitamin-A deficiency in the developing countries can be prevented.

In contrast to rice, tomato plants already produce carotenoids, and tomato products are viewed as the principal dietary source of lycopene and one of the major sources of β-carotene. Since lycopene and β-carotene are considered beneficial to health (reducing chronic conditions such as coronary heart disease and certain cancers), an attempt was made to enhance the carotenoid content and profile of tomato fruits via genetic engineering. Therefore, the bacterial carotenoid gene

(*crtI*), which encodes for the phytoene desaturase, has been introduced into tomato plants. Transgenic plants showed an increased β-carotene content (up to 45% of the total carotenoid content), though the total carotenoid content was not elevated.

The regular uptake of vitamin C (ascorbic acid) is essential for humans since they lack the ability to synthesize it. In plants, ascorbic acid can be regenerated from its oxidized form in a reaction catalyzed by dehydroascorbate reductase (DHAR). The overexpression of a DHAR cDNA from wheat in maize and tobacco led to a two- to fourfold increase in ascorbic acid levels in foliar and kernels.

3.2.2 Production of Very-long-chain Polyunsaturated Fatty Acids

Very-long-chain polyunsaturated fatty acids (VLCPUFAs) like arachidonic, eicosapentaenoic, or docosahexaenoic acid have important roles in human health and nutrition. They are components of membrane phospholipids, precursors of prostaglandins, required for the development of the fetal neuronal system and reported to reduce the incidence of cardiovascular diseases. The diet of most modern societies is relatively low in ω 3-PUFAs with a concomitant increased level of ω 6-PUFA intake. An important source of VLCPUFAs is oily fish, whereas all plant oils do not contain VLCPUFAs. Now first results have been obtained to genetically engineer the capacity to synthesize these fatty acids in oilseed species. The seed-specific expression of cDNAs encoding fatty acid acyl-desaturases and elongases resulted in the accumulation of up to 5% of VLCPUFAs in linseed.

3.2.3 Increased Iron Level

As cereal grains are deficient in certain essential mineral nutrients, including iron, several approaches have been used to increase iron accumulation and alter iron metabolism. Since ferritin is a general iron storage protein in all living organisms, ferritin genes have been introduced into rice and wheat plants. Goto et al. generated transgenic rice plants expressing soybean ferritin under the control of the seed-specific rice Glu-B1 promoter. Transgenic rice seeds accumulated up to three times more iron as wild-type seeds. Likewise, increased iron levels were found in transgenic rice seeds expressing bean ferritin under the control of the related Gt-1 promoter.

In order to not only increase iron accumulation, but also improve its absorption in the human intestine, two approaches have been adopted. First, the level of the main inhibitor of iron absorption, phytic acid, was decreased by the introduction of a heat-tolerant phytase from *Aspergillus fumigatus*. Transgenic rice plants exhibited at least double phytase activity, whereas in one individual transgenic line, the phytase activity of the grains increased about 130-fold. Second, as cysteine peptides are considered a major enhancer of iron absorption, the endogenous cysteine-rich metallothionein-like protein gene (*rgMT*) was overexpressed, and the cysteic acid content increased significantly in transgenic seeds. The authors suggested that high-phytase rice, with increased iron content and rich in cysteine-peptide, has the potential to greatly improve iron supply in rice-eating populations.

3.2.4 Improved Amino Acid Composition

Potatoes contain limited amounts of the essential amino acids lysine, tryptophan, methionine, and cysteine. In order to improve the nutritional value of potatoes, a nonallergenic seed albumin gene (*AmA1*) from *Amaranthus hypochondriacus* was

transferred to potato plants. The seed-specific albumin was under the control of a tuber-specific and a constitutive promoter, respectively. In both transgenic lines, a 35 to 45% increase in total protein content was reported in transgenic tubers, which corresponded to an increase in most essential amino acids. Additionally, a twofold increase in tuber number and a 3.0- to 3.5-fold increase in tuber yield were observed.

3.2.5 Reduction in the Content of Antinutritive Factors

Cassava is one of the few plants in nature that contains toxic cyanogenic glycosides in the leaves and roots. Sufficient processing of the harvested roots normally renders the cassava safe, although the processing that renders toxic cassava varieties safe also removes certain nutritional value. Therefore, Moller et al. have isolated the genes responsible for cyanogenic glycoside production and are now transforming cassava with antisense constructs of the respective genes *CYP79D1* and *CYP79D2*.

Another strategy for reducing the cyanide toxicity of cassava roots is to introduce a gene that codes for the enzyme hydroxynitrile lyase (HNL). This enzyme breaks down the major cyanogen acetone cyanohydrin, and is expressed only in leaves. After transformation of the cDNA encoding HNL, the HNL activities in cassava roots were comparable with those in leaves. Field trials will determine whether the expression of HNL in roots in fact reduces the cyanide toxicity of cassava food products.

3.2.6 Production of "Low-calorie Sugar"

Koops and colleagues have developed a new sugar beet that produces fructan, a low-calorie sweetener, by inserting a single gene from Jerusalem artichoke that encodes an enzyme for converting sucrose to fructan (1-sucrose:sucrose fructosyl transferase [1-sst]). Short-chain fructans have the same sweetness as sucrose, but provide no calories as humans lack the fructan-degrading enzymes necessary to digest them. Longer-chain fructans form emulsions having a fatlike texture, while fructans also promote the growth of beneficial bacteria present in the gut. Transgenic sugar beet roots produce the same amount of total sugar, but expression of the *1-sst* gene resulted in conversion of more than 90% of the stored sucrose into fructans. Under greenhouse conditions, the "fructan beets" developed normally and had almost the same amount of root dry weight as normal sugar beets. The yield of 110 μmol g^{-1} fresh weight of fructan makes the extraction of these compounds economically interesting.

3.2.7 Seedless Fruits and Vegetables

In plants that are able to develop fruits without fertilization (parthenocarpic fruits), the seeds are absent – a feature that can increase fruit acceptance by consumers. To achieve parthenocarpic development, it is common practice to treat flower buds with synthetic auxinic hormones. To mimic the hormonal effects by genetic engineering, the expression of a gene able to increase auxin content and activity should be induced in the ovule. Rotino and colleagues used the *iaaM* gene from *P. syringae* pv. *savastanoi* under the control of an ovule-specific promoter (*DefH9*) from *Antirrhinum majus* to induce parthenocarpic development in transgenic tobaccos and eggplants. In transgenic eggplants, fruit setting took place even under environmental conditions prohibitive for the untransformed line. Fruit size and weight were similar to that obtained by pollination in transgenic

and control plants. It was envisaged that this approach might also be valuable in other horticultural species such as pepper and tomatoes, in which fruit quality is susceptible to uneven pollination and seed set during lower temperature fluctuations associated with "winter season" production. A similar approach might also be used to produce seedless watermelons rather than the cumbersome triploid seed production system now employed.

3.3 Traits that Affect Processing

3.3.1 Altered Gluten Level in Wheat to Change Baking Quality

The bread-making quality of wheat flour depends primarily on the presence of high molecular weight (HMW) glutenins. Wheat is unique among cereals in having this property. The glutenin proteins are encoded by six genes, and the total glutenin content of the grain is proportional to the expression of these genes. It has been shown that the quality of dough can be influenced both by the quantity and quality of the expressed genes. When specific glutenin genes were added back to wheat lines missing some of the glutenin genes, the dough-mixing characteristics were improved significantly. This same technique could be applied to wheat lines that have already been optimized for baking, and could result in flour with glutenin levels higher than the current maximum of 10% of total protein. Concordantly, the quality of durum wheat (*Triticum turgidum* L. var. *durum*) for bread and pasta making has been modified by insertion of HMW glutenin subunit genes.

3.3.2 Altered Grain Composition in Barley to Improve Malting Quality

β-Glucan is the major constituent of the cell wall of the starchy endosperm of barley. These cell wall molecules are very large, water-soluble, and produce viscous worts if not sufficiently reduced in size by hydrolysis. This causes slow filtration of wort and beer, as well as glucan precipitate in the finished product. β-Glucan hydrolysis is likely to be a function of the level of (1–3, 1–4)-β-glucanase produced by the aleurone, and how much of the enzyme survives high-temperature kilning and mashing. Doubling the amount of β-glucanase activity is likely to ensure sufficient β-glucan hydrolysis, and this could be achieved either by increasing the amount of enzyme synthesized or by changing the heat stability of β-glucanase. The latter has been achieved by transferring a fungal thermotolerant endo-1,4-β-glucanase to two barley cultivars. The amount of heterologous enzyme has been shown to be sufficient to reduce wort viscosity by decreasing the soluble β-glucan content.

In another approach, biochemically active wheat thioredoxin *h* has been overexpressed in the endosperm of transgenic barley grain. Such overexpression in germinated grain effected an up to fourfold increase in the activity of the debranching enzyme pullulanase, a rate-limiting enzyme in the breakdown of starch. The breaking down of starch is a key step in the malting process, and tests with transgenic varieties showed that the time required could be reduced by up to a day.

3.4 Traits of Pharmaceutical Interest

3.4.1 Production of Vaccines

Vaccines are designed to elicit an immune response without causing disease. While typical vaccines are composed of killed or attenuated disease-causing organisms, recombinant vaccines are desirable as an

alternative, as they generally cause fewer side effects than those that occur when the whole organism is delivered. Many candidate proteins have been identified that may function as effective subunit vaccines. Currently, the most common large-scale production of recombinant proteins are genetically engineered bacteria and yeast, due to the ease of manipulation and their rapid growth. However, recombinant proteins overexpressed in microorganisms must be extensively purified to remove host proteins and compounds. Transgenic plants provide an alternative system, with the great practical advantage of directly producing an edible plant tissue for oral immunization. In addition, edible plant-based recombinant vaccines are safe, provide nutrition, and are easy to administer.

At present, a great deal of research is focused on the understanding of transgene expression, stability, and processing in plants. Typical experiments investigating in-planta protein expression employ plant model systems such as potato, tomato, and maize. The ideal plant for human vaccination would be bananas, because they are readily eaten by babies, are consumed uncooked, and are indigenous to many developing countries. Since regeneration and growth to maturity can take up to three years in bananas, it is nevertheless necessary to optimize high-level expression of a vaccine antigen in model plants.

For viral infections, virus-like particles (VLPs), which form by self-assembly of viral surface proteins, are effective as vaccines. The hepatitis B surface antigen (HbsAg) has successfully been used as a vaccine against hepatitis B virus. The vaccine was first produced in yeast by Merck and SmithKline Beecham, and was the first recombinant subunit vaccine. Hence, it served as a model for a first attempt to produce a plant-based vaccine. HbsAg was expressed in tobacco and potato plants and shown to assemble into VLPs that are similar to the yeast-derived commercial vaccine.

In the United States, preliminary clinical trials have been performed, and two out of three volunteers who ate transgenic lettuce carrying a hepatitis B antigen displayed a good systemic response. Likewise, 19 of 20 people who ate a potato vaccine aimed at the Norwalk virus showed an immune response.

Currently, clinical trials with a plant-based vaccine against a bacterial pathogen are underway in the United States. Arntzen and colleagues inserted a gene for a part of an *E. coli* enterotoxin (LT-B subunit gene) that caused diarrhea in humans, into potato plants, and all but one of the 11 volunteers who ate the transgenic raw potatoes produced antibodies to the toxin.

A common problem of vaccine antigens expressed in plants has been the low level of expression. In LT-B-expressing plants, this has been overcome by using a ''plant codon usage optimized'' synthetic gene encoding LT-B and the use of the tuber-specific patatin promoter.

Future considerations must include containment of the transgenes as well as quality control for antigen content. These considerations are particularly important since inappropriate dosing of vaccines can impair their effectiveness, and constant dosing can lead (potentially) to immunological tolerance. In a more recent discussion, the feasibility of direct oral immunization by eating transgenic plants was doubted because of the problem of lot-to-lot consistency and administering pills prescribed by doctors was favored.

3.4.2 Production of Pharmaceuticals

Some recombinant proteins are already available commercially, including human erythropoietin or glucocerebrosidase. Until now, commercial production has used fermentation in *E. coli* and yeast or mammalian cell systems. However, these expression systems have significant limitations: bacteria cannot perform the complex posttranslational modifications required for bioactivity of many human proteins and production of proteins such as growth regulators or cell cycle inhibitors would negatively impact the transgenic animal cell culture.

Plants have several advantages compared with traditional systems for the molecular farming of pharmaceutical proteins. These include: (1) low production costs; (2) reduced time to market; (3) unlimited supply; (4) eukaryotic protein processing; and (5) safety from blood- or animal tissue-borne human pathogens. The production of a range of therapeutic proteins in transgenic plants has proven their capability for production of bioactive human proteins of pharmaceutical value: the proteins appear fully functional and structurally comparable with the analogous proteins produced in animal cell culture.

Examples of human therapeutic proteins include serum proteins such as hemoglobin as blood substitute, interferons as viral protection agents, lysosomal enzymes lacking in patients with Gaucher or Fabry disease, and other proteins such as hirudin, which is effective as an anticoagulant.

The majority of these pharmaceuticals are produced in model plants that are easy to transform, such as tobacco and potato, by using the constitutive 35S promoter from the cauliflower mosaic virus. However, as high levels of protein accumulation may negatively impact on yield and/or growth of the transgenic plants, inducible or tissue-specific promoters are preferable. Tobacco is an excellent biomass producer, but does produce toxic compounds. Crop-based production systems (e.g. wheat, rice, corn) lack these toxic substances and provide an existing infrastructure for their cultivation, harvest, distribution, and processing. This makes food crops highly attractive but leads to the potential for the unintended presence of therapeutic proteins in human food. Recently publicized incidents in which genetically modified crops have inadvertently mixed with those destined for human consumption have highlighted the need for mechanisms to ensure the segregation of plants that express pharmaceuticals.

Cereal crops (rice and wheat) were first used as production and storage system for a single-chain antibody against carcinoembryogenic antigen (CEA), a well-characterized tumor-associated marker antigen. In fact, in dried seeds, the antibodies could be stored for at least five months without significant loss of activity of the antibody. An alternate technique employs targeting of the recombinant protein to the oil bodies of *Brassica napus* seeds. A synthetic gene coding for a hirudin variant was fused to an *Arabidopsis* oleosin gene and transferred to oilseed rape. The recombinant hirudin was correctly targeted and accumulated on the oilbodies of transgenic seeds, which, because of their lower density, could easily be separated by flotation centrifugation. The functional biopharmaceutical was then released by protease treatment.

A recent publication showed the potential for producing recombinant proteins in the guttation fluid of tobacco. Guttation, which is the loss of water and dissolved materials from uninjured plant organs, leads

to the production of a guttation fluid. This can be collected throughout the plant's life, thereby providing a continuous and nondestructive system for recombinant protein production.

4 Outlook

It is likely that, in the future, a rapid development of molecular and technological methods will take place, and this will comprise the initial development of new transgenic approaches in model plants such as *Arabidopsis*, followed by the transfer of ready-established methods to most crop plants. The combination of genetic engineering and molecular marker technology with conventional crossings and subsequent selection will enable a rapid progress in plant breeding.

Despite these possibilities, limitations of widespread application can be foreseen in the patent situation, and this will lead to a partial unpredictability in production costs. A hindrance to the worldwide trade – and therefore also to the marketability of genetically modified foods – is founded in the different legal regulations, for example, in the United States and Europe. Additionally, the lack of acceptance by the public of genetically modified food, especially in central Europe, might delay the commercial potential of transgenic plants, even when there might be clear advantages for the consumer.

Keywords

Anticodon
Three consecutive bases in tRNA that bind to a specific mRNA codon by complementary antiparallel base pairing.

Antiparallel Base pairing
Pairing through specific hydrogen bonds between base residues of two polynucleotide chains or two segments of a single chain with phosphodiesterbonds running in the $5' \rightarrow 3'$ direction in one chain or segment and in the $3' \rightarrow 5'$ direction in the other. In DNA and RNA, the hydrogen bonds are usually formed between complementary base pairs (adenine (A) with either thymine (T) or uracil (U), and guanine (G) with cytosine (C)).

Codon
Three consecutive bases in mRNA or DNA, which code for an amino acid in protein synthesis.

Elongation
The stepwise addition of amino acids to the carboxyl terminus of a growing polypeptide chain.

Fidelity
The accuracy with which the RNA sequence is translated into the correct amino acid sequence.

Initiation
A multistep reaction between ribosomal subunits, charged initiator transfer RNA and messenger RNA that results in apposition of the ribosome-bound initiator Met-tRNA with an AUG initiator codon in mRNA. In this position, the ribosome is poised to form the first peptide bond.

Polarity
The asymmetry of a polynucleotide or polypeptide. In DNA, the two strands have opposite polarity; that is, they run in opposite directions (5′ → 3′ and 3′ → 5’). The polarity of a polypeptide is defined as running from the N-terminus to the C-terminus.

Reading Frame
One of three possible ways of translating groups of three nucleotides in mRNA. The appropriate reading frame is determined by the initiation codon.

Template Strand
The strand of the DNA double helix that is used as a template for transcription of RNA. It has a base sequence complementary to the RNA transcript.

Termination
The end of polypeptide synthesis, which is signaled by a codon for which there is no corresponding aminoacyl tRNA. When the ribosome reaches a termination codon in the mRNA, the polypeptide is released and the ribosome–mRNA–tRNA complex dissociates.

Translation
The stepwise synthesis of a polypeptide with an amino acid sequence determined by the nucleotide sequence of the mRNA coding region. The genetic code relates each amino acid to a group of three consecutive nucleotides termed a *codon*. Decoding of mRNA takes place in the 5′ → 3′ direction, and the polypeptide is synthesized from the amino to the carboxyl terminus.

Translocation
The stepwise advance of a ribosome along the mRNA, one codon at a time, with simultaneous transfer of peptidyl tRNA from the A site to the P site of the ribosome.

Proteins have a linear primary sequence of no more than 20 encoded amino acids and this underlying simplicity is used to express great subtlety in structure and versatility in function. For these reasons, proteins are essential to the structure and function of living cells. The assembly of polypeptide chains from amino acids and their subsequent modifications, leading to the final three-dimensional protein structure, are exceptionally complex processes; many components are involved and much of the cell's energy is utilized. Each peptide bond requires the expenditure of four high-energy phosphate bonds (ATP is converted to AMP and two molecules of GTP are converted to GDP). This value excludes the energy used for initiation and release of the polypeptide chains and the cost of synthesizing and processing mRNA. The linear amino acid sequence of a protein is encoded within the gene as a linear deoxyribonucleotide sequence. Early steps in the biosynthesis of a protein include transcription of the gene and appropriate processing of the transcript leading to

the production of mature messenger RNA (mRNA). We describe the mechanisms involved in translating mRNA to produce a polypeptide chain which has the amino acid sequence specified by the gene. Translation takes place after mRNA is bound to small ribonucleoprotein particles called *ribosomes* through the mediation of aminoacyl tRNA which links the linear nucleotide sequence of mRNA with the linear amino acid sequence of the encoded polypeptide. The genetic message is read sequentially as mRNA moves relative to the ribosome. Thus, the polypeptide chain is formed by the sequential incorporation of amino acids into peptide linkage. The process of translation is achieved with high fidelity with less than one error per 10 000 amino acids incorporated into protein. The mechanisms of protein synthesis are essentially the same for all cells irrespective of whether they have a nucleus (eukaryotes) or not (prokaryotes).

1 Introduction

A gene or cistron is defined as the region of DNA that is transcribed into a functional RNA. The transcript functions either as such (e.g. tRNA, rRNA, snRNA) or as a messenger (mRNA), which after processing or editing as required, normally codes for one or more polypeptide chains in the translation process. A polynucleotide such as RNA is an asymmetrical polymer assembled from nucleoside triphosphates by a stepwise mechanism linking the 5′ position of one nucleotide by a phosphate bridge to the 3′ position of the adjacent nucleotide. In the finished polynucleotide chain, the first nucleotide residue has a 5′ position, which is not linked to another nucleotide, whereas the last nucleotide has an unlinked 3′ position. Thus, polynucleotide synthesis proceeds from the 5′ to the 3′ terminus and the polymer is said to have a 5′ to 3′ polarity. Usually, linear RNA sequences are written with the 5′ terminus on the left and the 3′ terminus on the right (Fig. 1a). Within the RNA chain, some bases may form antiparallel base pairs (Fig. 1b, as found in DNA).

The polypeptide chains of proteins are also asymmetrical polymers in which the amino acid residues are linked by peptide bonds between their α-amino and carboxyl groups (Fig. 2), leaving a free α-amino group at one end (the amino terminus) of the polymer and a free α-carboxyl group at the opposite end (the carboxyl terminus). The significance of the polarity of the RNA and proteins will become evident when the process of protein biosynthesis is explained below.

The genetic information stored in DNA is not usable directly for making proteins. Rather, it must be copied into a primary RNA transcript containing the coding sequences by an enzymatic transcription of segments of DNA containing the genes. In prokaryotes, the primary transcript is also the messenger (mRNA); that is, it can be used directly in polypeptide synthesis. In contrast, in eukaryotes the primary transcript (precursor-mRNA) is often much larger in size than the mature mRNA and requires extensive processing involving the excision of intervening and other noncoding sequences.

Messenger RNA serves as the template for protein synthesis; that is, the linear

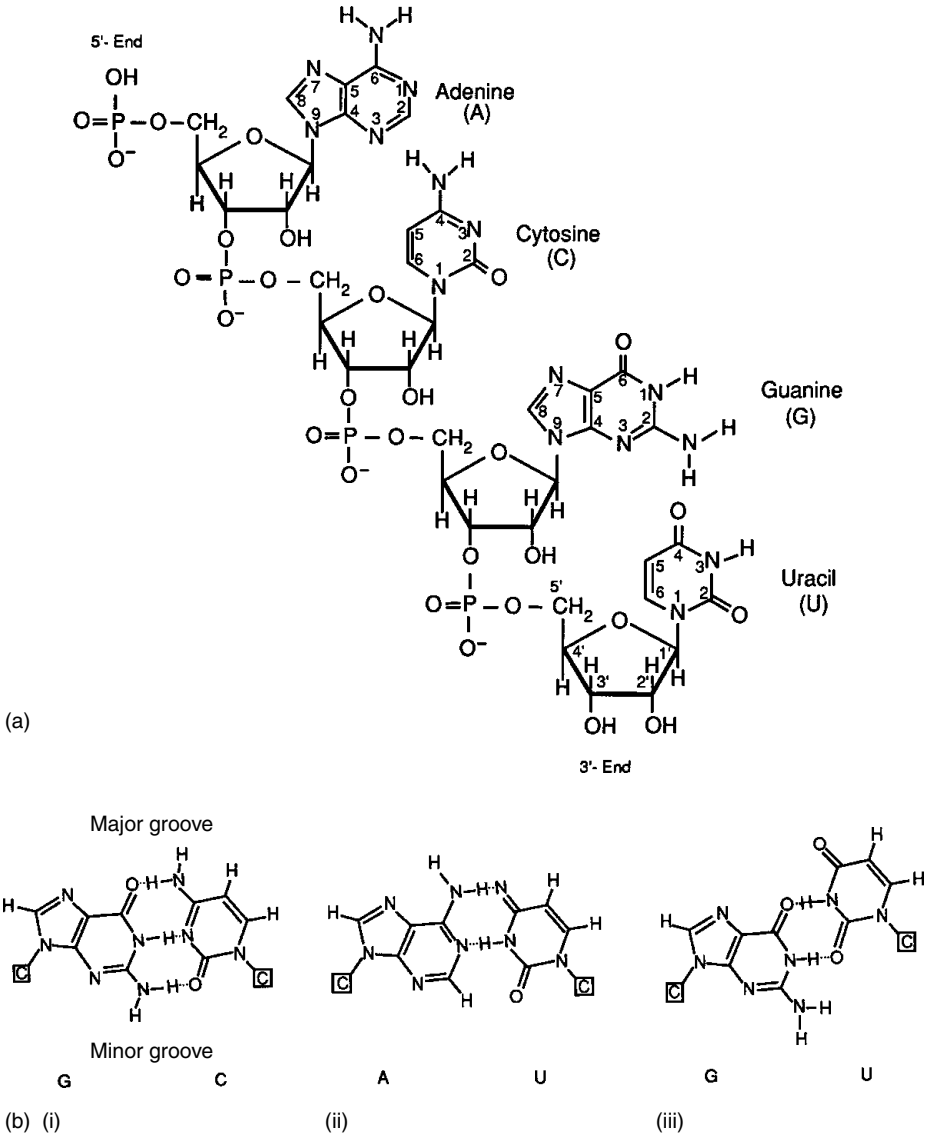

Fig. 1 Structural elements of ribonucleic acids. (a) Primary structure indicating the numbering system for purines, pyrimidines, and ribose. (b) Base-pairing interactions commonly found in RNA: (i) G + C base pair; (ii) A + U base pair; (iii) G + U base pair. Pairs (i) and (ii) are Watson and Crick base pairs; (iii) is a special type of base pairing found in intramolecular bihelical regions. The minor groove is on the side of the base pair with the glycosidic bond of which the carbon atom C 1′ of ribose is boxed. Note that DNA contains base pairs of types i and ii only but with thymine (5-methyluracil) in place of uracil. [From Arnstein, H.R.V., Cox, R.A. (1992) *Protein Biosynthesis*, Oxford University Press, Oxford. With permission.]

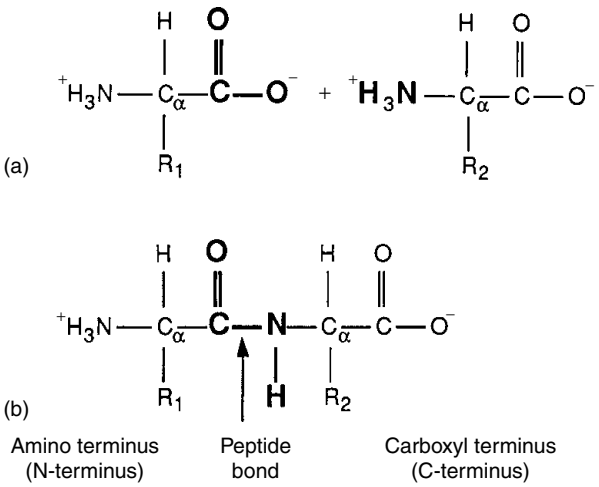

Fig. 2 Structure of the peptide bond. (a) Two L-amino acids with different side chains, R_1 and R_2; (b) a dipeptide formed from the two amino acids shown in (a).

nucleotide sequence of the mRNA dictates the amino acid sequence of the polynucleotide encoded originally by the gene. Conventionally, gene and mRNA nucleotide sequences are written in the 5′ to 3′ direction, which corresponds to the direction in which mRNA is decoded during polypeptide synthesis: The mRNA is read in the 5′ to 3′ direction, and the polypeptide is synthesized from the amino toward the carboxyl terminus.

The mechanism whereby RNA is translated into protein is complex, and the cell devotes considerable resources to the translational machinery. The components include 20 different amino acids, as well as transfer RNAs, aminoacyl tRNA synthetases, ribosomes, and a number of protein factors which cycle on and off the ribosomes and facilitate various steps in initiation of translations, elongation of the nascent polypeptide chain, and termination of synthesis with release of the completed polypeptide from the ribosome. The process depends on a supply of energy provided by ATP and GTP. The rate of protein synthesis is typically in the range of 6 (immature red blood cells of the rabbit) to 20 (*Escherichia coli* growing optimally) peptide bonds per second at 37 °C.

2 mRNA Structure and the Genetic Code

2.1 Structure

The sequence information of a gene that is copied (transcribed) into the nucleotide sequence of RNA from the complementary strand of DNA is called *the template strand*. The primary transcript is a single strand of RNA, which is a faithful copy of the nontemplate strand of DNA with substitution of U residues in place of T residues found in DNA. Sometimes, the primary transcript is altered, as described below, before it functions as mRNA; in these cases, the original unmodified transcript is the precursor or pre-mRNA. Usually, mRNAs have nontranslated sequences at the 5′ and

3′ ends in addition to the coding domain. These noncoding sequences sometimes affect the efficiency of translation and the stability of mRNA. The structures of typical mRNAs are shown in Fig. 3. The decoding process involves base pairing between three bases (designated a codon) in the mRNA and the three-base anticodon of a transfer RNA (tRNA). In a separate reaction, each tRNA is first linked to a particular amino acid and thus the pairing of mRNA with tRNA determines the sequence of amino acids in the resulting protein.

2.2 Prokaryotic mRNA

In prokaryotes, pre-mRNA usually undergoes little or no modification so that pre-mRNA and mRNA are very similar if not identical. Because pre-mRNA is colinear with DNA, DNA and proteins are usually colinear in these organisms. Gene expression in prokaryotes usually involves the cotranscription of several adjacent genes, and translation of mRNA sequences into polypeptides may begin at the 5′ end of mRNA while transcription is still in progress at the 3′ end.

2.3 Eukaryotic mRNA

In eukaryotes, the genetic information is stored mainly in the nucleus and to a minor degree in some organelles (mitochondria and chloroplasts). The description that follows pertains only to nuclear genes. Eukaryotic genes are more complicated than prokaryotic genes because the coding region is often discontinuous:

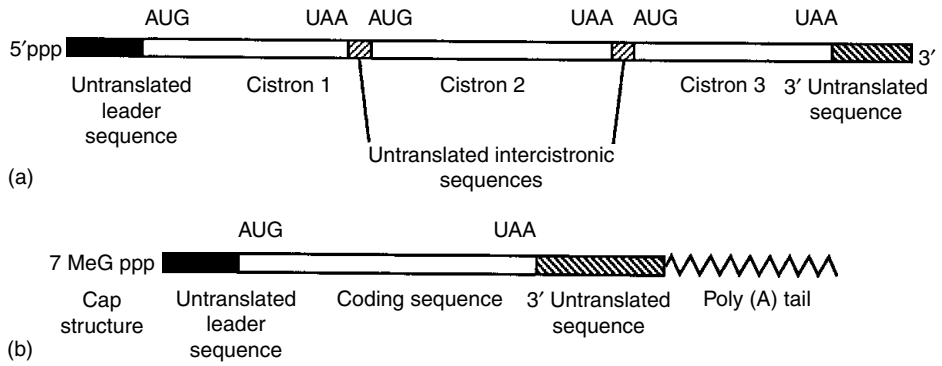

Fig. 3 Structure of typical mRNAs. (a) *Prokaryotic mRNA*. At the beginning of the transcript, there are two additional phosphate residues linked by pyrophosphate bonds to the 5′ phosphate group of the terminal nucleotide (see Fig. 1). The 5′ untranslated sequence often contains a ribosome-binding site (the Shine–Dalgarno sequence), which increases the efficiency of translation. AUG and UAA are representative initiation and termination codons, respectively. Cistrons (gene sequences) are separated by short (typically 12 to 24 nucleotides) noncoding intercistronic sequences. (b) *Eukaryotic mRNA*. Typically, the processed transcripts are monocistronic. The 5′ end is usually modified by the addition of 7-MeG, known as a cap structure, which is linked by two pyrophosphate groups to the terminal nucleotide of mRNA. The coding sequence is located between 5′ and 3′ untranslated sequences. In the majority of cases, the 3′ end is modified by the addition of 25 to 250 adenylate residues, termed the poly(A) tail. [From Arnstein, H.R.V., Cox, R.A. (1992) *Protein Biosynthesis*, Oxford University Press, Oxford. With permission.]

the coding sequences or exons are interrupted by intervening sequences (introns). Thus, genes and proteins are usually *not* colinear in eukaryotes. In the nucleus, a complicated set of splicing reactions removes all the introns from the pre-mRNA and fuses the exons into a continuous coding sequence. Other processing steps involve adding a "cap" to the 5′ end of the mRNA and a poly(A) "tail" to the 3′ end (see Fig. 3b). After completion of these nuclear maturation steps, the mRNA is transported to the cytoplasm where it is translated. As is the case with prokaryotic mRNA, the coding region is flanked by 5′ and 3′ nontranslated sequences.

2.4 The Genetic Code

The genetic code is triplet, comma-less, and nonoverlapping. As a consequence, a nucleotide sequence has three possible reading frames (Fig. 4). Because mRNA is normally translated into a unique polypeptide, an essential step in the translation process is the selection of the appropriate reading frame. This is achieved by starting translation at the initiation codon, usually AUG or less frequently GUG, which ensures that the following codons are read in phase within the required reading frame. Of the 64 theoretically possible triplets in the genetic code, 61 sense codons correspond to 20 genetically encoded amino acids found in all, or nearly all, proteins. When GUG is used as the initiation codon, it codes for methionine by interaction with the anticodon of the initiator Met-tRNA^{Met}, whereas elsewhere it codes for valine. All other codons specify only one amino acid but many amino acids are specified by two or more (up to six) codons; the code is unambiguous, but degenerate. The remaining three codons, termed *nonsense codons*, usually signify termination of synthesis and release of the finished polypeptide chain.

2.4.1 Deviations from the Standard Genetic Code

One of the nonsense codons, UGA, has an additional function in the synthesis of selenoproteins. The process involves the initial synthesis of selenocysteyl-tRNA from a novel seryl-tRNA and selenium. This tRNA contains an anticodon that is able to decode UGA and insert selenocysteine residues into the growing polypeptide chain, but only at UGA codons in a particular context of neighboring nucleotides. The insertion of selenocysteine residues into the polypeptide also requires a specific elongation factor T, which differs from the factor used for the

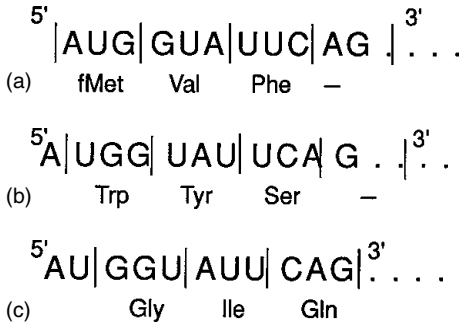

Fig. 4 Translation of a polynucleotide sequence into three alternative polypeptides using different reading frames.

incorporation of other aminoacyl tRNAs (see Sect. 4.2.3).

Mitochondria and chloroplasts, as well as certain organisms such as mycoplasma and ciliated protozoa, use a few non-standard genetic codons. For example, methionine is usually coded for by AUG (or occasionally GUG), but in human mitochondria this codon is replaced by AUA. Variations in the genetic code are thought to have arisen as a result of the loss of some tRNA genes and mutational pressure on DNA, giving rise to a predominance of either AT- or GC-rich codons.

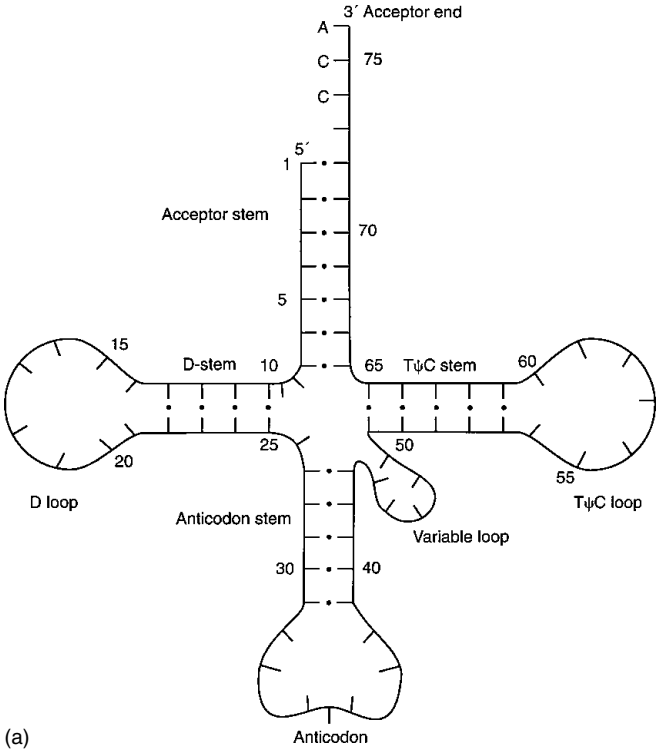
3 Transfer RNA (tRNA)

Transfer RNA nomenclature: The amino acid linked to a charged tRNA is indicated by a prefix and the specificity of the tRNA in the aminoacylation reaction is shown as a superscript on the right; for example, Phe-$tRNA^{Phe}$ indicates phenylalanine-specific tRNA charged with phenylalanine. The anticodon may be indicated as a right subscript or, alternatively, in the superscript after the amino acid; for example, $tRNA_{UGC}$ or $tRNA^{Ala/UGC}$. The right-hand subscript position is sometimes used to indicate the organism from which the tRNA is derived (e.g. $tRNA^{Val}_{yeast}$). The initiator tRNA, which is specific for methionine, is termed Met-$tRNA^{Met}_f$ or Met-$tRNA^{Met}_i$. Often the superscript ^{Met} is omitted. In prokaryotes and in the mitochondria of eukaryotes, the methionine residue of the charged initiator tRNA is formylated by transformylase using N^{10}-formyltetrahydrofolate as the donor, giving N-formylmet-$tRNA_f$. Commonly, this charged tRNA is termed fMet-$tRNA_f$. The methionine-specific elongator RNA, which inserted methionine into internal positions of the growing peptide chain is termed $tRNA^{Met}_m$ (or $tRNA_m$) when uncharged, and Met-$tRNA^{Met}_m$ (or Met-$tRNA_m$) when charged. By relating individual codons of mRNA to the cognate amino acids, tRNA functions as a key bilingual intermediate in the translation of the genetic code. All tRNAs are single-stranded molecules about 80 nucleotides long with a common 3′ terminal CCA sequence. Most of the bases are standard but some (e.g. pseudoU, dihydroU, and T) are derived by modification after transcription of the transfer RNA genes.

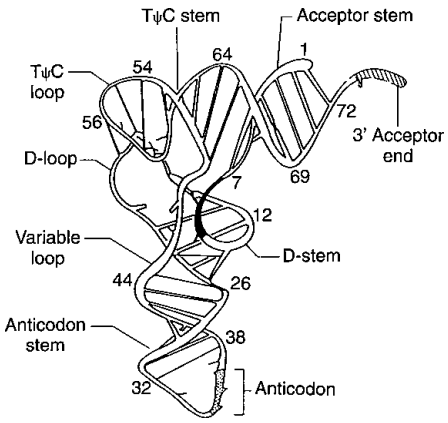
The secondary structure of tRNA is usually presented in two dimensions as a cloverleaf to highlight the regions of base pairing (Fig. 5a). X-ray crystallography reveals that additional hydrogen bonds give rise to an L-shaped tertiary structure (Fig. 5b). The CCA sequence carrying the amino acid is located distal to the anticodon.

The decoding process involves antiparallel base pairing between the three bases of mRNA codons and the complementary anticodons of tRNA during peptide bond formation (Fig. 6). The first and middle bases of the codon form conventional base pairs with the third and middle base of the anticodon, respectively, but the third base of the codon pairs with the first base of the anticodon by a less stringent interaction (e.g. base pairing of G with U as well as with C), giving rise to degeneracy. This so-called ''wobble'' considerably reduces the number of tRNA species required to decode the 61 sense codons. Thus, the protein synthesis system in the cytosol of eukaryotes contains only a few more than 40 different tRNAs, and in mitochondria, 22 to 24 species are sufficient.

The attachment of amino acids to tRNA involves the formation of an ester bond between the α-carboxyl group of the amino acid and the 3′ hydroxyl group of the terminal adenosine of tRNA. It requires specific enzymes, the aminoacyl tRNA synthetases. There are 20 different synthetases, each specific for one of the 20 amino acids, and each enzyme recognizes something unique in the structure of its cognate tRNA. The structural determinants that ensure accuracy of this



(a)



(b)

charging reaction vary for different tRNAs. The anticodon may play a part but sometimes even a single base elsewhere is sufficient to determine the specificity of the tRNA-synthetase interaction. The accuracy of the synthetase reaction in attaching an amino acid to its cognate tRNA is critically important to the fidelity of the

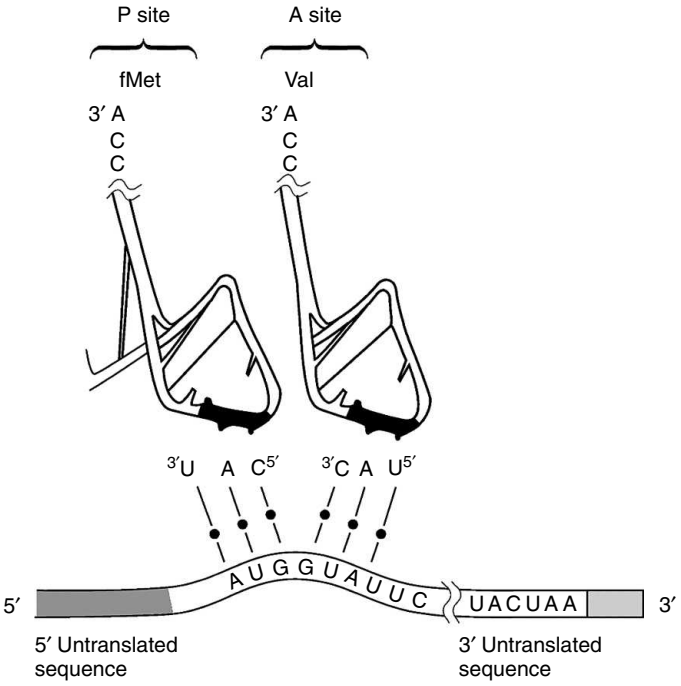


Fig. 6 Schematic illustration of base pairing between a codon and its anticodon. The diagram shows the interaction at the P site of the ribosome (see Fig. 9) between the initiation codon AUG of mRNA and the anticodon CAU of fMet-tRNA$_f^{Met}$ and the interaction at the A site between the codon GUA of mRNA and the anticodon UAC of Val-tRNA^{Val}. The polarity of an RNA species runs from the 5′ end to the 3′ end. The fragment of tRNA is representative of the general structure (see Fig. 5b) placed in the appropriate orientation. The interaction between the codon and the anticodon is antiparallel, and the three base pairs have a bihelical conformation. The shaded regions of mRNA denote untranslated sequences.

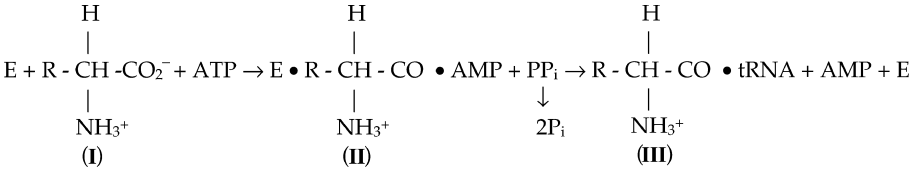
Fig. 5 Structure of phenylalanyl-transfer RNA. (a) Secondary cloverleaf structure. The 5′ and 3′ ends of the molecule are marked; the continuous line represents the sugar phosphate backbone. The short lines denote base residues and the dots denote base pairing through standard hydrogen bonds (see Fig. 1). The D loop contains dihydrouracil residues; the TψC loop contains thymine and pseudouridine. (b) Tertiary structure. The abbreviations for unusual bases are defined in (a). The sugar phosphate backbone is represented by double parallel lines. Standard base pairs are represented by short double parallel lines, and nonstandard base pairs by single lines. The anticodon sequence is stippled, and the acceptor end is shaded. [From Arnstein, H.R.V., Cox, R.A. (1992) *Protein Biosynthesis*, Oxford University Press, Oxford. With permission].

translation process. Once the aminoacyl tRNA has been formed, the subsequent incorporation of the amino acid residue into a polypeptide does not depend on the amino acid itself but only on the interaction between the anticodon of the aminoacyl tRNA with the codon of mRNA. Thus, an error in the synthetase reaction would lead to the incorporation of an inappropriate amino acid into the polypeptide.

Synthesis of aminoacyl tRNA (**III**) from amino acids (**I**) requires activation of the amino acid carboxyl group with formation of an intermediate enzyme-bound aminoacyladenylate (**II**) (Scheme 1).

The energy for the reaction (two high-energy phosphate bonds) is provided by ATP and stored in the ester bond of the aminoacyl tRNA to be used subsequently for peptide bond synthesis.



Where E = aminoacyl tRNA synthetase

4 Ribosome Structure and Function in Translation

4.1 Ribosome Structure

Ribosomes are high molecular–weight complexes of RNA (rRNA) and proteins (Table 1), and the electron-dense particles are easily visualized within cells by electron microscopy (see Fig. 7). Usually, several

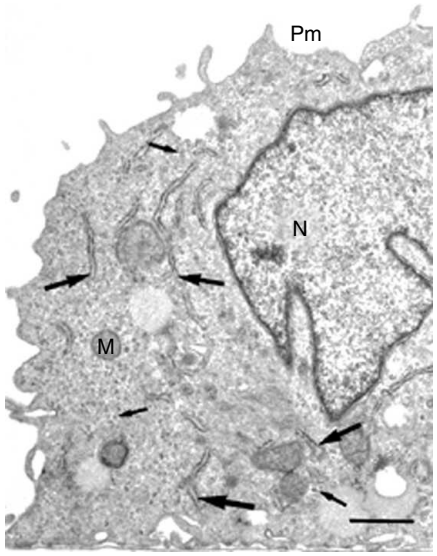

Fig. 7 Electron micrograph of a thin section through part of an epithelial cell showing plasma membrane (Pm), nucleus (N), mitochondria (m), and rough endoplasmic reticulum (large arrows) to which are attached numerous polysomes. Groups of free ribosomes (small arrows) occur in the cytoplasm. Bar represents 1000 nm. [Micrograph by I. D. J. Burdett, National Institute for Medical Research, London, UK.]

ribosomes become attached to one mRNA molecule giving rise to polyribosomes (also called *polysomes*; see Fig. 7). Ribosomes from various sources (prokaryotes, eukaryotic cytoplasm, mitochondria, chloroplasts, and kinetoplasts) vary in size from 20 to 30 nm in diameter, but all are composed of a large and a small subparticle or subunit and perform similar functions in protein synthesis. In general, cytoplasmic ribosomes of eukaryotes are larger than ribosomes of prokaryotes (Table 1). The principal functional domains of the ribosome and associated components are given in Fig. 8. More detailed resolution of the ribosome structure has allowed the

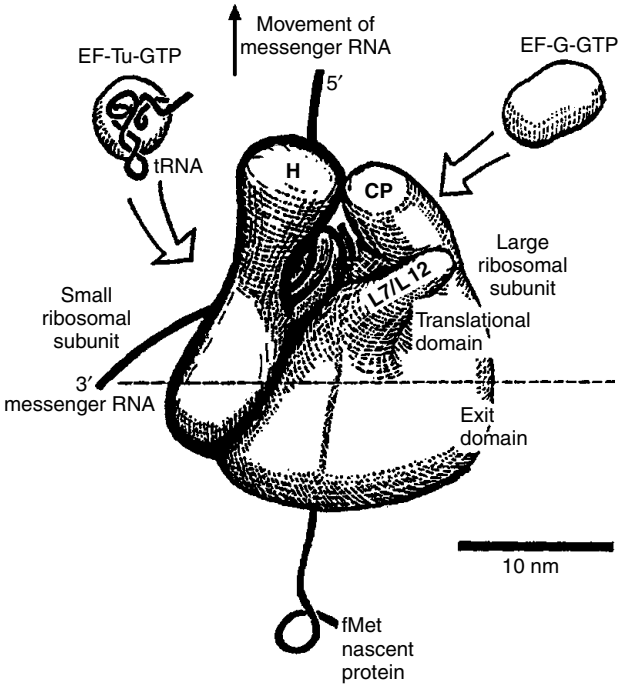

Fig. 8 Model of the *E. coli* ribosome, based on low resolution electron microscopy. The diagram shows the relative orientation of the large and small subunits and other functional components involved in polypeptide chain synthesis. H, head of the small subunit; CP, central protuberance and L7/L12 stalk of the large subunit; EF-Tu, elongation factor required for binding aminoacyl tRNA to the ribosomal A site; EF-G, elongation factor required for translocation of the peptidyl-tRNA from the A to the P site. The broken line indicates the boundary between the translational and exit domains that are involved in peptide bond formation and extrusion of the nascent polypeptide chain, respectively. Further details of ribosome structure and function are given in Fig. 11 for peptide bond formation, in Figs. 12 and 13 for the delivery of aminoacyl tRNA to the A site and Figs. 14 and 15 for translocation and Fig. 16 for the location of the nascent polypeptide chain. [a]Largest dimension.
[b]Mitochondrial ribosomes are preferentially associated with the inner mitochondrial membrane and are more diverse than cytoplasmic or chloroplast ribosomes. Particular features include posttranscriptional oligoadenylation of the 3′ ends of both the smaller and larger rRNA components. Except for mitochondrial ribosomes of higher plants, the essential sequence motifs 5S rRNA and 5.8S rRNA are present in the large rRNA component and are not found as individual species.
[c]Mitochondria of protists such as *Trypanosoma brucei* are also known as kinetoplasts.
[d]4.5S rRNA corresponding to the 100 nucleotides at the 3′ end of the 23S rRNA in eubacteria occurs as a separate species in chloroplasts of higher plants.
[e]This species is present only in plant mitochondria and is absent from all other mitochondrial ribosomes.
[f]Data not available.

placement of mRNA, aminoacyl tRNA, peptidyl tRNA, and the nascent polypeptide chain (see Sect. 4.3).

The small subunit comprises a single rRNA of $0.3–0.7 \times 10^6$ Da and single copies of 20 to 30 unique proteins. It has a major function in binding initiator tRNA and mRNA in the initiation of protein synthesis and in decoding the genetic message.

The large subunit comprises a high molecular–weight rRNA ($0.6–1.7 \times 10^6$ Da) and often one or two smaller rRNAs ($0.03–0.05 \times 10^6$ Da) and 30 to 50 different proteins are present, with one exception, as single copies. The large subunit binds aminoacyl tRNA at the A site, peptidyl tRNA at the P site, and discharged tRNA at the E (exit) site. The large subunit contains the peptidyl transferase center and, unusually, this enzyme activity resides in the rRNA molecule itself rather than in the associated ribosomal proteins. This subunit is also involved in binding elongation factor G, which is required for translocation (Fig. 8).

4.2 The Ribosome Cycle in Translation

Polypeptide synthesis can be divided into three stages: initiation, elongation, and termination. Initiation involves the binding of a ribosome to mRNA with the initiation codon correctly placed in the P site. Elongation leads to the stepwise increase in the length of the polypeptide chain through the transfer of the growing chain to the amino group of aminoacyl tRNA. Termination of chain elongation and release of the completed polypeptide occurs when a termination codon reaches the A site. All stages require the participation of protein factors. Advances in establishing the structures of translational factors by X-ray crystallography have been rapid in the last decade.

4.2.1 Formation of Preinitiation Complexes

The ribosome cycle starts with the stepwise formation of an initiation complex from mRNA, charged initiator tRNA, and ribosomal subunits. A number of preinitiation complexes are formed as intermediates and the process is facilitated by initiation factors. In outline, prokaryotic and eukaryotic systems are similar, but there are a few differences, particularly as regards the complexity of the initiation factors and details of the mechanisms.

Prokaryotic systems. Three proteins, initiation factors IF-1, IF-2, and IF-3 (see Table 2), are required for the initiation of protein biosynthesis (see Fig. 9a). Ribosomal subunits are released by dissociation of ribosomes following translation of the mRNA. Dissociation is facilitated by the combined action of the initiation factors IF-1 and IF-3; IF-1 increases the rate of dissociation and IF-3 acts as an antiassociation factor when bound to the (30S) ribosomal subunit, thereby displacing the equilibrium in favor of subunit formation. Initiation factor IF-2 is also able to bind to the small 30S subunit and this association is stabilized by IF-1 and GTP, the latter acting as a steric effector without being hydrolyzed at this stage. IF-2 plays a central role in binding fMet-$tRNA_f$ to the 30S preinitiation complex by specific recognition of the *N*-formylmethionine residue attached to the initiator tRNA, thus restricting this interaction to charged initiator tRNA. All three factors bind to the 30S ribosomal subunit near the 3′ end of the 16S ribosomal RNA at adjacent sites that are

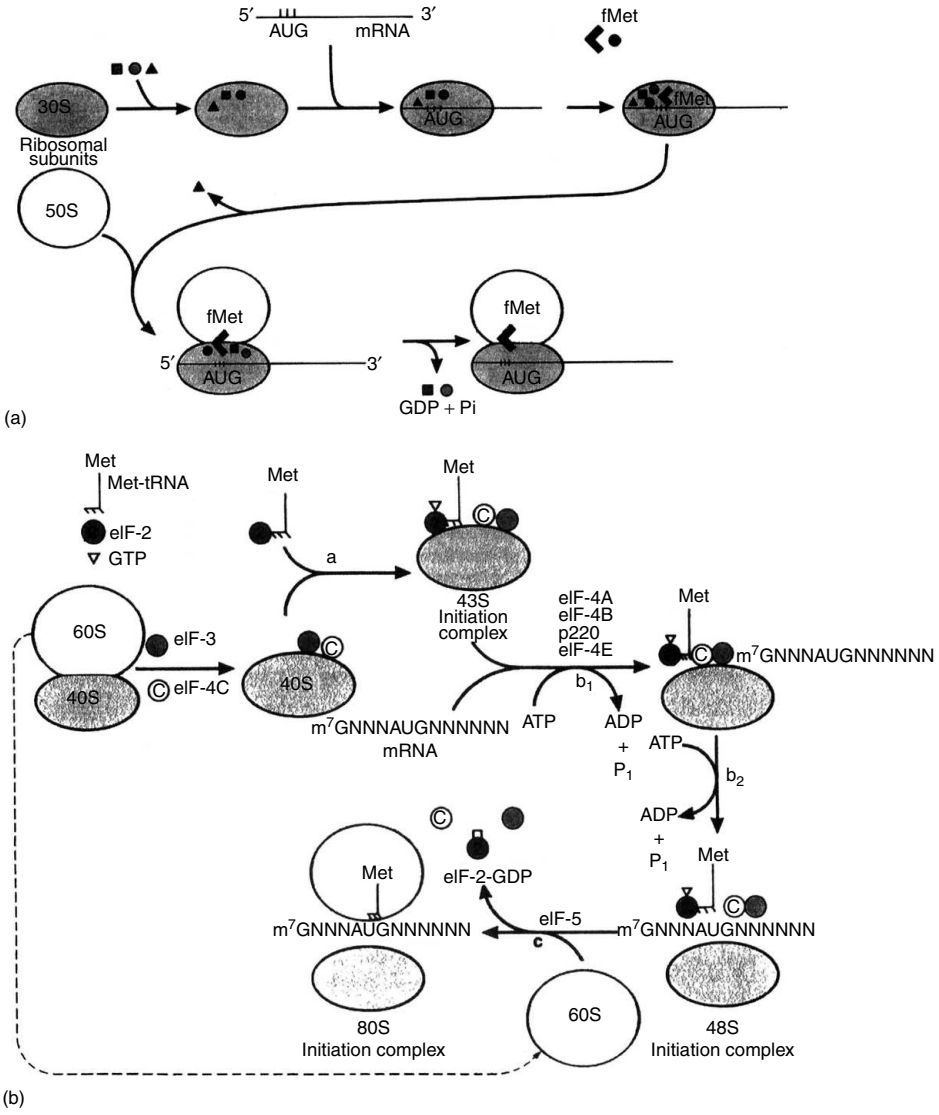

Fig. 9 Schematic diagram illustrating the formation of initiation complexes, (a) prokaryotic initiation. The following symbols are used for initiation factors and other components involved in the formation of the 70S initiation complex: ■, IF-1; ●, IF-2; ▲, IF-3; <, fMet-tRNA$_f$; ▽, GTP; other symbols are defined in the figure. (b) Eukaryotic initiation complexes in mammalian protein biosynthesis from components defined in the figure. The process may be divided into three stages: **a**, formation of a 43S preinitiation complex; **b**, binding of mRNA with formation of a 48S preinitiation complex; and **c**, synthesis of the 80S initiation complex containing the initiator tRNA in the correct position for peptide bond formation. Tab. 2 Prokaryotic initiation factors from *E. coli*.

Factor	*M_r [kDa]*	*Properties and function*
IF-1	9	Stimulates activity of IF-2; accelerates dissociation of unprogrammed ribosomes to subunits.
IF-2	100	Binds fMet-tRNA$_f$ to the ribosomal P site by a GTP-requiring reaction.
If-3	22	Binds natural mRNAs to the small ribosomal subunit probably by facilitating base pairing between the untranslated leader sequence and the 3′ end of 16S rRNA; prevents ribosomal subunit association when bound to the small subunit.

From Arnstein, H.R.V., Cox, R.A. (1992) *Protein Biosynthesis*, Oxford University Press, London. With permission.

located at the interface between the small and large ribosomal subunits.

In the next step, the initiator tRNA and mRNA associate with the 30S–IF-1–IF-2–IF-3 complex with release of IF-3. There is evidence from *in vitro* experiments that the binding of mRNA precedes that of the initiator tRNA.

Messenger RNA binds to the small ribosomal subunit immediately before formation of the final initiation complex with the initiation codon correctly positioned in the P site (see Fig. 9a). In the case of bacterial and bacteriophage messengers, the molecular recognition mechanism proposed by Shine and Dalgarno in 1974 involves base pairing between short nucleotide sequences, most often CUCC, near the 3′ end of the 16S ribosomal RNA and a complementary region, usually consisting of 3 to 9 bases on the 5′ side of the mRNA initiation codon, which has been found to be present in nearly all of more than 150 bacterial and bacteriophage messengers. Studies with mutants and mRNA fragments indicate that, in addition to the Shine–Dalgarno interaction, outlying upstream sequences in the leader region may also provide recognition signals between mRNAs and ribosomes, possibly by ensuring that the Shine–Dalgarno sequence is in an appropriate conformation.

The Shine–Dalgarno mechanism is also found in chloroplast protein synthesis as judged from sequence analysis of the 16S rRNA and mRNAs, but apparently not in mammalian mitochondria where the initiator codon occurs either directly at, or only a few nucleotides downstream from, the 5′ end of mRNA, which excludes the possibility of mRNA–rRNA base pairing in this region.

Eukaryotic systems. At least 12 proteins, the eukaryotic initiation factors (eIF) (see Table 3), are needed for initiation of protein biosynthesis (see Fig. 9b). The dissociation of cytosolic 80S ribosomes is facilitated by a complex initiation factor, eIF-3 (M_r approx. 5–700 000), consisting of 9 to 11 polypeptide chains, which binds to the small (40S) ribosomal subunit and prevents its reassociation to 80S ribosomes. Thus, this factor has antiassociation activity, but low molecular–weight proteins with similar activity have also been reported, and a protein, eIF-4C, of M_r 20 000, seems to function as an accessory factor to eIF-3 in the formation of a 43S ribosomal preinitiation complex. Also, another protein factor, eIF-6, of M_r 24 000, prevents

Tab. 3 Eukaryotic initiation factors.

Initiation factor	*Synonym*	*M_r (kDa) of factors and subunits*	*Properties and function*
eIF-1		15	Stabilizes initiation complexes
eIF-2		α, 38[a] β, 35[a] γ, 55	GTP-dependent binding of Met-tRNA$_f$ to the small ribosomal subunit
eIF-2B	GEF	27, 37, 52, 67, 85[a]	Conversion of eIF-2-GDP into eIF-3-GTPs
eIF-3		9–11 subunits 24–170[a]	Associates with 40S subunit to maintain dissociation; binds mRNA to 43S preinitiation complex
eIF-4A	50 kDa component of CBP-II	50	ATP-dependent unwinding of the secondary structure of the mRNA 5′ region; stimulates translation of exogenous mRNA in cell-free systems
eIF-4B		80[a]	mRNA binding; stimulates cell-free translation; ATPase activity of eIF-4A and eIF-4F; AUG recognition and recycling eIF-4F
eIF-4C		17	Ribosome dissociation; 60S subunit joining
eIF-4D		17	Formation of first peptide bond
eIF-4E	CBP-1; 24 kDa CBP	24–28[a]	Binds mRNA cap structure
eIF-4F	CBP-II; cap binding protein complex	24 (CBP-I)[a] 50 (eIF-4A), 200[a]	ATPase; unwinds mRNA secondary structure; stimulates cell-free translation
e-IF-4G		220	Stimulates protein synthesis by interacting with eIF-4E and poly(A) protein to circularize polysomes
eIF-5		60[a]	GTPase; release of eIF-2 and eIF-3 from preinitiation complex to allow joining of the 60S subunit
eIF-6		24	Antiassociation activity; binds o the 60S ribosomal subunit.

[a]Denotes subunit can be phosphorylated *in vivo*.

reassociation by binding to the large (60S) ribosomal subunit.

Initiation factor eIF-2 gives a stable binary complex with GTP which binds the initiator tRNA, Met-tRNA$_f$, forming a ternary complex. Interaction of this ternary complex with the 40S ribosomal subunit containing bound initiation factors eIF-3 and eIF-4C gives rise to the 43S preinitiation complex, which is competent to bind messenger RNA in the presence of three further initiation factors, eIF-4A, eIF-4B, and eIF-4E, together with ATP.

The binding of cytosolic eukaryotic messenger RNAs to the small ribosomal subunit probably does not involve base-paring with the 18S rRNA, as no uninterrupted sequences of the Shine–Dalgarno type have been found. Instead, a ''scanning model'' has been proposed, in which the preinitiation complex, composed of the 40S ribosomal subunit, Met-tRNA$_f^{Met}$ and associated initiation factors binds at or near the 5′ cap of the mRNA and slides along the messenger until it encounters the first AUG triplet, at which point the 60S ribosomal subunit joins to give rise to the 80S initiation complex. Recognition of the cap is facilitated by cap binding proteins (CBP), which mediate an ATP-dependent melting of the mRNA secondary structure at the 5′ terminal region to allow the mRNA to thread through a channel in the neck of the 40S subunit. The cap structure is required for efficient binding and translation even in cases where the initiating AUG codon occurs hundreds of nucleotides downstream. As a rule, scanning by the 40S subunit stalls at the first AUG codon, which is recognized mainly by interaction with the anticodon of the Met-tRNA$_f^{Met}$. However, this recognition also depends in some way on eIF-2 and may be modulated as a result of deviation of the mRNA structure from the consensus sequence GCCGCCA/G CCAUGG. Sequence context may also account for the rare cases where initiation occurs downstream of the 5′ proximal AUG codon. Where this sequence context is unfavorable, initiation becomes inefficient, hence most 40S subunits will tend to initiate further along the mRNA at another AUG triplet in a more favorable context. This model also explains rare cases where initiation is not restricted to one particular AUG codon and translation of a single mRNA gives rise to two proteins.

4.2.2 Initiation Complex Formation: Joining of the Large Ribosomal Subunit

The last event in the initiation of protein synthesis involves the joining of the large ribosomal subunit to the preinitiation complex (Fig. 9). In the prokaryotic system, association of the 50S subunit with the 30S preinitiation complex takes place with hydrolysis of GTP by the GTPase activity of IF-2 and release of IF-1, IF-2, GDP, and P_i. GTP hydrolysis is essential for release of IF-2 from the initiation complex, which is prerequisite for allowing the fMet-tRNA$_f$ to engage in the formation of the first peptide bond. In eukaryotic protein synthesis, the 80S initiation complex is formed by joining the 60S ribosomal subunit to the 48S preinitiation complex consisting of the 40S ribosomal subunit, eIF-2, eIF-3, GTP, Met-tRNA$_f$, mRNA, and possibly eIF-4C. This coupling reaction requires an additional factor, eIF-5, which mediates the hydrolysis of GTP to GDP with release of eIF-2-GDP, P_i, and eIF-3 from the 48S preinitiation complex.

By this stage, all initiation factors have been released and are available for recycling, although the exact steps at which factors are released from intermediate complexes are not known in every case.

There is thus an initiation factor cycle within the ribosome cycle, and regulation of the activity of factors, particularly eIF-2, is an important control mechanism in translation (see Sect. 5.4.1).

4.2.3 Polypeptide Chain Synthesis: The Elongation–Translocation Cycle

In the initiation complex, location of the charged initiator tRNA in the P site of the ribosome (see Fig. 10a) allows transfer of the methionine residue to the amino group of another aminoacyl tRNA in the A site (Fig. 10b) by peptidyl transferase to form dipeptidyl tRNA (see Fig. 10c). Functional insertion of Met-tRNA$_f$ directly into the P site can be demonstrated using the trinucleotide AUG as a synthetic mRNA and another trinucleotide, for example, UUU, to bind an acceptor aminoacyl tRNA (in this case Phe-tRNA).

It is possible to measure the peptidyl transferase activity of the large subunit in the absence of mRNA by using the antibiotic puromycin, which resembles the 3′ terminal region of Phe-tRNA in structure; as an artificial acceptor it forms methionyl puromycin with Met-tRNA$_f$, which can be assayed.

Elongation. The first peptide bond is formed when the aminoacyl tRNA in the ribosomal A site is converted into the corresponding methionyl-aminoacyl-tRNA by transfer of the methionyl (or *N*-formylmethionyl) residue from the charged initiator tRNA in the P site (Fig. 10c). In artificial cell-free systems, any *N*-substituted aminoacyl tRNA, such as peptidyl tRNA or *N*-acetylaminoacyl-tRNA, can function in peptide bond synthesis as a donor in the P site in place of the charged initiator tRNA. The reaction is catalyzed by the peptidyltransferase activity of the large ribosomal subunit (see Fig. 11). No soluble cofactors appear to be involved, but monovalent cations (K^+) at a concentration of 100 mM or more and divalent cations (Mg^{2+}) below 2 mM are required.

Efficient entry of aminoacyl tRNA into the ribosomal A site requires the participation of an elongation factor, termed EF-Tu in prokaryotes (see Table 4) and eEF-1 (EF-1A) in eukaryotes (see Table 5), and GTP. The appropriate elongation factor forms a ternary complex with GTP and all aminoacyl tRNAs except initiator

Tab. 4 Properties of prokaryotic elongation and termination factors from *E. coli*.

	M_r [kDa]	Properties and function
Elongation factors		
EF-Tu	43	N-terminal acetyl-serine; heat labile; binds aminoacyl tRNA to the ribosomal A site
EF-Ts	30	Heat stable; regeneration of EF-Tu-GTP
EF-G	77	GTP-dependent translocation of peptidyl-tRNA and its mRNA codon from the A site to the P site.
Termination (release) factors		
RF1	36	Requires UAA or UAG codons for hydrolysis of peptidyl-tRNA
RF2	38	Requires UAA or UGA codons for hydrolysis of peptidyl-tRNA
RF3	46	Enhances RF1 and RF2 activity

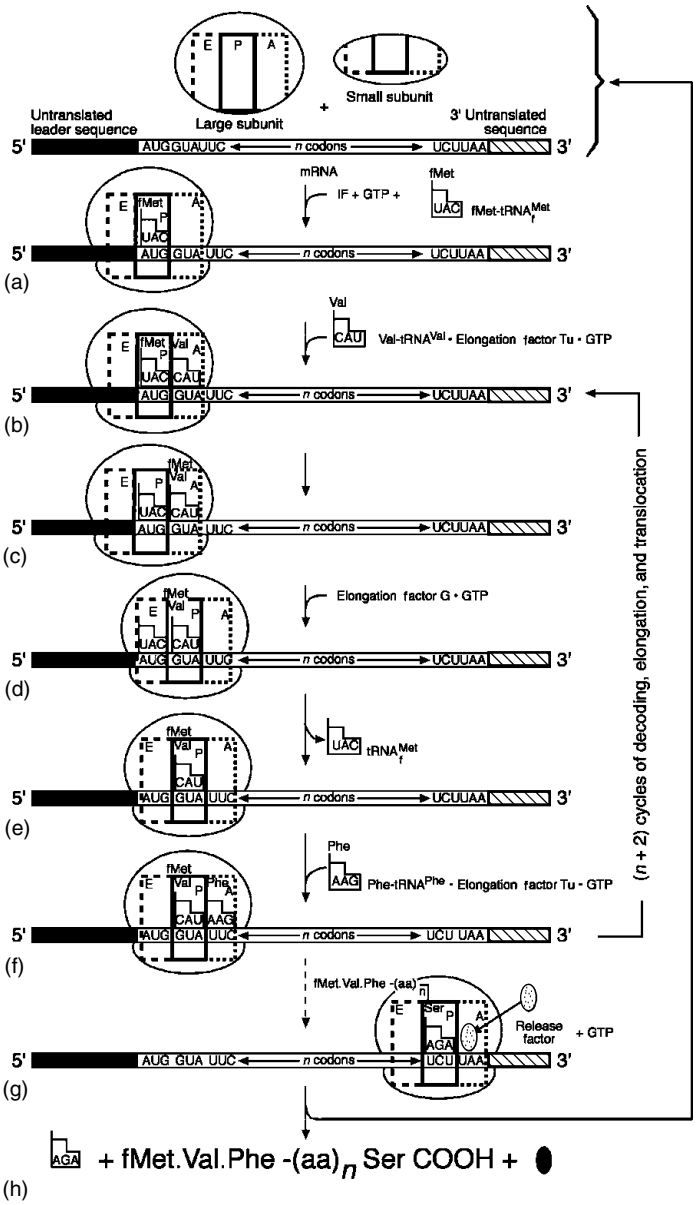
tRNA, but not with uncharged tRNA, thus ensuring that only appropriately charged tRNAs are efficiently bound in the A site. A special elongation factor showing extensive homology with both EF-Tu and IF-2 is involved in the synthesis of selenoproteins (see Sect. 2.4.1) from selenocysteyl-$tRNA^{UCA}$ in *E. coli*.

The above-mentioned aminoacyl tRNA binding reaction catalyzed by EF-Tu is the



rate-limiting step in the elongation cycle; peptide bond formation and translocation are much faster. The initial binding of the ternary complex to the ribosome is readily reversed, but the interaction is stabilized by the subsequent codon recognition, which induces the GTPase conformation of EF-Tu leading immediately to the hydrolysis of the GTP component of the ternary complex to GDP. Hydrolysis of the GTP moiety causes a further change in the conformation of EF-Tu from the GTP-binding to the GDP-binding form. This conformational change leads to the release of aminoacyl tRNA, allowing its CCA end to align with the peptidyl transferase center of the ribosome and the instantaneous formation of the peptide bond. The elongation factor is later released from the ribosome as a complex with GDP. The operation of EF-Tu is thus similar to that of initiation factor 2 which binds charged initiator tRNA to the small ribosomal subunit. The kinetic changes and the changes in ribosome structure that accompany these events are enumerated below (see Sect. 4.3).

Following dissociation from the ribosome, the EF-Tu–GDP complex interacts with another elongation factor, EF-Ts,

The position shown is reached by repeating the cycle $n + 2$ times after formation of fMet.Val-tRNA. (h) Release of the completed polypeptide, fMet.Val.Phe-$(aa)_n$Ser COOH, ribosomal subunits, release factor, mRNA and $tRNA^{Ser}$. The cycle may be repeated starting at (a).

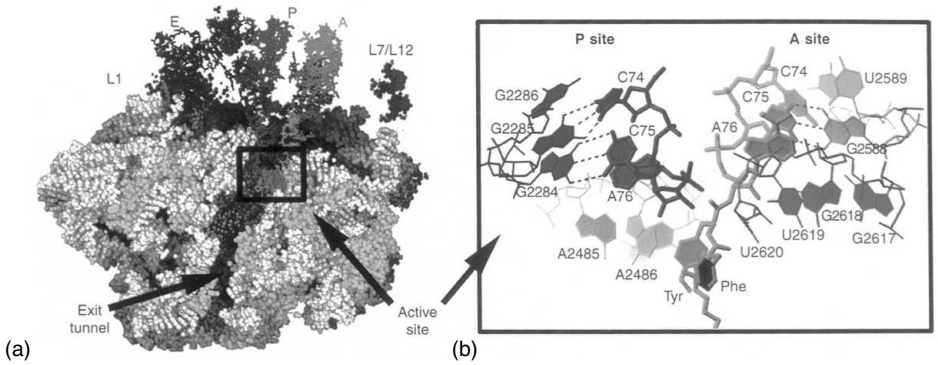

Fig. 11 Fine structure of the peptidyl transferase center interactions of the CCA ends (C74, C75, and A 76) of aminoacyl tRNA and peptidyl-tRNA with the rRNA moiety of the large subunit. Aminoacyl tRNA was represented by a C74 puromycin derivative of tRNA and peptidyl-tRNA was represented by CCA-phenylalanine-caproic acid-biotin. When these model compounds were bound to the A and P sites respectively, the large subunit catalyzed the formation of a peptide bond leading to newly extended peptidyl-tRNA (C74 puromycin–phenylalanine-caproic acid-biotin) in the A site and a deacylated tRNA in the P site. (a) a space filling representation of the 50S subunit (RNA in white and protein in yellow). The tRNAs in the A (green), P (purple), and E (brown) sites are placed according to the structure of the complete ribosome. The subunit has been split though the tunnel and the front section was removed to reveal the peptidyl transferase center (boxed). (b) Base-pairing interactions of CCA sequences of tRNA with 23S rRNA. The analog of deacylated tRNA (purple) is bound to rRNA through base pairing between C74 with G2285) and C75 with G2284. The analog of the newly formed peptidyl-tRNA is bound through base pairing between C75 and G1588. [From Schmeing, et al. (2002) A pretranslocational intermediate in protein synthesis observed in crystals of enzymatically active 50S subunits, *Nat. Struct. Biol.* **9**, 225–230. With permission.] (see color plate p. xxxiii).

with formation of an EF-Tu–EF-Ts heterodimer and release of GDP. Reaction of the heterodimer with GTP regenerates the EF-Tu–GTP complex required for binding aminoacyl tRNA. The sequence of events is similar in eukaryotes with eEF-1A (M_r 50 000) corresponding to EF-Tu and eEF-1B (M_r 30 000) to EF-Ts.

Selection of the specific aminoacyl tRNA to be bound at the ribosomal A site is by base pairing between the relevant mRNA codon and the tRNA anticodon. Because this interaction involves only a triplet of bases and hence a maximum of nine hydrogen bonds (see Fig. 1B), it is intrinsically unstable at physiological temperatures and is stabilized by a network of interactions with 16S rRNA in the decoding site where bases of 16S rRNA interact with the codon–anticodon complex. It is inferred that these interactions allow sufficient time for peptide bond synthesis to occur. Also, the codon–anticodon pairing must be monitored for fidelity in order to minimize errors in translation. In *E. coli*, there is genetic and biochemical evidence that one of the proteins of the small ribosomal subunit, S12, is involved in ensuring the fidelity of normal translation and in causing the mistranslation that occurs in the presence of the antibiotic streptomycin due to incorrect codon–anticodon interactions.

Translocation. Translocation involves the movement of the ribosome along the

mRNA in the 5′ → 3′ direction. Immediately after synthesis of the first peptide bond, the ribosomal A site contains dipeptidyl tRNA while uncharged initiator tRNA remains in the P site. Thus, both these sites are occupied, and to allow the next aminoacyl tRNA to enter the A site it is necessary to eject the uncharged tRNA and shift the dipeptidyl tRNA from the A into the P site. This translocation (Fig. 10d) takes place as a concerted process involving movement of both messenger RNA and dipeptidyl RNA together into the P site, leaving the A site occupied by the next mRNA codon and free to accept the cognate aminoacyl tRNA (see Fig. 10e). At the same time, the deacylated tRNA moves first into an E (exit) site with subsequent ejection when the next aminoacyl tRNA enters the A site.

Translocation requires the participation of another elongation factor (EF-G in prokaryotes (Table 4) and EF-2 in eukaryotes (Table 5)) and GTP. It seems that when EF-G and GTP bind to the ribosome, translocation occurs but GTP hydrolysis is required only subsequently to release EF-G and GDP. The location of the EF-G binding site of the ribosome overlaps with that for EF-Tu; thus, EF-G must be released before EF-Tu–aminoacyl-tRNA–GTP complex can enter the A site. Analogous reactions occur in eukaryotic systems. The kinetic steps involved in translocation and the structural changes that take place are described below (Sect. 4.3).

After translocation, the ribosomal P site is occupied by dipeptidyl tRNA and the vacant A site contains the third mRNA codon. Entry of the next aminoacyl tRNA, selected as before by the codon–anticodon interaction into the A site (Fig. 10f) enables peptide bond synthesis to continue and repeated operation of the elongation–translocation cycle gives rise to a stepwise elongation of the nascent polypeptide chain, each complete cycle elongating the chain by one amino acid residue and moving the mRNA by one codon in the 5′ to 3′ direction. When the end of the coding sequence is reached, one of the termination (or stop) codons has entered the A site, translation stops, and the completed polypeptide chain is released.

Termination. (See Figs. 10g-h.) The presence of one of the three termination codons, UAA, UAG, or UGA, in the A site results in the binding of a release factor (Table 4) instead of an aminoacyl tRNA to the ribosome. In prokaryotes, two release factors have been identified, one (RF1) recognizing UAA and UAG, the other (RF2) functioning with UGA. Ribosomal binding and release of RF1 and RF2 are stimulated by a third factor, RF3, which interacts with GTP and GDP. In eukaryotic cells, such as reticulocytes, one release factor (eRF) has been found to function with all three termination codons, and the binding of this factor to ribosomes is stimulated by GTP but not GDP. Although the details are not entirely clear, GTP hydrolysis appears to be required for the release of the finished polypeptide chain by cleavage of the peptidyl tRNA bond and completion of the termination process leading to dissociation of the release factor from the ribosome.

Thus, at the end of the ribosome cycle, the coding sequence of messenger RNA has been translated to produce a particular polypeptide chain, and all the components involved become available for reuse in another round of the cycle (Fig. 10h). Usually, several ribosomes, each at a different stage in completing the process of translation, are attached to one mRNA molecule, giving rise to polyribosomes (also called *polysomes*; Fig. 7). In eukaryotic

cells, the efficiency of protein synthesis is stimulated by factor eIF4-G (Table 3), which interacts with both factor eIF-4E and a poly A-binding protein to link the 5′ and 3′ ends of mRNA. The resultant circularized polysomes show an enhanced ability to reinitiate after release of the ribosomal subunits from the messenger RNA at the end of a round of translation.

4.3 High-resolution Structural Studies of the Ribosome

Early structural studies based on electron microscopy provided sufficient information to allow the construction of static models showing the location of mRNA and the relative orientations of the ribosomal subunits (Fig. 8). The modern technique of high-resolution cryo-electron microscopy (cryo-EM) has provided views of the ribosome at a level of resolution (0.9 nm) approaching that achieved by X-ray diffraction studies. Although prokaryotic ribosomes are the principal subjects of structural studies because they are simpler than eukaryotic ribosomes, the insights into structure and function are thought to apply to all ribosomes.

During the last 10 years, X-ray diffraction studies have led to considerable advances in the elucidation of the structure of the ribosome in more detail, culminating in the determination of the *E. coli* ribosome at 0.78-nm resolution and of the small and large subunits at resolutions of 0.30 and 0.25 nm respectively. The structures have revealed the identity of each amino acid and each nucleotide. The findings provide insights at the atomic level into the reactions leading to the decoding of mRNA and the formation of the peptide bond (Fig. 11). Moreover, the importance of the role of rRNA in ribosome function has become evident from the structures; the functional regions of both small and large subunits are rich in RNA. The peptide bond is formed by nucleophilic attack on the ester carboxyl group of peptidyl tRNA bound to the site by the α-amino group of aminoacyl tRNA in the A site. Peptide bond formation is catalyzed by the peptidyl transferase center of the large subunit of the ribosome. Structural studies confirm that this catalytic site comprises 23S rRNA sequences only. The location of the peptidyl transferase center and the role of the CGA ends of tRNA are illustrated in Fig. 11. The three-dimensional structures also highlight the dynamic aspects of ribosome function leading to the view that the ribosome is a highly sophisticated motor driven by GTP with rRNA playing a leading role.

The first of the two GTP requiring steps is the delivery of aminoacyl tRNA to the A site of the ribosome. The distinct kinetic steps involved as the ternary complex of aminoacyl tRNA, EF-Tu and GTP binds to the ribosome are illustrated in Fig. 12 and the conformational changes that have been found to take place are depicted in Fig. 13. Please note that one molecule of GTP is converted to GDP irrespective of whether peptide bond formation ensues. The peptide bond is formed soon after the selection of the aminoacyl tRNA (the accommodation step in Fig. 12), leading to the newly formed and extended peptidyl tRNA residing in the A site. The second GTP requiring step then follows; namely, translocation of aminoacyl tRNA from the A site to the P site of the ribosome. The kinetically resolved stages of the translocation are shown in Fig. 14 and the conformational changes so far identified are illustrated in Fig. 15.

The ribosome also influences the secondary and tertiary structure (folding)

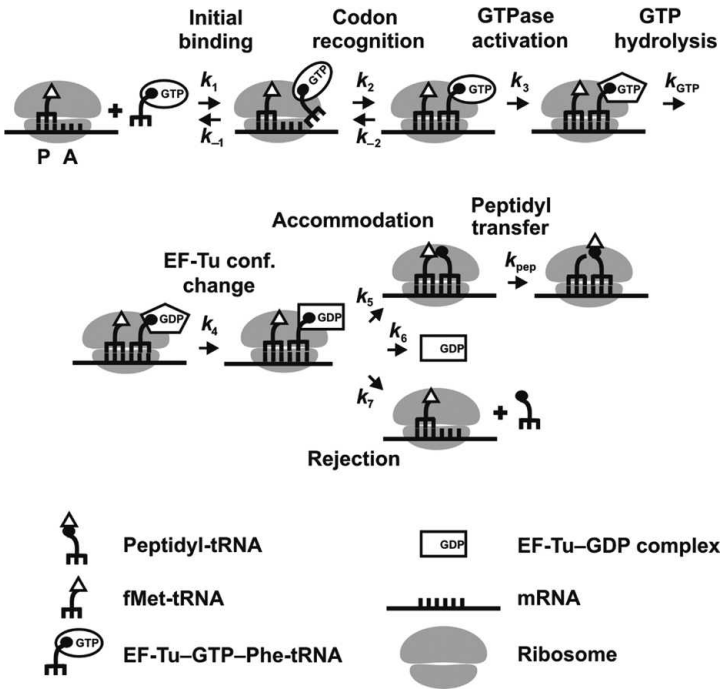

Fig. 12 Kinetically resolved stages in the interaction of ternary complex of aminoacyl tRNA●EF-Tu●GTP with the A site of the ribosome. Individual steps are shown by the numbered rate constants and by k_{GTP} and k_{pep}. The factor EF-Tu is shown in different conformations in GTP and GDP bound states and in the activated GTPase state. The ribosome is able to distinguish between cognate aminoacyl tRNA (for example, with anticodon 3′AAG 5′) and near cognate aminoacyl tRNA (for example, with anticodon 3′GAG 5′): this ability is called proof reading. [From Gromadski, K.B., Rodnina, M.V. (2004) Streptomycin interferes with conformational coupling between codon recognition and GTPase activation on the ribosome, *Nat. Struct. Mol. Biol.* **11**, 316–322. With permission.]

of the nascent polypeptide chain during its passage through the 10-nm long × 1 to 2 nm-diameter tunnel that is present in the large ribosomal subunit (Fig. 16). The wall of the tunnel comprises nucleotides of 23S rRNA and nonglobular parts of two ribosomal proteins, L4 and L2; proteins L23 and L29 flank the exit from the tunnel. Thus, the nascent polypeptide chain passes through an environment that influences the way in which it folds. As nascent polypeptide chains emerge from the tunnel, they are free to encounter molecular chaperones that prevent accumulation and aggregation of newly synthesized proteins. For example, the chaperone Trigger factor (TF) has a binding site involving protein L23 close to the exit of the tunnel. Signal recognition particles that convey secretory and transmembrane proteins to their appropriate destinations have bonding sites near to the exit of the tunnel in the regions of proteins L23 and L29.

The higher resolution studies of subunits have also revealed the mode

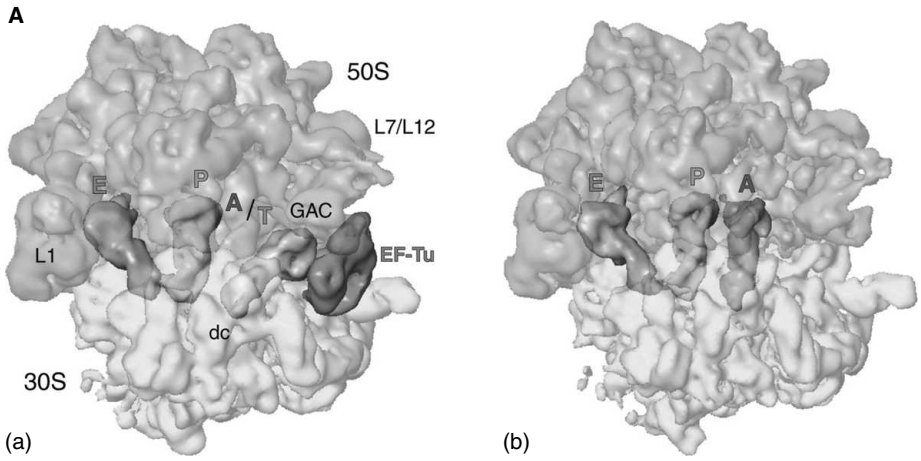

Fig. 13 Cryo-electron microscopy maps showing the incorporation of aminoacyl tRNA into the A site of a bacterial ribosome at a resolution of 0.9 nm and a conformational change in the GTPase-associated center. **A** The location of the binding site for the ternary complex of Phe-tRNA^{Phe}•EF-Tu•GDP-Kir. (a) The antibiotic Kirromycin (Kir) binds to the ternary complex and prevents dissociation of EF-Tu•GDP-Kir from the ribosome after GTP hydrolysis. The stalled complex is located below the L7/L12 stalk of the 50S subunit. EF-Tu is in red and A/T site tRNA is in pale pink. (b) Structure of the ribosome after peptide bond formation. The P site contains tRNA$_f^{Met}$ and the A site contains fMet•Phe-tRNA^{Phe} which is shown in magenta. In both panels, the ribosomal subunits are rendered semitransparent to illustrate the densities for tRNAs in the ribosomal intersubunit space. The sites for the tRNAs are labeled as follows: A/T, A/T site for the aa-tRNA bound to EF-Tu, reaching the decoding site in the A site of the 30S ribosomal subunit; A, aminoacyl site; P, peptidyl site; E, exit site. The P site tRNA is green, the E site tRNA is orange. **B** Conformational change in the GTPase-associated center of the 50S subunit. The cryo-electron microscopy maps show; (a) fMet-tRNA$_f^{Met}$ bound to the P site of the ribosome with a vacant A site; (b) fMet-tRNA$_f^{Met}$ in the P site and Phe-tRNA^{Phe}•EF-Tu•GDP-Kir complex with the A/T site between tRNA colored pink and EF-Tu colored red. The arrow indicates the site at the base of the L7/L12 stalk, which undergoes a conformational change during the binding of the ternary complex; (c) tRNA$_f^{Met}$ bound in the P site and fMet•Phe-tRNA^{Phe} bind in the A site. Insets (b) and (c) focus on the conformational changes of the GTPase-associated center. The view from the intersubunit space allows the movement of the GTPase-associated center to be observed. The E site is shown in orange; (d) Superposition of the 50S ribosomal subunits from the ribosome bound with the stalled ternary complex (semitransparent blue) and from the ribosome bearing a dipeptidyl-tRNA in the A site (solid red). Ribosomal subunits are blue (50S subunit) and yellow (30S subunit). Features of the large ribosomal subunit: L7/L12, stalk of proteins L7/L12 from the 50S ribosomal subunit; GAC, GTPase-associated center; SRC, sarcin-ricin loop; L16, ribosomal protein L16; L1, stalk of ribosomal protein L1. Features of the small ribosomal subunit: h, head of the 30S subunit; dc, decoding center. [From Valle, M., Zavialov, A., Li, W. et al. (2003) Incorporation of aminoacyl tRNA into the ribosome as seen by cryo-electron microscopy, *Nat. Struct. Biol.* **10**, 899–906. With permission] (see color plate p. xxxvii).

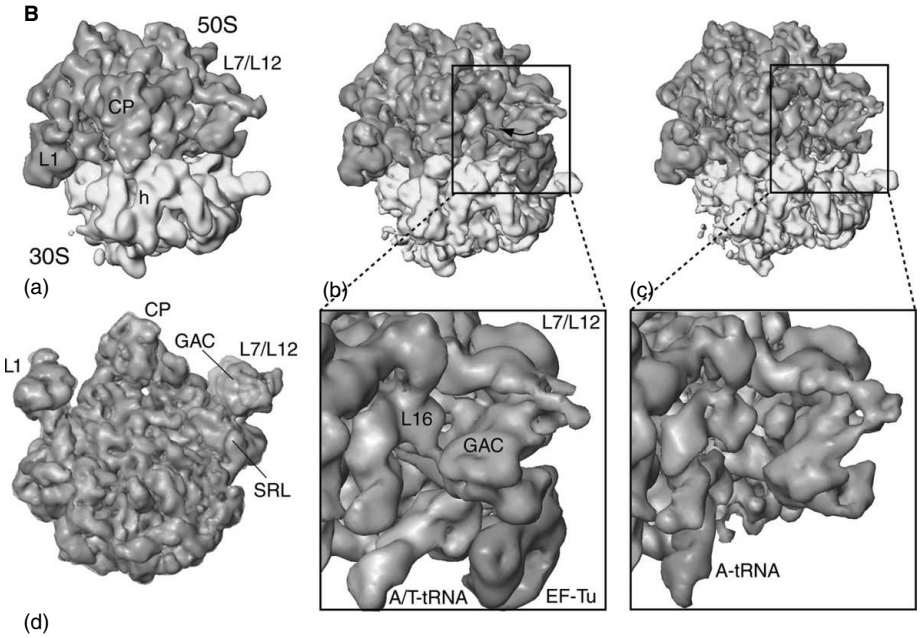

Fig. 13 (*Continued*)

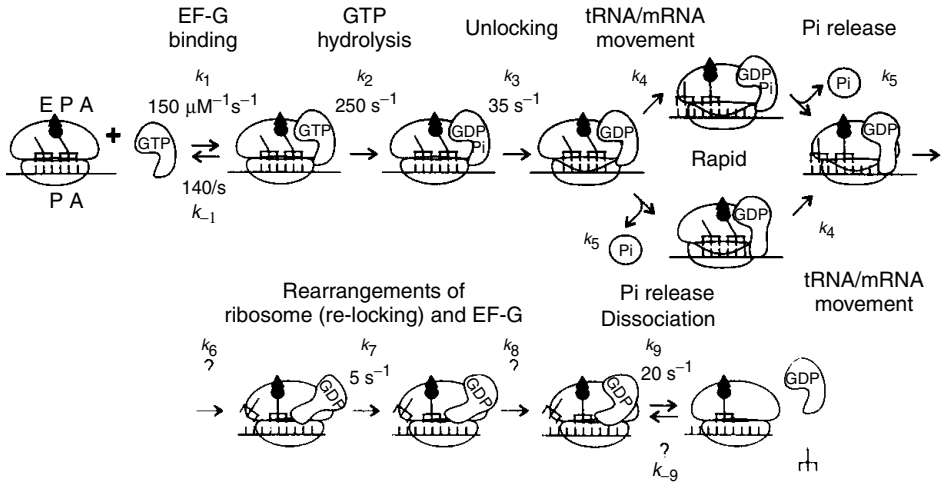

Fig. 14 A kinetic model of translocation. The diagram indicates several steps identified by several biochemical and rapid kinetic techniques. Ribosomes are shown in two conformations, closed and open. In the closed or locked conformation, bound tRNAs interact extensively with the ribosome. These interactions need to be disrupted to allow translocation (the open or unlocked conformation) and to be reestablished (relocked) after translocation. EF-G is shown in different conformations and orientations based on cryo-electron microscopy (see Fig. 5). [Reproduced from Peske, F., Savelsbergh, A., Katunin, V.I., Rodnina, M.V., Wintermeyer, W. (2004) Conformational changes of the small ribosomal subunit during elongation factor G-dependent tRNA-mRNA translocation, *J. Mol. Biol.* **343**, 1183–1194. With permission].

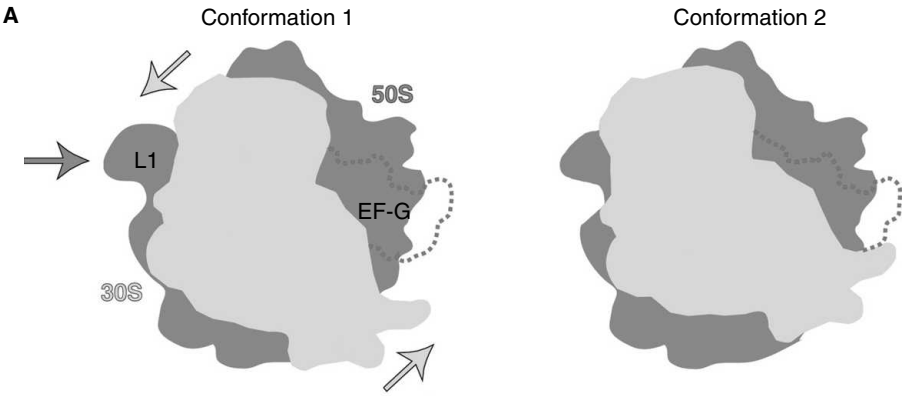

Fig. 15 Changes detected by cryo-electron microscopy (1.75–1.84 nm resolution) in the conformation of ribosomes during translocation. (A) After the peptide bond is formed, deacylated tRNA is located in the P site with peptidyl tRNA in the A site (conformation 1), the translocational state. A ratchet-like motion follows when EF-G●GTP is bound to the ribosome leading to conformation 2. The conformational change involves a counterclockwise rotation of the 30S subunit with respect to the 50S subunit with the L1 stalk moving in the direction opposite to the head of the 30S subunit. The outline of EF-G is shown by the dotted line. (B) Conformational changes in the L7/L12 stalk and in EF-G during translocation. The figures show that EF-G (shown in red) links the decoding site with the L7/L12 stalk. The cryo-electron microscopy maps shown in (c) and (d) correspond to conformation 2 in (a) with deacylated tRNA in the P site and peptidyl-tRNA in the A site and EF-G●GTP bound to the ribosome. The L7/L12 stalk (shown on the right of the dotted line) is bifurcated. Part of EF-G is shown close to the A site (marked A in (c)). A third conformation is observed after hydrolysis of GTP to GDP and before EF-G●GDP is released from the ribosome as shown in (a) and (b). In this conformation, the stalk is extended but not bifurcated and part of the EF-G is implicated in an arclike structure. The pretranslocational state is regained (see (a)) when EF-G●GDP is released from the ribosome. At the end of the translocation process, tRNAs in the A and P sites are transferred to the P and E sites, respectively, with the concomitant advance by one codon of mRNA. The insets show the appropriate orientations of the ribosome with 30S subunits and 50S subunits colored yellow and blue respectively. Features of the 30S subunit: b, body; h, head; sp, spur; ch, channel. Features of the 50S subunit: cp, central protuberance; L1, L1 protein; st, L7/L12 stalk. (A was reproduced from, Gas, A., Valle, M., Ehrenberg, M. and Frank, J. (2004). Dynamics of EF-G interaction with the ribosome explored by classification of a heterogenous cryo-EM dataset J. Structural Biol. **147**, 283–290. B was reproduced from Agrawal, R.K., Heagle, A.B., Penczek, P., Grassucci, R.A., Frank, J. (1999) EF-G dependent GTP hydrolysis induces translocation accompanied by large changes in the conformation of the 70S ribosome, *Nat. Struct. Biol.* **6**, 543–647. With permission) (see color plate p. xxxix).

of action of several antibiotics such as paromomycin, streptomycin, and spectinomycin, which modify the decoding function of the small subunit, and chloramphenicol, puromycin, and vernamycin, which affect peptide bond formation.

5 Translational Control of Gene Expression

Cells need to synthesize specific proteins in the required amounts at particular times and to deliver them to the correct locations.

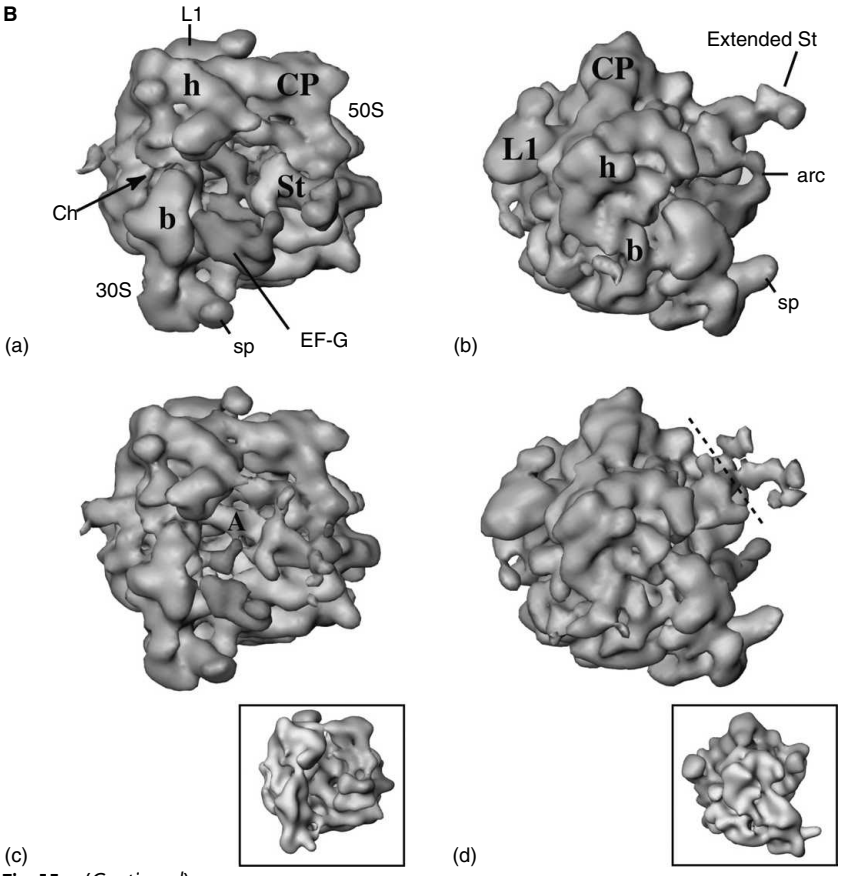

Fig. 15 (*Continued*)

These processes depend on a great many interactions and numerous mechanisms exist for the translational control of gene expression. Examples of the ways used by cells to control the translation of mRNA are presented in the sections that follow. This material is intended to be illustrative rather than comprehensive, and it is to be expected that novel control mechanisms will continue to be discovered.

5.1 mRNA Stability

Provided all other components of the translational systems are present in optimum amounts, control of translation may be achieved through the availability of the relevant messenger RNAs at the site of protein synthesis. The steady state level of mRNA is determined by the rate of its synthesis and degradation. Control of transcription is of major importance for synthesis in both prokaryotes and eukaryotes. The stability of mRNA depends on its primary and secondary structure as well as on the presence of factors such as stabilizing proteins and nucleases.

The secondary structure of mRNA is determined by its nucleotide sequence. For any mRNA, a number of coding sequences are possible because of the degeneracy

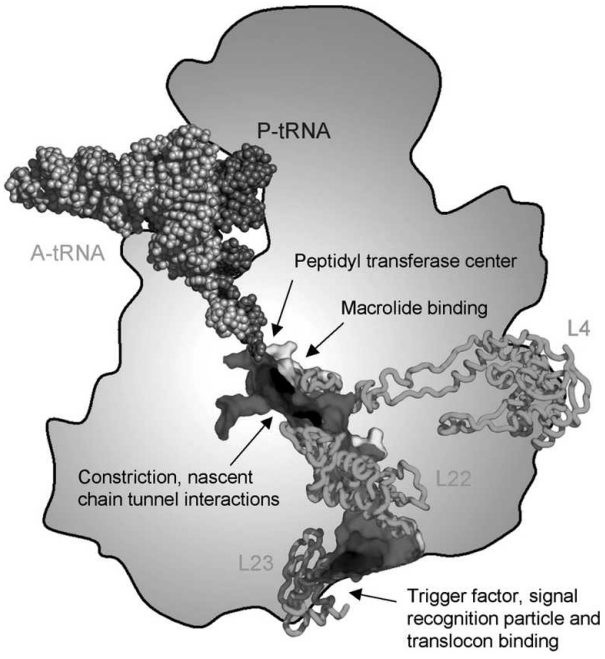

Fig. 16 Protein synthesis and the path of the nascent chain through the ribosome exit tunnel. The contour of the large ribosomal subunit is shown in gray. The aa-tRNA and pept-tRNA are represented by spheres, colored copper, and gray respectively. Ribosomal proteins L4, L22, and L23 are shown as green ribbons. The surface of the ribosomal exit tunnel corresponds to the empty space in the 50S subunit, which is sliced on the side. The surface is colored yellow outside and blue inside. The acceptor stems of aa-tRNA and pept-tRNA point toward the PTC, where peptide bond formation occurs. Nascent polypeptides escape the ribosome through the tunnel. They have to pass the narrow constriction where ribosomal proteins L4 and L22 contact the wall of the tunnel. This region is a target of antibiotics and the site of regulatory interactions between nascent chains and the tunnel. Ribosomal protein L22 mediates the interaction between nascent chains and the tunnel. Ribosomal protein L23 mediates the interaction between nascent chains emerging from the ribosome and cytosolic chaperones such as Trigger Factor (TF) and protein targeting factors such as Signal Recognition Factor (SRFF) and translocons. [From Jenni, S., Ban, N. (2003) The chemistry of protein synthesis and voyage through the ribosomal tunnel, *Curr. Opin. Struct. Biol.* **13**, 212–219. With permission] (see color plate p. xlii).

of the genetic code. Thus, degeneracy allows for particular features of secondary structure (often termed *cis* factors) to be favored, which may act either to stabilize or destabilize the mRNA, according to the needs of the cell, by determining its susceptibility to degradative enzymes (often termed *trans*-acting factors).

Whereas the structure of mRNA determines its susceptibility to degradative enzymes, the detailed mechanisms are complex. In prokaryotes, the enzymes involved include two endonucleases (RNase E and RNase III) and two exonucleases (polynucleotide phosphorylase and RNase II). Other nucleases may be active in particular cases such as phage infection. In eukaryotes, a major pathway involves the removal of the 3′ poly(A) tail (deadenylation), followed by removal of the 5′ cap, which renders the mRNA susceptible to rapid endonucleolytic degradation in the $5' \rightarrow 3'$ direction.

5.2 Control by Interaction of Proteins with mRNA

Throughout the ribosome cycle, dynamic protein-mRNA interactions are functionally important in the initiation, elongation, and termination of polypeptide synthesis. In addition, more stable associations between proteins and mRNAs have been observed, particularly in eukaryotic cells. These messenger ribonucleoprotein complexes (mRNPs) occur both in polyribosomes and free in the cytosol, some of the latter being either temporarily or permanently unavailable for translation. Thus, protein-mRNA interactions contribute to the efficiency with which mRNAs are translated. Some proteins, such as the poly(A)-binding protein (p78), are present in most if not all mRNPs, whereas others appear to be cell specific and mRNA selective. In unfertilized sea urchin eggs and *Xenopus* oocytes, for example, untranslated messenger is sequestered by association with proteins that prevent translation until later stages of development. Duck reticulocytes contain globin mRNP, which cannot be translated *in vitro*, whereas the mRNA obtained by deproteinizing the complex can be translated, showing that in this case translation is prevented by the mRNP proteins.

Formation of a site-specific mRNA-protein complex is involved in the translational control of the biosynthesis of ferritin, an iron storage protein, which is stimulated in response to the presence of iron. In this instance, a cytoplasmic repressor protein of 85 kDa binds to a highly conserved 28-nucleotide stem-loop structure in the 5′ untranslated region of ferritin mRNAs in the absence of iron. In the presence of iron, the protein dissociates from the mRNA, which is then available for translation. A similar loop motif occurs in the 3′ untranslated region of transferrin receptor mRNA, which is also subject to translational control by an iron-responsive repressor.

During the cell cycle, histone mRNA is destabilized after completion of DNA replication, resulting in a 30- to 50-fold decrease. This change appears to be due to an increase in the level of free histones, which form a complex with histone mRNA by interaction with a stem-loop structure at the extreme 3′ terminus. Formation of this histone–histone mRNA complex is thought to activate a ribosome-associated $3' \rightarrow 5'$ exonuclease, which degrades the histone mRNA. During the S phase, newly synthesized DNA binds free histones to form nucleosomes, thus preventing the degradation of histone mRNA at this stage of the cell cycle.

Specific regulation of gene expression at the level of translation also exists in prokaryotes. For example, the synthesis of *E. coli* threonyl-tRNA synthetase is negatively autoregulated by an interaction of the tRNA-like leader sequence

of its mRNA with the synthetase that inhibits translation by preventing the binding of ribosomes. The synthetase is displaced from the mRNA by $tRNA^{Thr}$, which thus acts as a translational antirepressor. This regulatory mechanism allows the cell to maintain a balance between the tRNA synthetase and its cognate tRNA.

Similarly, there is a mechanism used to control the synthesis of proteins encoded by a polycistronic mRNA. In this case, selective binding of the ribosomal protein to the region of the mRNA involved in the initiation of translation leads to the regulatory protein controlling both its own synthesis and that of other ribosomal proteins. A specific example is the role of ribosomal protein S4, which acts as a translational repressor of four ribosomal proteins (S4, S11, S13, and L17). Protein S4 appears to function as a repressor through an unusual "pseudoknot" linking a hairpin loop upstream of the ribosome-binding site with sequences 2 to 10 codons downstream of the initiation codon. (A pseudoknot structure contains intramolecular base pairs between base residues in the loop of a stem-loop structure and distal complementary regions of the RNA.) Stabilization of this structure by S4 would prevent the binding of ribosomes, and this control mechanism may contribute to the coordinated synthesis of the different ribosomal proteins required for ribosome assembly.

5.3 Control by mRNA Structure

The secondary structure of some eukaryotic mRNAs regulates translation by a mechanism involving a ribosomal frameshift which gives rise to a directed change of the translational reading frame to allow the synthesis of a single protein from two or more overlapping genes by suppression of an intervening termination codon. Several retroviruses use this mechanism to move from one reading frame to another in the expression of the viral RNA-dependent DNA polymerase. Other examples of the operation of such a frameshift include the synthesis of the reverse transcriptase enzymes of several retrotransposons, such as the yeast Ty1. The mechanism of changing the reading frame involves "slippery" sequences and a complex folding of the mRNA into a structure termed a *pseudoknot*.

In *E. coli* phages, translational control of the three cistrons of Q_β, f2, and related bacteriophage RNAs (Fig. 17) accounts for the synthesis of coat protein:replicase:A protein in the approximate ratio of 20 : 5 : 1. These quantitative differences are due to the differential and independent initiation of translation at each cistron as a result of differences in the secondary structure of the mRNA initiation sites. Furthermore, *in vivo* there is a delay in the synthesis of coat protein and this temporal control involves translational repression of the cistron by ribosomal protein S1. In addition, S1 functions as one of the subunits of the f2 RNA replicase; therefore, association of the newly synthesized translation product of the f2 replicase cistron with S1 will favor its dissociation from the phage RNA, thus allowing translation of the coat protein cistron to start.

5.4 Control by Modification of Translation Factor Activity

5.4.1 Initiation Factors

In eukaryotes, initiation of protein synthesis is inhibited by phosphorylation of the initiation factor eIF-2. In particular cases,

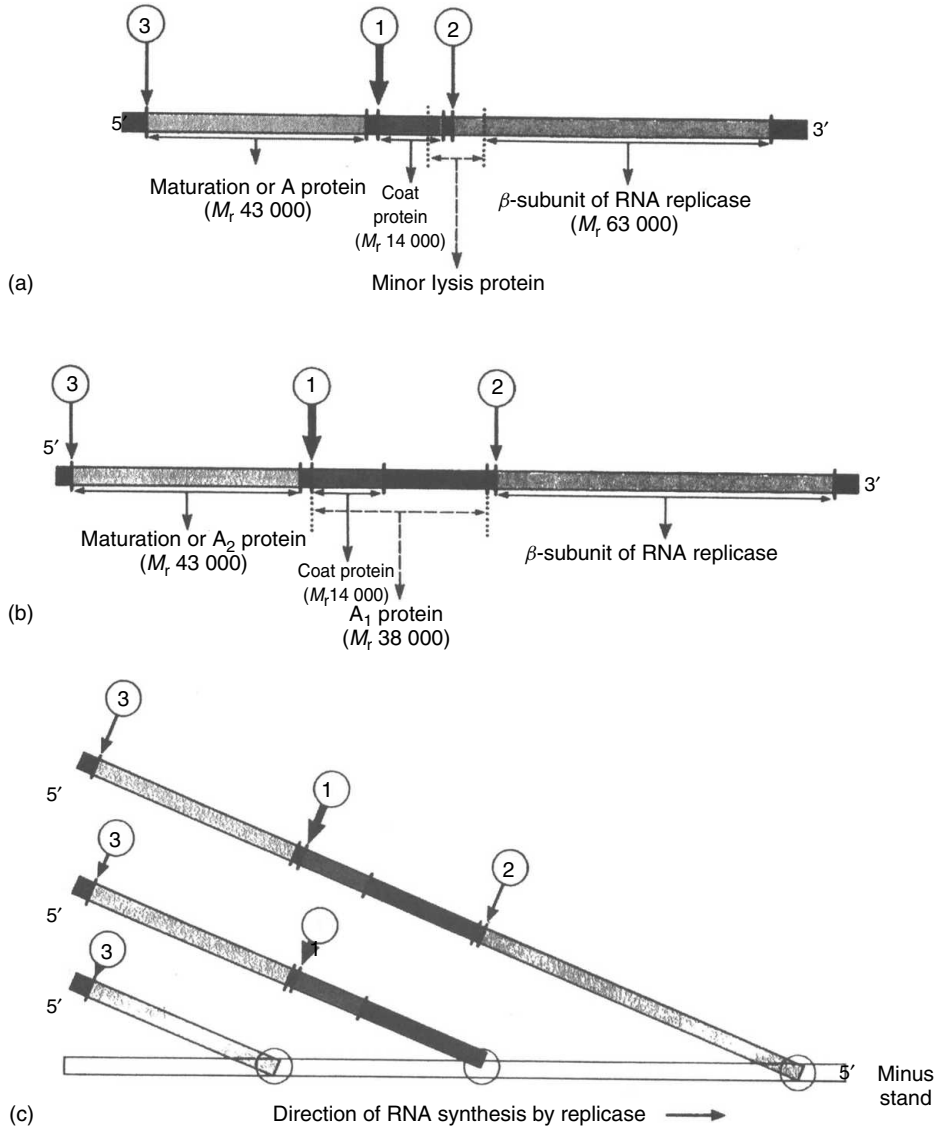

Fig. 17 Translational control of bacteriophage synthesis: (a) arrangements of MS2 and f2 bacteriophage cistrons, (b) arrangement of Q_β bacteriophage cistrons, and (c) replicative intermediate synthesizing new plus strands on the complementary minus-strand copy of the original bacteriophage RNA. The ribosome-binding sites (RBS) are indicated by the numbered arrows. The major RBS (1) binds ribosomes efficiently but can be blocked by ribosomal protein S1. The secondary RBS (2) becomes available only after translation of at least part of the coat protein cistron by ribosomes. RBS 3 is masked by the secondary structure of native bacteriophage RNA but is accessible in nascent RNA (c) or *in vitro* when the secondary structure is destroyed. Noncoding regions are shown in black. [Reproduced from Arnstein, H.R.V., Cox, R.A. (1992) *Protein Biosynthesis*, Oxford University Press, Oxford. With permission].

phosphorylation of eIF-2 is stimulated by a lack of heme or the presence of double-stranded RNA. Two different protein kinases capable of phosphorylating the α-subunit of eIF-2 have been characterized. One substrate, called the heme-controlled repressor (HCR) or heme-regulated inhibitor (HRI), is a cytoplasmic protein (95 000 Da) that is activated by phosphorylation. Double-stranded RNA activates phosphorylation of a 67 000-Da protein, which in turn phosphorylates eIF-2. Thus, a cascade of protein phosphorylation is involved. Phosphorylated eIF-2 is unable to exchange GDP for GTP, which prevents it from functioning in the binding of initiator tRNA to ribosomes.

Conditions other than lack of heme (e.g. heat shock, serum deprivation, or the presence of oxidized glutathione), which are known to inhibit protein synthesis, also stimulate the phosphorylation of eIF-2α. Conversely, the activity of eIF-4F is decreased by dephosphorylation of the 24-Da subunit (see Table 3) rather than by phosphorylation. Thus, a number of different kinases and phosphatases are involved in modulating the activities of different factors.

Small RNAs may also be involved in regulating the translation of mRNA in eukaryotic cells. Of the stimulatory RNAs, the best characterized is a small RNA of about 160 nucleotides, which accumulates in cells after infection with adenovirus. This virus-associated RNA, VA-RNA$_1$ sustains general protein synthesis by inhibiting the phosphorylation of the α-subunit of initiation factor eIF-2.

Two features of mRNA structure are implicated in several regulatory processes involving initiation factors, namely, the 5′ cap structure and a cytoplasmic polyadenylation element (*c*PE) located within the 3′ untranslated region. For example, embryonic cells have mRNAs that are stored until particular stages in development are reached. During storage, eIF-4E is thought to bind to the 5′ cap structure and a protein *c*PEB is bound to the *c*PE element; a third protein binds to both eIF-4E and *c*PEB. Similar nucleoprotein structures have been proposed to regulate the synthesis of key proteins during progression through the cell division cycle. Furthermore, eIF-2 and eIF-4E are targets for changing the patterns of protein synthesis associated with tumorigenesis. Phosphorylation of the α-subunit of eIF-2 (eIF-2α) regulates its activity. Phosphorylation of a small family of eIF-4E binding proteins (4E-BPs) regulates the binding of eIF-4E to eIF-4G. The activities of the appropriate kinases and phosphatases may, in turn, be controlled by cellular and viral oncogenes and tumor-suppressor genes.

A novel pathway for the initiation of translation has been found which permits initiation in a manner that is independent of the 5′ end of mRNA. Particular RNA sequences are involved, termed *internal RNA entry sites* (IRES). IRES elements have been found in both viral and cellular RNAs. The IRES elements intervene in the initiation of translation during cellular stress and during infection by viruses, for example, poliovirus or hepatitis C virus. The cricket paralysis virus RNA possesses an IRES element, which, in the absence of initiation factors and initiator tRNA, can bind to the P site and assemble 80S ribosomes. In this way, the reading frame is set so that the first codon is in the A site. The first translocation step takes place without a peptide bond being formed. However, aminoacyl tRNA is delivered to the P site so that chain elongation can

proceed normally. The cricket paralysis virus IRES bound to the small subunit and to ribosomes was visualized by cryo-electron microscopy.

5.4.2 Other Translation Factors

A Ca^{2+}/calmodulin-dependent protein kinase phosphorylates eEF-2. The phosphorylated factor appears to be inactive. Dephosphorylation of the factor by phosphatase restores its activity.

5.5 Effects of Antisense Polynucleotides

Antisense RNAs, which are polynucleotides with base sequences complementary to messenger RNAs, have been found in both prokaryotes and eukaryotes. Natural antisense RNAs are not common but synthetic RNAs directed at specific targets have been widely studied. It has been demonstrated that they can function as inhibitors of messenger RNA translation. In prokaryotes, the most effective inhibitors appear to have a base sequence complementary to the 5′ leader region, including the Shine–Dalgarno sequence, which is involved in the binding of mRNA to the small ribosomal subunit. In eukaryotes, translation of mRNA is inhibited by polyribonucleotides complementary to the 5′ untranslated region of mRNA, indicating a direct effect on initiation as in prokaryotes. Polynucleotides complementary to the 3′ untranslated region of mRNA also inhibit translation in some cells, and this effect may be due to destabilization of mRNA by ribonucleases specific for double-stranded RNA. The effect of antisense polynucleotides is not restricted to translation of mRNAs, but transcription as well as the processing of transcripts may also be inhibited.

5.6 Availability of Amino Acids, tRNA Abundance, and Codon Usage

5.6.1 Amino Acids

Polypeptide synthesis depends on an adequate supply of tRNAs charged with the 20 protein amino acids and appropriate interactions between their anticodons and the codons of mRNA. Peptide chain elongation is decreased or inhibited by lack of amino acids or other conditions giving rise to an imbalance or deficiency in aminoacyl tRNAs.

5.6.2 Abundance of tRNAs and Codon Usage

Different tRNAs are present in the cytosol in unequal amounts, and elongation rates are slower at codons corresponding to rare tRNA species. The existence of synonymous codons raises the question of preferential use of some codons and its possible significance in relation to translational efficiency and control. In some bacteria (e.g. *Pseudomonas aeruginosa*, which has a high content of G + C, 67.2%, in DNA), the most common codons are those with the strongest predicted codon–anticodon interaction – that is G + C base pairs – but this preference is not universal and, for example, does not apply to *E. coli*, which has a lower proportion of G + C (50%). Although codon usage may affect elongation rates, it is probably of less importance in translational control than the secondary structure of mRNA in relation to the rate of initiation of protein synthesis.

5.7 Modulation of Ribosome Activity

Specific ribosomal components have an important function in relation to the fidelity of protein synthesis. Thus, in *E. coli*

ribosomal protein, S12 determines the accuracy of codon–anticodon interactions and modulates the translational error frequency in the presence of the antibiotic streptomycin.

To what extent reversible modifications of ribosomal constituents are involved in translational control of protein synthesis is uncertain. Although phosphorylation of ribosomal protein S6 increases with cell proliferation, it is not known whether this change is directly related to the accompanying increase in protein synthesis by an effect on the translation rate.

5.8 Ribosome-inactivating Proteins

Many molds and plants produce toxins, which are protective agents, termed ribosome-inactivating proteins (RIPs), directed at particular cells and their ribosomes. These toxins are classified as either type I or type II RIPs according to the number of polypeptide chains.

Type I RIPs comprise a single polypeptide chain; for example, α-sarcin, an extracellular cytotoxin produced by *Aspergillus giganteus*, consists of a single chain of 150 amino acid residues.

Type II RIPs comprise two polypeptide chains, A and B. The A chain has the ability to inactivate ribosomes, and the B chain is a galactose-specific lectin responsible for the entry of the toxin into the target cell. Ricin, which is isolated from castor oil beans, is representative of type II RIPs.

Ribosomes are inactivated as a result of the RNA N-glycosidase activity of RIPs. These toxins have different specificities for particular cells and ribosomes. However, the target site for all RIPs is an adenylate residue (position 2660 in the *E. coli* 23S rRNA sequence) located within a highly conserved sequence of 12 nucleotides ($5'_{2654}$AGUACGAGAGGA$_{2665}3'$). Cleavage of the GpA$_{2660}$ internucleotide bond or depurination of A$_{2660}$ is sufficient to inactivate the ribosome. The target residue is located in the loop region of a stem–loop element of the secondary structure, which is termed the α-sarcin stem–loop. Thus, the target adenylate is either directly or indirectly essential for ribosome function. The α-sarcin stem–loop is known to be important for binding elongation factors EF-Tu and EF-G to the ribosome. RIPs have attracted interest as active components of reagents directed at particular targets such as cancer cells.

6 Concluding Remarks

The control of protein synthesis, either by regulation of the amount of mRNA available for translation or by the efficiency with which it is translated, is important in cell growth and development as a factor determining the level of cellular and extracellular proteins. Subversion of this control occurs in cells infected by viruses when the viral nucleic acid uses the protein-synthesizing machinery of the host cell and thereby changes normal cell metabolism in favor of the synthesis of viral proteins needed for the production of virus progeny.

The polypeptide chains of all proteins are synthesized by the process described above. This mechanism gives rise to primary polypeptide chains, which are often further modified; for example, by cleavage into smaller peptides, by structural modification of selected amino acid residues, by splicing of the polypeptide chain, or by the formation of covalent bonds between polypeptide chains. Some of these

secondary modifications are related to the correct folding of polypeptide chains and to the production of active enzymes or peptide hormones from inactive precursors (e.g. insulin from proinsulin). Also, the transport of proteins within the cell or the secretion of extracellular proteins is often linked to structural changes in polypeptide chains either during or after completion of synthesis.

Keywords

Diabetes Mellitus
Dysregulation of glucose and lipid metabolism in the course of reduced insulin secretion by pancreatic ß-cells and insulin action/sensitivity in muscle, adipose, and liver cells resulting in elevated blood glucose levels in the short term and diabetic late complications, atherosclerosis, and cardiovascular problems in the long term.

Hormone-sensitive Lipase
Hydrolase expressed in many cell types, which specifically cleaves mono/di/triacylglycerol in response to lipolytic stimuli, such as ß-adrenergic hormones, fasting, and muscle contraction.

Insulin
Major hormone regulating blood glucose and lipid homeostasis predominantly by inducing reesterification of postprandial glucose and free fatty acids to yield triacylglycerol for storage in lipid droplets predominantly in adipose tissue.

Lipid Droplets
Storage form of neutral lipids covered by a phospholipid monolayer and specific protein components involved in (regulation of) their synthesis and degradation.

Lipolysis
Enzymatic release of fatty acids and glycerol from mono/di/triacylglycerol stored in lipid droplets in many cell types.

Lipotoxicity
Impairment in responsiveness and sensitivity of insulin target cells (e.g. muscle, fat, and liver cells) toward insulin and of insulin-secreting β-cells toward glucose in the course of their prolonged exposure to elevated concentrations of fatty acids and intracellular accumulation of fatty acids in free and/or esterified form.

Translocation
Apparent movement of hormone-sensitive lipase from the cytoplasm to the surface of lipid droplets where cleavage of neutral lipids occurs in response to its stimulus-dependent phosphorylation.

Abbreviations

AA:	amino acid(s)
AC:	adenylate cyclase
AR:	adenosine receptor
α/β-AR:	α/β-adrenergic receptor
(M/D/T)AG:	(mono/di/tri)acylglycerol
DGAT:	acyl-CoA:diacylglycerol acyltransferase
DIGs:	detergent-insoluble glycolipid-enriched lipid raft microdomains
ER:	endoplasmic reticulum
(F)FA:	(free) fatty acids
H/LDL:	high/low density lipoprotein
HSL:	hormone-sensitive lipase

LD:	lipid droplets
LPL:	lipoprotein lipase
NA:	nicotinic acid
NEFA:	nonesterified fatty acids
NIDDM:	noninsulin-dependent diabetes mellitus
PDE:	phosphodiesterase
PI3K:	phosphatidylinositol-3-kinase
PKA/B/C:	protein kinase A/B/C
PP:	protein phosphatases
TNF-α:	tumor necrosis factor-α
VLDL:	very low-density lipoproteins
WAT:	white adipose tissue

A growing number of enzymes that are involved in lipid metabolic pathways are being identified and characterized. Here we summarize recent developments in the understanding of lipid storage and mobilization and assess the potential of lipid metabolic enzymes and mechanisms as targets for the pharmacological treatment of lipid disorders, noninsulin-dependent diabetes mellitus (NIDDM), obesity, and metabolic syndrome. We focus on enzymes and pathways that have been implicated in the biogenesis of lipid droplets and their degradation (lipolysis) on the basis of studies using (1) animal models that overexpress or harbor targeted deletions of the genes encoding the corresponding enzymes/proteins, (2) genetic and/or family studies of NIDDM and lipid disorders, and (3) modern biochemical/molecular biological methods for the identification and functional analysis of components involved in lipid metabolism.

1 Triacylglycerol and Energy Storage

Triacylglycerol (TAG) is the most concentrated form of energy available to biological tissues that emerged during biological evolution. For instance, the work covered by birds during their nonstop long-distance migrations is powered almost exclusively by fat reserves. The extra weight of carbohydrate required to produce the same calories would prevent the birds from ever taking off. In terms of human survival, the first unaided crossing of the polar ice cap was made possible by the very high butter-fat content of the 220-kg of food reserves transported by the sledges that were man-powered over the frozen wastes. The extra weight of a similar energy content as carbohydrate would have made this pioneering journey impossible in the short and medium terms. TAG also exhibits relatively low ''biological toxicity'' compared to FA (see below) and is well tolerated even at high concentrations in the blood plasma. TAG therefore provides a benign form of FA storage and transport. Before its use as an energy source, however, it must

undergo lipolytic mobilization to provide FA. The potent ''toxicity'' of FA in the long term requires a finely tuned regulatory mechanism that ensures that their release from TAG stores is correctly balanced by uptake and utilization. A number of clinical disorders of increasing incidence are associated with secondary hyperlipidemia affecting distinct lipoprotein subtypes via different mechanisms (Table 1).

Although the cells of most tissues synthesize TAG, only a few are adapted to store TAG in considerable quantity. Some, such as heart and skeletal muscle,

Tab. 1 Clinical disorders associated with secondary hyperlipidemia.

Disorder	***Lipoprotein type***	***Elevated plasma lipoprotein***	***Proposed mechanism***
Endocrine/Metabolic			
NIDDM	IV, V	VLDL, chylomicrons	VLDL production ↑ VLDL catabolism ↓
Hypothyroidism	IIa (III)	LDL (ß-VLDL)	LDL clearance ↓

store small quantities of TAG for their own use (albeit the fact that the heart has been recently shown to have low capacity for lipoprotein export). In other tissues, for instance, in the pancreatic ß-cells, TAG synthesis, storage, and lipolysis may be involved in the regulation of the production of molecules, such as DAG and FA(-derivatives), which participate in various signal transduction processes or in providing a source of FA committed to membrane phospholipid synthesis. In mammals, of course, adipose tissue is the most important storage pool of whole-body TAG and, consequently, the body's largest energy reservoir; for example, an adult with 15 kg of body weight has >460 MJ of TAG fuel stores, which could provide 8.37 MJ daily for 2 months. The primary role of adipocytes is to store TAG during caloric excess and to mobilize this reserve when expenditure exceeds intake. Mature adipocytes are uniquely equipped to perform these functions. They possess the full complement of enzymes and regulatory proteins needed to carry out both TAG storage and mobilization (see below). In adipocytes, the regulation of these processes is exquisitely responsive to hormones, cytokines, and other factors that are involved in energy homeostasis.

Nevertheless, the liver also has an important TAG storage function. These two tissues export a proportion of their mobilized TAG. FA are released from adipose tissue, and TAG is exported as very low-density lipoproteins (VLDL) from the liver. Both organs are connected via a metabolic cycle in which FA released from adipose tissue are the major substrates for hepatic VLDL production and, in turn, FA from TAG contained in VLDL are returned to adipose tissue by the action of lipoprotein lipase (LPL). In addition, TAG in adipose tissue represents the major source of plasma glycerol, which accounts for about 90% of the substrates for hepatic gluconeogenesis at fasted condition in rodents. Central to the control of this intertissue cycle between white adipose tissue (WAT) and liver is the regulation of TAG mobilization and release by both organs. The different cellular and molecular mechanisms involved in the regulation of TAG mobilization from the storage pools in each of these tissues reflect the importance of the different roles of the lipids and FA, which are exported.

FA stored within the TAG of adipose cells constitutes the vast majority of energy reserves in animals. While the TAG pool in adipocytes provides a reservoir of energy for times of prolonged restricted caloric intake, there is also a normal "acute" flux of FA into and out of adipose tissue in response to meals and other factors, such as insulin. TAG hydrolysis in adipocytes, termed lipolysis, contributes to the increased levels of plasma nonesterified fatty acids (NEFA) by two mechanisms, one direct and the other indirect. In the postabsorptive state or during starvation FA are normally released from adipocytes directly into the plasma and transported to various tissues where they serve as a source of energy. In the insulin-resistant state, this direct release of FA is exacerbated, because the reduction in the antilipolytic action of insulin (see below) leads to increased lipolysis and a consequent increase in the release of FA from adipocytes into plasma. In contrast to the postabsorptive direct FA release, there is an indirect effect of adipocyte lipolysis on FA release in the postprandial state. There is a normal postprandial influx into adipocytes of FA produced by LPL action on VLDL and chylomicrons in the adipose endothelium, and this influx depends on a favorable downhill FA concentration gradient across the

adipocyte plasma membrane. Again, this indirect effect is exacerbated in the insulin-resistant state, since the increased lipolysis and, in consequence, the increased intracellular FA concentration in adipocytes abrogate the FA concentration gradient required for influx of FA. Thus, in an indirect fashion, adipocyte lipolysis can increase plasma FA by reducing the postprandial influx of FA into adipocytes. Given the apparent interrelated contribution of the cellular and LPL-mediated lipolytic reactions in adipose tissue to the plasma NEFA pool, it is important to understand the molecular basis of TAG hydrolysis by these mechanisms.

1.1 Storage and Mobilization of TAG

The two key enzymes involved in TAG mobilization within adipose tissue are LPL and (hormone-sensitive lipase) HSL. The function of LPL in mobilizing FA from TAG contained in VLDL and chylomicrons in the capillary endothelium of adipose tissue is not so clear as originally thought. It is now becoming evident that a variable (and regulated) proportion of NEFA released by LPL from TAG-rich lipoproteins does not enter adipose tissue but ''leaks'' into the plasma compartment and that this proportion may be under metabolic control dependent upon the nutritional state. For instance, in the postabsorptive state and during starvation, very little, if any, NEFA derived from TAG of VLDL enter the adipose tissue. The major portion enters the blood plasma and supplements the HSL-mediated provision of NEFA to the periphery during this period. Any excess NEFA produced, which override the immediate oxidative capacity of energy-requiring tissues, are reesterified by the liver and stored as TAG or VLDL. The potential hazards of hyperlipidemia for the cardiovascular system in the postprandial state are now well established and accepted (Table 1). The liver may, thus, play a major protective role during this period by removing excessive NEFA from the circulation, temporarily storing them as a ''benign'' derivative, TAG, and secreting them later as VLDL when the period of maximum danger has passed. This protective function may prove to be yet another facet of the liver's more general role as a front-line defense to protect body tissues from the potentially dangerous but inevitable consequences of major and abrupt physiological transitions. In this way, the liver may act as an essential (storage) buffer by which the supply of and demand for adipose tissue FA are matched in a way that does not result in or neutralize the potential FA-induced ''lipotoxicity'' to peripheral tissues.

1.2 Lipolysis and Reesterification

Adipocytes are highly differentiated cells specialized in handling large quantities of long-chain FA (Fig. 1). During lipid storage in the fed state, FA are released by LPL bound to the endothelial capillary wall into the blood from chylomicrons and lipoproteins assembled and secreted by intestinal and liver cells, respectively (step 1), or from albumin, move through the endothelium via passage through tight junctions or endothelial cells (step 2), bind to the outer leaflet of the plasma membrane of the target cells, and cross the membrane bilayer by simple diffusion or protein-mediated transport (step 3). While the direct involvement of FA not bound to albumin in FA uptake by adipocytes is generally accepted, it is still debated whether,

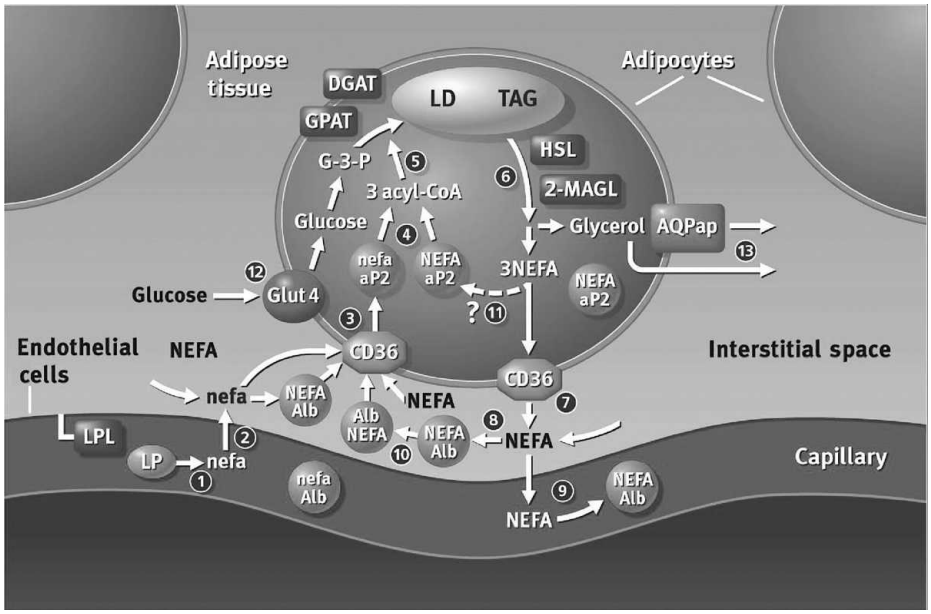

Fig. 1 Working model of FA reesterification and its control by the efficacy of removal of newly released NEFA from the interstitial space into the circulation. Elevation/reduction of the blood flow would decrease/increase the accumulation of NEFA in the interstitial space in the vicinity of adipocytes where the endogenously released NEFA intermingle with and are diluted by the nefa generated by LPL action from lipoproteins (LP) in the endothelial capillaries, and thereby decrease/increase the probability of reuptake and reesterification of NEFA released from adipocytes by HSL and 2-monoacylglycerol lipase (2-MAGL) action. This allows rapid adaptation of the supply of NEFA from adipose tissue according to the acute requirements of the organism (e.g. during starvation), which, to a certain degree, operates independent of the actual (insulin-controlled) lipolytic/antilipolytic state of the adipocytes. The major portion of NEFA/nefa in the interstitial space and capillaries is bound to serum albumin (Alb). The transport of glucose (as precursor for glycerol-3-phosphate, G-3-P) and the bidirectional flux of NEFA/nefa across the adipocyte plasma membrane is facilitated by GLUT4 and CD36/FAT, respectively, whereas simple diffusion and/or specific transport via AQPap is involved in the release of glycerol from adipocytes. See text for details.

and if so to what extent, the albumin-bound FA pool is directly engaged in this process. Using the hindlimb perfusion technique, it was demonstrated recently that FA incorporation into intramyocellular TAG depends not only on the unbound to albumin FA concentration but also, to some extent, on the total FA concentration. This supports the previous speculation that albumin-bound FA could be directly involved in the uptake process mediated by an interaction of the FA-albumin complex with an albumin receptor located at the cell surface, putative candidates for which are the albumin-binding proteins (ABP). They could either promote a direct transfer of FA from the complex into the plasma membrane or facilitate dissociation of FA molecules from albumin, and thus locally increase the number of FA molecules available for uptake. Subsequently, FA transported across the plasma

membrane are trapped in the cytoplasm by conversion into acyl-CoA (step 4), reesterified, and stored primarily as TAG in LD (lipid droplets) (step 5). During lipolysis of stored TAG in the fasting state, FA are released from intracellular LD primarily by action of HSL and 2-monoacylglycerol lipase (step 6), move to and cross the plasma membrane (step 7), and are released into the interstitial space, where they bind to albumin (step 8). Subsequently, the FA pass through the endothelial cells via transcytosis or diffuse through the spaces between them (tight junctions) to reach the blood (step 9).

The temporal and spatial relationship between breakdown (lipolysis) and resynthesis (reesterification) of TAG (TAG-FA cycling) has to be tightly controlled to either provoke or avoid generation of heat and energy expenditure through the utilization of ATP during substrate cycling. A substrate cycle exists when opposing, nonequilibrium reactions catalyzed by different enzymes are operating simultaneously. At least one of the reactions must involve the hydrolysis of ATP. Thus, a substrate cycle both liberates heat and increases energy expenditure in the absence of net conversion of substrate into product. Some of the NEFA formed during lipolysis can be reesterified to TAG, whereas little or no glycerol is reutilized by fat cells. This pathway of lipolysis and NEFA reesterification forms an important cycle for energy turnover, allowing the fat cell to respond rapidly to changes in peripheral requirements for NEFA (Fig. 1). This is reflected in the FA concentration gradient between plasma and adipose tissue (mainly fat cell cytosol), which is determined by both the bloodstream and uptake of NEFA by peripheral tissues. Two types of NEFA reesterification in fat cells can be recognized. Primary reesterification is the total amount of NEFA that is reesterified during a given situation and reflects the TAG synthesis capacity of the fat cells. Fractional reesterification is the proportion of NEFA reesterified in relation to the amount of NEFA formed by lipolysis in fat cells. The latter constitutes a futile cycle, energy-rich NEFA first being formed by lipolysis of TAG and then resynthesized to TAG. There is experimental evidence that NEFA have to be released from adipocytes into the interstitial space, where they form a common pool with NEFA generated by LPL action, and subsequently be taken up by the adipocytes for efficient reesterification rather than that NEFA accumulating in the cytoplasm can be used for a ''short-circuit'' reesterification. Fat cell reesterification can be determined *in vitro* by simultaneous measurement of the release of glycerol and NEFA using fluorescence, luminescence, or dual radioisotope techniques or a combination thereof.

1.3 TAG Storage/Mobilization and Disease

1.3.1 Diabetes Mellitus and Metabolic Syndrome

During the last decade, the traditional glucose-insulin axis with respect to examining glucose tolerance and as a basic pathophysiological mechanism operating in diabetes, although remaining diagnostically useful, has been criticized. The glucose-insulin axis has been overemphasized, while alterations in the insulin to NEFA ratio and ''NEFA'' metabolism received much less attention. The major change in the appreciation of the nature of molecules supplying body energy came with the discoveries that plasma NEFA are the major ''lipid vehicles'' in the mammalian organism. Furthermore, NEFA are

the only form of TAG mobilization from adipose tissue, subject to hormonal regulation. The very rapid turnover of plasma NEFA indicates that they are an important fuel even in nonfasting conditions and represent an energy source to body tissues equivalent to or greater than glucose. The importance of NEFA in the regulation of gluconeogenesis was extensively dealt with, but no clear pathogenic conclusion with relation to major diabetes perturbations emerged. A breakthrough was the demonstration in 1964, that infusion of a very small amount of insulin through the brachial artery in human forearm leads to a significant decrease in plasma NEFA concentrations without any concomitant effect on glucose uptake. Consequently, the restraint of NEFA release from adipose tissue is the most sensitive action of insulin compared with other insulin effects. The lack of restraint of NEFA mobilization in hypoinsulinemic states during pathogenesis of noninsulin-dependent diabetes mellitus (NIDDM) leads to a marked plasma NEFA increase, ectopic deposition of TAG and insulin resistance with regard to nonoxidative as well as oxidative glucose metabolism. The latter fact stresses the negative effect of excessive availability of NEFA in the short term on insulin-mediated glucose utilization in muscle. It involves a reduction of muscle glycolysis by inhibiting phosphofructokinase in the course of elevated cytosolic concentrations of citrate and consequent accumulation of glucose-6-phosphate. Pyruvate dehydrogenase is also inhibited by rising mitochondrial concentrations of acetyl-CoA and NADH. In the liver, the same changes in redox ratio and activation of pyruvate carboxylase by acetyl-CoA result in stimulation of gluconeogenesis. This mechanism links acute NEFA oversupply to impaired glucose tolerance or hyperglycemia in the developing or frank NIDDM, respectively.

Moreover, the increased plasma NEFA concentration in NIDDM patients provides substrate for VLDL production by the liver (see above), which is manifested as hypertriglyceridemia. Thus, drugs with the potential of lowering NEFA levels may reduce hepatic VLDL production, improve glucose tolerance and counteract lipotoxicity and therefore be useful for antidiabetic therapy. The generation and careful analysis of transgenic and knockout animals has aided insight into the recognized but partly misunderstood participation of cellular lipid metabolism in energy homeostasis. Numerous mouse models with disruptions in pathways relevant to FA as well as TAG storage and mobilization have been generated with dysregulated circulation of FA in the bloodstream as nonesterified molecules, bound to albumin, or in the core of lipoproteins, such as VLDL (see below).

1.3.2 Lipotoxicity

In the last decade, the deleterious effects of the deposition of TAG in nonadipose tissues during long-term elevations of plasma NEFA have been widely acknowledged. Whereas adipocytes have a unique capacity to store excess FA in the form of TAG in LD, nonadipose tissues, such as cardiac and skeletal muscle myocytes and pancreatic ß-cells, have a limited capacity for storage of TAG. In hyperlipidemic states, accumulation of excess TAG in nonadipose tissues leads to cell dysfunction and/or cell death, a phenomenon known as lipotoxicity and lipoapoptosis, respectively. Excess lipid accumulation in skeletal muscle is associated with the development of insulin resistance.

The "lipotoxic" consequences of excessive FA release from adipose tissue for pancreatic ß-cells have been described in a provocative report by Unger and colleagues. Abnormal ß-cell function and insulin resistance are the major characteristics in the pathogenesis of NIDDM. Lipotoxicity was proposed as an attractive concept to explain parallel developments in the impairment of insulin signaling and ß-cell function. Before the onset of overt NIDDM, insulin resistance was closely associated with ß-cell dysfunction characterized by ß-cell hyperplasia and insulin hypersecretion. During further progression of the disease, however, the ß-cell could no longer compensate for peripheral insulin resistance and declined in its function. From animal models of obesity-linked NIDDM, such as the obese and insulin-resistant Zucker rats, as well as *Psammomys obesus*, both impairment of insulin secretion linked to intracellular fat deposition and loss of cell mass by FA-induced apoptotic cell death contribute to the development of relative insulinopenia. Exposure of NEFA has cytostatic and proapoptotic effects on human pancreatic ß-cells. Lipid overload in pancreatic ß-cells also leads to dysregulated insulin secretion followed by apoptotic cell death. Furthermore, human autopsy studies show a relative reduction of ß-cell mass in patients with NIDDM compared with weight-matched nondiabetic subjects. These findings support the idea that, in genetically predisposed human subjects, prolonged exposure to elevated NEFA may contribute to ß-cell death and development/progression of NIDDM. The intracellular signaling pathways for FA-induced ß-cell apoptosis are incompletely understood. Different mechanisms for lipoapoptosis, such as increased ceramide formation, mitochondrial cytochrome *c* release, and nitric oxide generation, have been suggested. Furthermore, in different cell types, the FA-dependent signaling process might involve activation of different protein kinases C isoforms. However, the exact role of PKC isoforms in FA-induced apoptosis has not been defined (see below).

TAG storage and lipolysis in the pancreatic ß-cell may play a dual role. First, by way of storage, as a protective mechanism against the toxic effects of excess NEFA, and second by way of lipolysis to provide a signal (FA, DAG) that participates in the stimulus/secretion-coupling that regulates acute insulin release. With regard to the latter function, islets depleted of TAG show an abrogated stimulation of insulin release by glucose. HSL may balance TAG storage and TAG mobilization in pancreatic ß-cells, and, thus, via PKA, provide a critical link in the stimulus/secretion-coupling response. HSL is predominantly expressed in pancreatic islets as a 3.1-kb mRNA encoding an 89-kDa isoform containing an additional 43 aa N-terminal to the adipocyte form of the protein, as well as the 2.8-kb mRNA encoding the 84-kDa adipocyte form. HSL immunoreactivity in islets is detected primarily in ß-cells, but some HSL is also observed in α-cells. Long-term incubation of ß-cells or islets with high concentrations of glucose increases HSL mRNA and protein expression, as well as HSL activity. This induction of HSL expression appears to be regulated transcriptionally and also appears to depend on the metabolism of glucose. Treatment of ob/ob mice with leptin increased HSL expression in islets along with a decrease in islet TAG content and an improvement in insulin secretion. HSL is definitely functional in islets, since islet TAG content is increased 2

to 2.5-fold in HSL null mice compared with wild-type mice. These observations together with studies on insulin release in HSL null mice upon glucose challenge suggest that HSL might be important in glucose-induced insulin secretion and are consistent with the current view that FA metabolites are critical for insulin secretion, but that excessive NEFA can lead to lipotoxicity and dysfunction of ß-cells. The exact function of HSL in insulin secretion from ß-cells awaits further study.

The FA supply to ß-cells for lipid-signaling processes can be from exogenous and endogenous sources. Studies with HSL-deficient mice show roles for HSL in the maintenance of both exogenous and endogenous FFA supplies and, in at least some circumstances, the preservation of normal glucose-stimulated insulin secretion (GSIS). Thus, with respect to the exogenous FFA supply and consistent with previous reports, HSL deletion in male mice was associated with markedly reduced plasma FFA and TAG levels during fasting. For the endogenous supply, there is evidence of reduced access to islet TAG stores, as the TAG stores were increased in association with reduced islet TAG lipase activity and lipolysis, particularly in 7-month-old mice. Given that the TAG lipase activity was most affected in older mice, and plasma lipid levels were most reduced in the fasting state in male mice, ß-cell islet FA deprivation was almost certainly greatest in the older fasted male mice. Therefore, the finding of the greatest loss of GSIS in the fasted 7-month-old male $HSL^{-/-}$ mice, together with the reversibility of this loss with FFA replacement, are completely consistent with the essential role of FA supply in normal insulin secretion. Furthermore, triacsin C-experiments showed that activation of FFA to long-chain acyl-CoA is necessary for this FA effect, consistent with the malonyl-CoA/long-chain acyl-CoA signaling pathway of insulin secretion. These findings are also consistent with triacsin C diminishing FFA augmentation of insulin secretion stimulated by glucose or nonfuel secretagogues. The distal mechanism by which long-chain acyl-CoA promote insulin secretion, however, is not known. Possibilities include a direct long-chain acyl-CoA effect on exocytotic processes or indirect actions *via* acylation of proteins or esterification into lipid-signaling molecules, such as phosphatidate and DAG. Importantly, available data underscore a role for ß-cell HSL in the provision of an endogenous FFA supply when exogenous FA supplies are low. The importance of lipolysis for the formation of a lipid-derived coupling signal was confirmed by the fact that inhibition of lipolysis in rat islets by orlistat reduced insulin secretion.

The islet neutral cholesterylester hydrolase and TAG lipase activity data are consistent with lipase activity distributions in other tissues, which show the responsibility of HSL for most or all of the cholesterylester hydrolase and part of the TAG lipase activity. However, it remains unknown if DAG hydrolase activity is reduced in $HSL^{-/-}$ islets. Although HSL is the main source of DAG hydrolase activity in adipocytes, this activity in liver and skeletal muscle may occur *via* another enzyme(s)(see below). Interestingly, the relative importance of HSL-TAG lipase activity to overall TAG lipase activity increased as the $HSL^{-/-}$ mice aged. This provides an explanation for the detection of reduced basal lipolysis in the older mice only. The higher islet TAG content in the islets

from 4-month-old $HSL^{-/-}$ mice, however, strongly suggests abnormal lipolysis was also present in these islets, although hardly measurable as glycerol release in the *in vitro* assay. Clearly, the lipase and lipolysis results are indicative of at least one other lipase with TAG lipase activity in islets. The degree to which this other enzyme(s) is upregulated in the ß-cell of the $HSL^{-/-}$ mice to compensate for the total deficiency of HSL remains to be elucidated.

Of considerable interest is the demonstration of glucose-stimulated lipolysis in islets from $HSL^{+/+}$ and $HSL^{-/-}$ mice. Thus, glucose-stimulated lipolysis has now been shown to occur in mouse and rat islets. This process may prove to be important for signal transduction in GSIS. The finding that glucose increased lipolysis in $HSL^{-/-}$ islets is indicative of an alternate lipase being responsive to glucose. Why this does not prevent loss of GSIS, however, is not known. It may have been due to differences in subcellular localization of the lipases. Interestingly, islet HSL has recently been shown to be associated with insulin secretory granules.

Several groups have now generated $HSL^{-/-}$ mice, and much heterogeneity is reported in the metabolic phenotype, particularly in relation to the measurement of insulin sensitivity and ß-cell function. Insulin sensitivity assessed in one study by the intraperitoneal insulin tolerance test was reduced, whereas in another study, insulin sensitivity, calculated from the intraperitoneal glucose tolerance test, was enhanced in the $HSL^{-/-}$ mice, as glucose levels during the tolerance test remained unaltered in the face of reduced circulating insulin in $HSL^{-/-}$ mice. Furthermore, GSIS in isolated islets from fasted $HSL^{-/-}$ mice was impaired in male mice but enhanced in female mice. Although at first sight the data and literature seem confusing, some patterns relating to nutritional state and sex are now evolving. With respect to nutritional state, serum FFA and TAG levels are usually unchanged in the fed state, but markedly reduced in the fasted state in $HSL^{-/-}$ mice compared to $HSL^{+/+}$ mice. Similarly, hepatic TAG content has been reported as unchanged or increased in the fed state and decreased in the fasted state in $HSL^{-/-}$ mice. With the well-known inverse correlations between plasma FFA and hepatic TAG content and insulin sensitivity, it is conceivable that these abnormally wide fluctuations in whole animal lipid partitioning with nutritional state cause swings between relatively reduced (fed state) and enhanced (fasted state) insulin sensitivity in the $HSL^{-/-}$ mice compared to wild-type mice. This favors the hypothesis on the differences in the nutritional state (fed vs. fasted) at the time of assessment. The degree to which insulin sensitivity changes with the nutritional state, however, may also relate to the amount of fat in the diet and whether the mice are male or female.

It is of interest to discuss these findings in relation to results obtained with mice transgenic for HSL specifically in ß-cells. These mice, having been fed a high-fat diet, have impaired glucose tolerance with poor GSIS. It was concluded that excess HSL activity in the islet prevented detoxification of the increased fat supply, as the potentially protective diversion of FA to TAG stores was blocked. Both these HSL-transgenic mice and the $HSL^{-/-}$ mice highlight the importance of normal lipolysis pathways with normal regulation of lipid stores for normal insulin secretion.

1.3.3 Molecular Mechanisms of Lipotoxicity

In various experimental systems, saturated and unsaturated FA differ in their contributions to lipotoxicity. Previous studies in (Chinese hamster ovary) CHO cells, cardiac myocytes, pancreatic ß-cells, breast cancer cell lines, and hematopoietic precursor cell lines suggest that lipotoxicity from the accumulation of long-chain FA is specific for saturated FA. This selectivity has been attributed to the generation of specific proapoptotic lipid species or signaling molecules in response to saturated but not unsaturated FA. The nature of such signals may differ across cell types, but includes reactive oxygen species generation, *de novo* ceramide synthesis, nitric oxide generation, decreases in (phosphatidylinositol-3-kinase) PI3K, primary effects on mitochondrial structure and function and suppression of antiapoptotic factors, such as *Bcl*II.

A recent study provided evidence that the differential toxicity of these FA is directly related to their ability to promote TAG accumulation. It was demonstrated that exogenous or endogenously generated unsaturated FA rescue palmitate-induced apoptosis by promoting palmitate incorporation into TAG. Moreover, unsaturated as well as saturated long-chain FA were toxic in cells with impaired TAG synthetic capacity (e.g. lack of DGAT activity). *In vivo*, TAG accumulation and storage in nonadipose tissues may occur in the setting of mismatch between cellular FA influx and FA utilization. TAG accumulation in nonadipose cells provoked by either enhanced synthesis or impaired mobilization in response to acute FA overload may represent an initial cellular defense mechanism against lipotoxicity. Consequently, accumulation of TAG in nonadipose tissues probably serves as a barometer of the FA overload state in human disorders such as hyperlipidemia and lipodystrophies, and in animal models such as the Zucker (diabetic) fatty rat or the ob/ob mouse. Accumulation of cellular TAG *per se* does not seem to be toxic, at least initially. Rather, storage of excess FA in TAG pools of ''inert'' LD probably diverts these molecules from pathways that lead to cellular dysfunction and/or cytotoxicity and may thus serve as a buffer against lipotoxicity. In pathologic states, lipotoxicity may occur over time, despite TAG accumulation and storage, when either the cellular capacity for TAG storage is exceeded or when TAG pools are hydrolyzed (during HSL action), resulting in increased cellular NEFA levels. Thus, the duration and extent of TAG overload in conjunction with (regulation of) TAG storage and mobilization may determine whether a cell is protected or damaged.

This mechanism may also underlie the FA-induced apoptosis in rat and human pancreatic ß-cells. Chronic treatment with high physiological levels of saturated FA, but not with mono- or polyunsaturated FA, triggers apoptosis in about 20% of cultured ß-cells. Apoptosis restricted to saturated FA was also observed in primary cultured human ß-cells, suggesting that this mechanism is potentially relevant *in vivo* in humans. Apoptosis was accompanied by a rapid nuclear translocation of protein kinase C-delta (PKC-d) and subsequent lamin B1 disassembly. This translocation was impaired by inhibition of phospholipase C, which also considerably reduced apoptosis. Furthermore, lamin B1 disassembly and apoptosis were decreased by cell transfection with a dominant-negative mutant form of PKC-d. These data suggest that nuclear translocation and kinase activity of PKC-d are both necessary for saturated FA-induced

lipoapoptosis. In analogy to recent findings with CHO cells, it is conceivable that in ß-cells accumulation of DAG generated by phospholipase C action and the resulting activation of PKC-d can be prevented by conversion of DAG into and storage as TAG via an ill-defined regulatory process of DAG acylation that is stimulated by unsaturated FA.

2 Components for TAG Storage and Mobilization

2.1 TAG in Lipoproteins

Homozygous VLDL receptor knockout mice are resistant to both genetic and diet-induced obesity caused by a decreased peripheral and whole-body uptake of NEFA with no alterations in either food intake or fat absorption. The reduction in adipocyte TAG storage as shown by a decreased average fat cell size in VLDL receptor-deficient rodents implies an impaired FA delivery to adipose tissue in the absence of this lipoprotein receptor. Analogously, hepatic overexpression of human apolipoprotein C-I leads to hyperlipidemia accompanied by decreased visceral fat depots and lack of subcutaneous WAT in mice. Conversely, overexpression of apoA-II, the second most abundant HDL component, increases adiposity and insulin resistance in relation to decreased skeletal muscle glucose utilization. In the capillaries of skeletal muscle and adipose tissue at the luminal face of endothelial cells, LPL catalyzes the rate-limiting step in the hydrolysis of TAG from circulating VLDL and chylomicrons. Thus, LPL plays an important role in directing fat partitioning. In fact, complete LPL deficiency in mice results in minimal amounts of tissue lipids, leading to neonatal death due to marked hypoglycemia and hypertriglyceridemia. In heterozygotes, only mild hypertriglyceridemia with impaired LDL clearance and mild hyperinsulinemia accompanied by an approximately 20% decrease in fasting glucose concentrations were observed. Exclusive LPL deficiency in adipose tissue on a standard genetic background leads to normal growth and body composition. This implies that, although LPL controls FA entry into adipose tissue, fat mass is preserved by endogenous FA synthesis. When the same lack of LPL in adipose tissue is generated on an ob/ob background, a diminished weight gain is attained owing to an impaired lipid accumulation in adipocytes. Conversely, targeted overexpression of LPL in skeletal muscle or liver has no effect on body weight, but produces an increase in FA uptake into the respective tissue that adversely affects glucose metabolism.

2.2 TAG in Adipose Cells

Adipocytes, which vary enormously in size (20–200 μm in diameter), are embedded in a connective tissue matrix and are uniquely adapted to store and mobilize energy as TAG and NEFA/glycerol, respectively. Surplus energy is assimilated by fat cells and stored as TAG in LD. To accommodate the TAG, adipocytes can change their diameter up to 20-fold and their volumes by several 100-fold. Because ~90% of the cell volume is constituted by LD(s), the nucleus and the thin cytoplasm rim are pushed to the periphery of the adipocytes. WAT is actively involved in cell function regulation through a complex network of endocrine, paracrine, and autocrine signals that influence the response of many tissues,

including hypothalamus, pancreas, liver, skeletal muscle, and others. Until recently, adipocytes were seen as passive tissues for the storage of excess energy as TAG. However, they clearly act as endocrine secretory cells, releasing in constitutive or regulated fashion, several hormones (e.g. leptin), growth factors (TGFß), cytokines (e.g. TNF-α), and other factors (e.g. ASP) that act as feedback signals for the adipose tissue itself or for other tissues. Adipose tissue signaling pathways, arranged in a hierarchical fashion, constitute one of the voices of the body that enable the organism to adapt to a range of metabolic challenges, such as starvation, stress, and infection, as well as periods of energy excess.

2.2.1 Enzymes of TAG Synthesis

Accumulating evidence for important functions of enzymes involved in lipid synthesis and its control has been obtained through targeted disruption in rodent models of the corresponding genes (Fig. 2). However, direct links between abnormal expression or genetic variants and human disorders, such as obesity, hyperlipidemia, insulin resistance, and NIDDM await further clarification.

2.2.1.1 **Glycerol-3-Phosphate Dehydrogenase.** Glycerol-3-phosphate dehydrogenase (GPDH) is a ubiquitously expressed enzyme that participates in TAG synthesis and in shuttling NADH into mitochondria for oxidative metabolism. Transgenic mice overexpressing GPDH show a normal body weight but with an increased interscapular brown fat depot and virtually no WAT. Conversely, animals lacking mitochondrial GPDH show a decreased body weight compared with wild-type mice with no reported effect on adipose tissue depots but a marked insulin release defect when the malate–aspartate shuttle is blocked. This indicates an important role of the NADH shuttle or glycerol phosphate system in glucose-induced

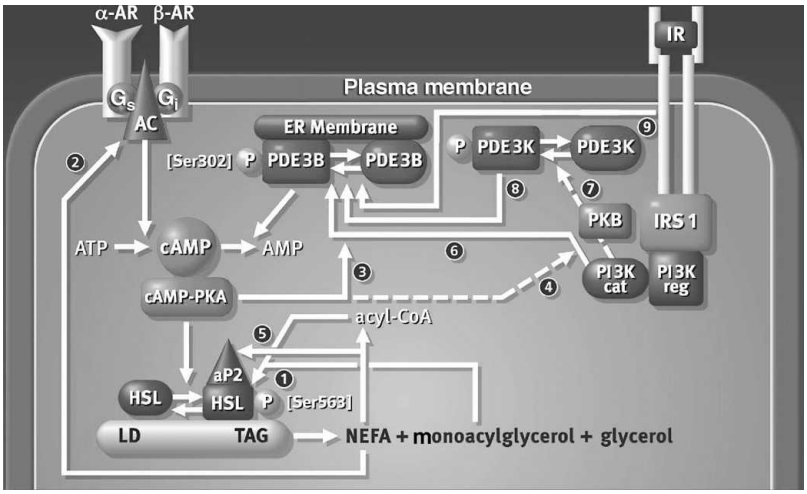

Fig. 2 Schematic model of the main signaling and metabolic pathways coupling hormonal stimuli and NEFA to (regulated) TAG synthesis, storage, and mobilization in adipocytes. PKA-dependent phosphorylation is depicted as filled circles. See text for details.

activation of mitochondrial metabolism and insulin secretion. Therefore, the two mouse models with altered expression of GPDH provide evidence for an involvement of this enzyme in lipogenesis and WAT development as well as in the regulation of the glycolytic pathway.

2.2.1.2 **Acetyl-CoA Carboxylases.**

Malonyl-CoA is a, key metabolite generated by acetyl-CoA carboxylases (ACC), which plays a pivotal role in linking FA and carbohydrate metabolism through regulation of FA synthesis and oxidation, respectively, in response to hormonal and dietary influences (Fig. 2). In mammals, ACC exists in two isoforms, ACC1 and ACC2, which are encoded by two different genes. ACC1 is the principal isoform in lipogenic tissues, whereas ACC2 is predominantly expressed in oxidative tissues, such as the heart and skeletal muscle. Both isoforms are expressed in the liver, where FA synthesis and oxidation coexist. ACC1 is a cytosolic enzyme, whereas ACC2 is associated with the mitochondrial membrane through its extended amino terminus. This difference in compartmentalization might contribute to the diverse roles of the two isoforms in fat metabolism; ACC1 is believed to regulate fat synthesis in lipogenic tissues, whereas ACC2 controls the rate of lipid oxidation in oxidative tissues. However, the recent identification of a mitochondrial form of FAS indicates that ACC2 might also have a role in FA synthesis in mitochondria.

ACC activity is mainly regulated by citrate and AMP kinase (AMPK). Citrate is believed to be an allosteric activator of ACC, as evidenced by a strong positive correlation between levels of malonyl-CoA and citrate concentrations. For example, elevated ACC activity occurs concomitantly with a threefold increase in cellular citrate concentration following the acetoacetate treatment of acini cells isolated from lactating rat mammary gland. Phosphorylation of ACC by AMPK inhibits its activity, which is accompanied by a reduction in malonyl-CoA levels. This is seen both in reperfused rat hearts following ischemia and in skeletal muscle following treadmill exercise or electrical stimulation. Furthermore, the incubation of isolated rat soleus muscles with the AMPK activator AICAR decreases ACC2 activity and simultaneously increases the rate of FA oxidation.

The effect of ACC2 on FA oxidation is also observed in knockout mice that are deficient in this enzyme. *Acc2*-null mice have a elevated rate of FA oxidation concomitant with decreased malonyl-CoA levels in the skeletal muscle and heart. These knockout mice are resistant to diet-induced obesity and related diabetes, with improved insulin sensitivity and decreased FA levels. The mRNA levels of uncoupling proteins (UCPs) are markedly higher in the adipose, heart (UCP2), and muscle (UCP3) tissues of mutant mice, which together with increased ß-oxidation might account for an upregulation of energy expenditure. Further analysis has also confirmed an important role of ACC2 in the malonyl-CoA/CPT1 axis, as illustrated by an increase in the CPT1 activity of hepatocytes that are isolated from *Acc2*-null mice. Surprisingly, CPT1 activity in skeletal muscle was not notably changed by ACC2 deficiency. The knockout mice have a normal lifespan with no apparent pathophysiological conditions caused by ACC2 deficiency. Several mammalian ACC inhibitors have been developed and tested for physiological effects on TAG synthesis, although ACC2-specific inhibitors have not been reported. One of the mammalian ACC inhibitors, CP-610431, shows dual inhibition of both

ACC1 and ACC2. When tested *in vivo*, several of the dual inhibitors reduced TAG synthesis and increased FA oxidation in rats, with a concurrent reduction in malonyl-CoA levels in the liver, muscle, and heart. These results further support a role for malonyl-CoA and validate the concept that the inhibition of ACC enzymes with small molecules might provide a viable treatment option for obesity. In addition, the development of dual inhibitors can prevent the feedback responses that are caused by the inhibition of a single ACC isoform, as observed in *Acc2*-knockout mice, therefore providing better overall efficacy.

2.2.1.3 **Fatty Acid Synthase.** Mammalian fatty acid synthase (FAS) catalyzes the *de novo* synthesis of saturated FA, such as myristate, palmitate, and stearate, using acetyl- and malonyl-CoA. It functions as a homodimer of a multifunctional protein that contains seven catalytic domains and a site for the prosthetic group 4′-phosphopantetheine. The enzyme is abundantly expressed in lipogenic tissues, such as liver, adipose, and lactating breast. FAS is believed to be important in coordination with CPT and ACC in maintaining energy homeostasis by converting excess food intake into lipids for storage and providing energy by upregulating the rate of mitochondrial oxidation. FAS might also have a role in carcinogenesis and increased FAS levels in cancer tissues indicate a poor prognosis. Much of our understanding of the metabolic role of FAS comes from investigations using two FAS inhibitors: cerulenin and C75. C75 was initially developed for its antitumor activity. Administration of C75 caused a dose-dependent decrease in food intake in BALB/c mice, and blocked the fasting-induced upregulation of orexigenic neuropeptides and the downregulation of anorexigenic neuropeptides in the hypothalamus. Similar results were observed with cerulenin, although with much less efficacy. Intracerebroventricular (ICV) injection of C75 resulted in the dose-dependent inhibition of feeding, which could be circumvented by ICV injection of neuropeptide Y.

One of the most popular models put forward to explain the weight-loss effects of FAS inhibitors posits that the level of malonyl-CoA in a subset of neurons regulates feeding, and inhibition of FAS causes a buildup of malonyl-CoA in the central nervous system, thereby suppressing the appetite of animals. This model was supported by the observations that administration of C75 to fasted mice rapidly increased hypothalamic malonyl-CoA and blocked feeding when the mice were presented with food. However, this model was challenged by the recent finding that C75 lacked target specificity for proopiomelanocortin (POMC) neurons and acted as a nonspecific neuronal activator. In support of the argument, C75 was reported to act as a possible alkylating agent and cerulenin was shown to inhibit protein acylation. In addition, C75 was reported to activate CPT1. Treatment of mice with C75 led to increases in both energy consumption and FA oxidation in diet-induced obesity that could be reversed by etomoxir, which is an inhibitor of CPT1.

2.2.1.4 **Glycerol-3-Phosphate Acyltransferase.** The synthesis of TAG and glycerophospholipids starts with the acylation of glycerol-3-phosphate by glycerol-3-phosphate acyltransferase (GPAT) to form lysophosphatidic acid (Fig. 2). GPAT activity in most mammalian tissues involves at least two isoforms of GPAT enzymes, the mitochondrial (GPAT1) and endoplasmic reticulum (erGPAT) isoforms, which are

encoded by two different genes. erGPAT accounts for 90% of the total enzyme activity in most tissues, with the exception of the liver, in which GPAT1 contributes about 50%. GPAT1 expression and enzyme activity are regulated by nutritional and hormonal factors in a manner that is consistent with a crucial role in TAG synthesis. Overexpression of GPAT1 in mammalian cell lines results in a notable increase in TAG synthesis. By contrast, inactivation of GPAT1 in mice causes a reduction in weight gain accompanied by significant decreases in hepatic TAG content, plasma TAG, and low-density-lipoprotein TAG secretion. Ablation of GPAT1 also results in mice that show a marked shift in the incorporation of unsaturated FA into TAG and phospholipids.

How GPAT1 enzyme deficiency affects TAG synthesis remains elusive, as mitochondria lack a complete set of TAG synthesis enzymes, such as DGAT, which catalyzes the final step in TAG synthesis. One proposed mechanism for the fat loss that is observed in *Gpat1*-knockout mice predicts a role for GPAT1 as a mediator of lipid oxidation. Accordingly, as GPAT1 and carnitine palmitoyltransferase-1 (CPT1) reside on the outer mitochondrial membrane, and both seem to be reciprocally regulated by AMP-activated kinase, elimination of GPAT1 activity would prevent the direction of fatty acyl-CoAs toward TAG synthesis and avoid competition with CPT1 for acyl-CoAs. Further investigation is needed to verify this hypothesis; for example, comparing the rate of mitochondrial oxidation between *Gpat1*-knockout mice and controls. Although no obvious pathophysiological conditions are associated with GPAT1 deletion, a real concern with targeting GPAT1 for obesity is its effect on phospholipid synthesis. For example, the inhibition of GAPT1 could potentially impair the synthesis of cardiolipin, which is a glycerophospholipid that is important in maintaining the normal function of mitochondria. Despite the considerable progress that has been made in deciphering individual residues that are important for the catalytic activity of GPAT1, information is still lacking on the three-dimensional structure of the enzyme and on any reported efforts to develop GPAT1 inhibitors.

2.2.1.5 **Monoacylglycerol Acyltransferase.** Monoacylglycerol acyltransferase (MGAT) catalyzes the first step in TAG resynthesis, which is involved in dietary absorption in enterocytes and represents one of the two main biochemical pathways that are involved in TAG synthesis. The activity of each pathway is determined by the relative abundance of 2-monoacylglycerol and FFA relative to glycerol-3-phosphate. In intestinal mucosa under normal lipid-absorption conditions, the MAG pathway contributes 80% of the TAG that is incorporated into chylomicrons and is believed to inhibit the glycerol-3-phosphate pathway. Consistent with a role in dietary fat absorption, all three of the MGAT genes (MGAT1-3) are predominantly expressed in the gastrointestinal tract. Although high MGAT2 expression at mRNA levels was detected in the human liver, little MGAT activity was identified in this organ. MGAT expression and activity in the liver is inducible by diabetes, obesity, and lactation in rodents. MGAT expression at the mRNA level is also detectable in adipogenic tissues, although at much lower levels than in the small intestine, which indicates a possible role of the enzyme in *de novo* lipid synthesis. However, the MGAT2 protein is below detection limits in all nongastrointestinal tissues. MGAT2 expression and activity in the small intestine are

induced by a high-fat diet, which correlates well with the pattern of dietary fat absorption; this enzyme is therefore an attractive drug target for dietary fat absorption. Its primary site of expression is limited to the gastrointestinal tract, which would minimize any potential side effects of an MGAT inhibitor on other tissues. Furthermore, discharge of MAG and FA (in contrast to TAG) as an unabsorbed energy source in the feces might minimize the gastrointestinal side effects that are caused by orlistat. MGAT is a member of the acyltransferase superfamily of enzymes, which have recently been shown to be druggable through the successful development of small-molecule inhibitors of acyl-CoA:cholesterol acyltransferase and 1-acyl-glycerol-3-phosphate acyltransferase as potential treatments for hypercholesterolemia and cancer, respectively.

2.2.1.6 **Acylglycerol-3-Phosphate Acyltransferase.** 1-Acyl-glycerol-3-phosphate acyltransferase (AGPAT) catalyzes the acylation of lysophosphatidic acid at the *sn*-2 position to form phosphatidic acid, which is an important intermediate in the *de novo* biosynthesis of TAG and glycerophospholipids. Dephosphorylation of phosphatidic acid results in the formation of *sn*-1,2-DAG, which joins the MGAT pathway for TAG synthesis that is catalyzed by diacylglycerol acyltransferase (DGAT). *AGPAT2* is one of only two identified human genes that, when mutated, cause congenital generalized lipodystrophy, which is a rare autosomal recessive disorder that is also known as Berardinelli–Seip syndrome. Mutation of *AGPAT2* also causes voracious appetite and increased energy expenditure as a result of leptin deficiency. AGPAT activity is markedly induced during 3T3-L1 adipocyte differentiation, and overexpression of AGPAT1 in 3T3-L1 adipocytes results in increased TAG synthesis. One obvious concern for intervention in AGPAT2 activity as a treatment for obesity is the potential side effect of lipodystrophy, which is associated with diabetes and extreme insulin resistance. However, this might not occur with small-molecule inhibitors, which are unlikely to impose total inhibition of the enzyme activity *in vivo*. AGPAT2 has proved to be druggable, as small-molecule inhibitors of AGPAT2 that were developed as a potential treatment for cancer have been shown to prevent cellular growth and induce apoptosis of tumor cells.

2.2.1.7 **Diacylglycerol Acyltransferase.** The final step in TAG synthesis occurs by the action of diacylglycerol acyltransferase (DGAT) with DAG and fatty acyl-CoA as substrates (Fig. 2) that merges the MGAT and glycerol-3-phosphate pathways. In contrast to MGAT enzymes, which are predominantly expressed in tissues that are involved in dietary fat absorption, both DGAT1 and DGAT2 are widely expressed in a range of tissues. DGAT1 polymorphism is linked with certain types of human obesity. Levels of DGAT1 protein increase sharply following the differentiation of 3T3-L1 into mature adipocytes, and the overexpression of DGAT1 and DGAT2 in cell lines results in a marked increase in TAG synthesis in mature adipocytes and stably transfected McA-RH7777 cells. In contrast to the minor role of DGAT in dietary fat absorption, mice that are deficient in DGAT1 show a reduction in adiposity and resistance to diet-induced obesity, which is accompanied by an increase in energy expenditure and hyperlocomotive activity. The phenotype can be recapitulated by adipose-tissue transplantation from *Dgat1*-knockout mice to normal controls, which

points to the adipocyte as the principal regulatory site for DGAT1 function.

By contrast, targeted inactivation of DGAT2 resulted in lethal neonatal lipopenia and skin-barrier abnormalities. DGAT2 is crucial to TAG synthesis in various tissues, as evidenced by the near absence of TAG in liver and white adipose tissue, and a greater than 70% reduction in plasma levels of TAG, FA, and glucose in *Dgat2*-knockout mice. The lethal phenotype is not compensated for by DGAT1; this possibly is a result of the different roles of the proteins in regulating endogenous TAG synthesis, as evidenced by the different subcellular localizations of TAG catalyzed by these two enzymes. Furthermore, the content of linoleic acid (C18:2) in FA from liver and plasma is greatly reduced in *Dgat2*-null mice, which indicates an important role for DGAT2 in the selective retention of essential FA that are vital for the maintenance of normal skin function. Although the heterozygous *Dgat2*-knockout mice seem to be indistinguishable from wild-type controls, further analysis is needed to investigate whether they are more resistant to diet-induced obesity. The difference in phenotype between *Dgat1*- and *Dgat2*-knockout mice has confirmed the theory that two distinct DGAT enzymes are responsible for storage and mobilization, and that separate pools of TAG exist for storage and oxidation. Several natural products from various microorganisms have been reported to inhibit DGAT activity, although the specificity of these compounds has not yet been confirmed against cloned DGAT enzymes.

2.2.2 Lipid Droplets

2.2.2.1 Morphology and Lipid Composition. In different types of mammalian cells, intracellular lipids are stored in discrete LD. White adipocytes have only one or a few large TAG-rich LD (10–100 μm diameter) per cell. Brown adipocytes, which occur in some hibernating animals and the fetuses/neonates of many mammals, contain many smaller storage LD (2–10 μm diameter). Small LD (<1 μm) are also present in various other cells such as liver, muscle, kidney, intestine, and mammary gland, cultured lines such as 3T3-L1 fibroblasts, CHO cells, melanocytes, cultured pulmonary epithelial cells, various animal tissues and macrophages. Other cells, such as cultured HepG2 hepatoma cells and primary lung lipofibroblasts may contain LD up to 2 to 3 μm in diameter. Cholesterylester-rich LD are contained in steroidogenic cells of adrenal cortex, testes, and ovary.

First reports on the composition of LD in mammalian cells in the 1960s revealed a high content of TAG and a small amount of protein in LD from bovine heart. Subsequently, membrane-bound LD of rat liver, which consist mainly of neutral lipids, and a lipid-rich fraction of pig liver, which mainly contains TAG, were isolated and characterized. Further investigations revealed that the composition of cellular LD varies depending on the cell type. LD from bovine heart have similarities to the fat globule of bovine milk in structure and, to a certain extent, in chemical composition. Under electron microscopy, bovine heart LD appear as irregular bodies 0.5 to 2 μm in diameter. Occasionally, a few larger particles (5–8 μm in diameter) were detected as distinct structures without indication of fusion. They consist of a core of TAG surrounded by a phospholipid monolayer with some proteins attached to the surface.

Approximately 95% of total lipids of LD from bovine heart are constituted by

TAG. The amount of protein present in these LD is about 5% of total mass, and the amount of phospholipids varies from 3 to 7% of total lipid. The major phospholipids forming the monolayer of these LD are phosphatidylcholine (ca. 50%) and phosphatidylethanolamine (30–40%). The NEFA content is very low. The chemical composition of LD in beef heart with their high TAG content and the rather small amount of phospholipids resembles the composition of chylomicrons. A striking difference, however, is the lack of cholesterol and cholesterylesters in LD from beef heart, whereas these lipid species occur at approximately 1 to 2% of total lipid in chylomicrons. Furthermore, the protein content of LD is two to three times higher than that of chylomicrons. In contrast to bovine heart LD, those of stellate cells from the rat liver consist of retinylesters, TAG, free cholesterol and a small amount of phospholipids. A general characteristic of LD regardless of the cell type appears to be the content of approximately 5% phospholipids of the total mass.

However, electron microscopy of conventional resin-embedded ultrathin sections cannot visualize any membranous structure around the LD. In the ultrathin section of LD specimens fixed by aldehydes and then by osmium tetroxide there appears to be no phospholipid, and its periphery is usually seen as a thin intermittent line. In many diagrams, the LD surface has been depicted as a phospholipid monolayer with the hydrophilic head group facing the cytoplasm and the hydrophobic acyl chains extending into the LD content. It has also been assumed that LD form by accumulation of TAG between the two leaflets of the ER (endoplasmic reticulum) membrane because hydrophobic TAG molecules may exist stably in the aqueous cytoplasm only when covered with amphiphilic molecules with the hydrophilic moiety facing outward. However, experimental evidence to support the above assumptions is scarce. Only freeze-fracture electron microscopy showed that the fracture plane along the LD surface is occasionally continuous with the cytoplasmic leaflet of the ER membrane. Because it is difficult to retain lipid-rich structures by conventional morphological methods, cryoelectron microscopy is of advantage since it observes biological specimens at atomic resolution without fixation or staining. The microscopy showed that the LD surface is indeed a hemi-membrane, or a phospholipid monolayer.

A phospholipid monolayer in the surface is consistent with the current model that LD are formed by TAG deposition between the two leaflets of the ER membrane and may remain connected to it. Distribution of acyl-CoA:cholesterol acyltransferase-1, a major enzyme that synthesizes cholesterylester, in the entire ER seems to indicate that LD may bud anywhere along the membrane. However, Cap-LC/ESI mass spectrometry showed that FA moieties of phosphatidylcholine and lyso-phosphatidylcholine in LD are distinct from those in the rough ER. The results do not rule out the generation of the LD surface generated from the ER membrane but indicate that the former is a highly differentiated domain. Mature LD might be independent of the ER. Alternatively, the LD may be connected to the ER, but some molecular mechanism may demarcate the LD surface from the bulk ER membrane as postulated for other ER domains. Whatever is true, TAG synthesized in wide areas of the ER do not deposit indiscriminately but are concentrated to loci specialized to make

LD. ADRP or other LD-associated proteins may be involved (see below).

Cap-LC/ESI mass spectrometry has also shown that the LD surface differs from the detergent-insoluble glycolipid- and sphingolipid/cholesterol-rich microdomains (DIGs) in FA composition. Interestingly, DIGs contain a higher proportion of long saturated FA than rough ER, whereas LD do not. This indicates that not only interaction between sphingolipids and cholesterol but interaction between saturated phospholipids and cholesterol are also important in forming DIGs, as predicted from model membrane studies. The discovery of caveolin sequestration (see below) led to speculation that the LD surface might be similar to DIGs. However, the present results do not support this in terms of the FA composition. Furthermore, thin-layer chromatography showed that the relative amount of sphingomyelin and free cholesterol in comparison with phosphatidylcholine is far less in LD than in DIGs. In addition to the ER, the LD of mammalian cells seem to be closely associated with other organelles. A close association of LD of beef heart with mitochondria has been reported, suggesting a role of the LD as a source for FA utilized for energy production by mitochondrial ß-oxidation. Cytoskeletal intermediate filament proteins, particularly vimentin, were detected forming a network in the vicinity of LD. The interaction of intermediate filaments and LD was confirmed by transmission electron microscopy and field-emission scanning electron microscopy.

2.2.2.2 **Protein Composition.** Little is known about proteins on the surface of mammalian intracellular LD. Two groups of proteins whose association with LD in animal cells is well documented are the perilipins and adipocyte differentiation related protein (ADRP). The human ortholog of ADRP has been termed adipophilin. Other proteins at or near the surface of the LD of adipocytes include the ''capsular'' proteins and vimentin. Furthermore, certain enzymes, for example, eicosanoid-forming enzymes, associate with LD in various types of cells.

Perilipins and ADRP Perilipins belong to a family of polypeptides that are expressed in adipocytes and steroidogenic cells of adrenal cortex, testes, and ovary. Two related classes of full-length cDNAs have been isolated that encode perilipins A and B from rat adipocyte cDNA expression library. Perilipin A and B, 56 kDa (517 aa) and 46 kDa, respectively, share a common amino-terminal sequence of 406 aa. Similar to adipocytes, steroidogenic cells express perilipin A, but these cells also contain relatively high amounts of perilipin C, a protein of approximately 42 kDa that is not detectable in adipocytes. Perilipins are encoded by a single copy gene that gives rise to the three protein isoforms by alternative mRNA splicing with perilipin A being the most abundant. In murine adipocytes, a forth perilipin, named *perilipin D*, occurs at the mRNA level. The perilipin D polypeptide, however, has not yet been reported. Perilipins exhibit sequence similarity to a few other proteins, one of which is ADRP. The amino termini of perilipin and ADRP are highly homologous at a region of approximately 100 aa. ADRP was first identified during a search for genes being expressed in an early stage of differentiation of murine adipocytes in culture. The mRNA of ADRP is present in various tissues and cultured cell lines. Immunocytochemical examination revealed that ADRP localizes to LD in murine 3T3-L1 adipocytes, murine MA-10 Leydig cells,

CHO fibroblasts, and human HepG2 hepatoma cells. In MA-10 Leydig cells, ADRP and perilipins colocalize to LD. In 3T3-L1 adipocytes, the two proteins were found on small LD although at different stages of differentiation. ADRP is present on these LD in early differentiated adipocytes and is then replaced by perilipins, which can only be found on the surface of the LD at a later growth stage. It was suggested that ADRP is involved in the management of TAG stores in nonadipose tissues. Interestingly, recently, ADRP was found to colocalize with insulin and at the LD surface in human islet cells. Incubation with glucose or FA alone and a combination of glucose and FA increased ADRP expression by 2- and 10-fold, respectively. Oleate induced ADRP expression more potently than palmitate, which correlated with higher levels of neutral lipid accumulation by islets. Consistent with increased ADRP expression, the initial uptake rate of FA in islet cells was elevated in islet cells treated with FA *plus* glucose compared with control cells. In addition, ADRP expression is considerably increased in ob/ob mice islets and its upregulation is tightly correlated with TAG accumulation in islets, demonstrating an inverse relationship with impairment of ß-cell function. Thus, ADRP may play a role in regulating TAG metabolism also in ß-cells and, in particular, be involved in the loss of ß-cell function during the pathogenesis of NIDDM.

Perilipins remain tightly bound to LD through alkaline carbonate or urea wash conditions, and require detergents to remove them. Stable expression of perlipin A in 3T3-L1 fibroblasts and subsequent immunofluorescence microscopy and immunoblotting revealed that neither the amino- nor the carboxyl-terminus is required to target perilipin A to LD. Full-length perilipin A is associated with LD via hydrophobic interactions, as shown by the persistence of perilipins on LD after centrifugation through alkaline carbonate solution. Mutagenesis studies indicate that the signals responsible for tight anchoring of perilipin A to LD are, most probably, multiple, partially redundant targeting sequences of moderately hydrophobic amino acids located within the 25% of the central domain. These signals seem to be, at least in part, constituted by the three regions of moderate hydrophobic character and the five domains with characteristics of amphipathic ß-pleated sheets (see below). Cytochemical analysis by immunogold labeling suggests that the perilipins are located on or within the limiting surface of the LD.

TIP47 A cDNA of another protein, named TIP47 or pp17, which has similarity to ADRP has also been described. TIP47/pp17 is a cargo protein involved in the trafficking of the mannose-6-phosphate receptor between endosomes and the Golgi network. Perilipin A, ADRP, and TIP47/pp17 exhibit strong sequence homology at their amino-terminal regions. Starting from the amino terminus, perilipin A contains a sequence of 105 aa similar to adipophilin and TIP47 (aa 17–121), five 10-aa domains with amphipathic ß-pleated sheet character (between aa 11 and 182), three sequences of moderate hydrophobicity (aa 243–260, 320–342, 349–364), a highly acidic region (aa 291–318), and six consensus sites for PKA phosphorylation. Two such hydrophobic regions and three areas of amphipathic ß-pleated sheet structure were detected in ADRP. A protein named S3-12 is also highly homologous to ADRP in a 33-aa repeated sequence. The mRNAs of perilipins, ADRP, and S3-12 are expressed much higher in adipose than in other tissues.

It was suggested that lipids regulate transcription of perilipin mRNA, because the amount of perilipin mRNA and the corresponding protein increase in the presence of exogenous lipids. In analogy, formation of the mRNA of ADRP and protein expression in preadipocytes was also shown to be stimulated by FA in a time- and dose-dependent way. Stimulation could be only achieved by long-chain FA, whereas the degree of saturation had no influence. Treatment of such stimulated cells with actinomycin D inhibited the expression of ADRP, suggesting that FA stimulate the gene expression at the transcriptional level. Recently, the protein expression of perilipin and ADRP in human muscle was studied in greater detail. Perilipin was detectable in biopsies of vastus lateralis muscle (VLM) only at levels consistent with adipocyte infiltration. ADRP was highly expressed in VLM, irrespective of whether derived from obese nondiabetic or diabetic subjects. Weight loss of the latter led to increased whole-body insulin sensitivity and ADRP content in VLM. Treatment of the obese nondiabetic subjects with either troglitazone or metformin in combination with glibenclamide considerably improved the glycemic control, as reflected in lowering of HbA1c and plasma fasting TAG levels, which was well correlated to post-treatment increases in ADRP expression in VLM. These results demonstrate that ADRP is the predominant LD-associated protein in VLM and that its expression is upregulated under conditions of improved glucose tolerance. It is tempting to speculate that increased expression of ADRP may act to sequester FA in TAG of LD contained in skeletal muscle and thereby protects the muscle from the inhibitory (''lipotoxic,'' see above) effects of FA (or derivatives thereof) on insulin signaling and action. In consequence, this study provided additional evidence that TAG in LD represents the ''benign'' storage form of FA and accumulates during overfeeding of myocytes and β-cells with FA, which is compatible rather than interferes with insulin action and secretion, at least up to a certain extent of LD deposition.

CGI-58 Recent studies have expanded the list of LD-associated proteins to include several with known enzymatic functions in sterol synthesis and lipid metabolism, as well as numerous proteins with unknown functions. Recently, the identification of CGI-58 as a component of LD isolated from cultured 3T3-L1 adipocytes was reported. The name CGI-58 derives from a Comparative Gene Identification initiative that annotated 150 novel transcripts conserved between *Caenorhabditis elegans* and humans. CGI-58 is a member of the esterase, thioesterase, and lipase subfamily of α/β-hydrolase fold enzymes. The protein sequence includes a highly conserved active site that, in most α/β-hydrolases, includes a nucleophilic serine residue known to be important in catalysis. Interestingly, the CGI-58 sequence encodes an asparagine in place of this catalytic serine. Significantly, eight different mutations in CGI-58 were recently identified as causative factors in Chanarin–Dorfman Syndrome, a neutral lipid storage disorder (NLSD) characterized by ichthyosis, hepatic steatosis, and hepatomegaly, developmental defects, and the accumulation of TAG-containing LD in leukocytes, basal keratinocytes, hepatocytes, myocytes, and other cells. The eight mutations known to lead to NLSD include truncations, null alleles, and three distinct point mutations. This suggests that the lipid storage phenotype of NLSD most likely arises from loss

of function of CGI-58, leading to excessive storage of TAG in LD.

CGI-58 mRNA is highly expressed in adipose tissue and testes, tissues that also express perilipins, and at lower levels in liver, skin, kidney, and heart. Both endogenous CGI-58 and an ectopic CGI-58-GFP chimera show diffuse cytoplasmic localization in 3T3-L1 preadipocytes, but localize almost exclusively to the surfaces of LD in differentiated 3T3-L1 adipocytes. The localization of endogenous CGI-58 was investigated in 3T3-L1 cells stably expressing mutated forms of perilipin using microscopy. CGI-58 binds to LD coated with perilipin A or mutated forms of perilipin with an intact C-terminal sequence from amino acid 382 to 429, but not to LD coated with perilipin B or mutated perilipin A lacking this sequence. Immunoprecipitation studies confirmed these findings, but also showed coprecipitation of perilipin B and CGI-58. Remarkably, activation of PKA by the incubation of 3T3-L1 adipocytes with isoproterenol and isobutylmethylxanthine disperses CGI-58 from the surfaces of LD to a cytoplasmic distribution. This shift in subcellular localization can be reversed by the addition of propranolol to the culture medium. Thus, CGI-58 binds to perilipin A-coated LD in a manner that is dependent upon the metabolic status of the adipocyte and the activity of PKA.

The CGI-58 binding site was mapped to a sequence of 48 aa between positions 382 and 429 near the C terminus of perilipin A; this sequence spans the junction at aa405 where the sequences of perilipin isoforms A and B diverge. Consistent with these results, CGI-58 failed to localize to LD coated with perilipin B, suggesting that a portion of the unique C terminus of perilipin A is required for binding. The deletion of short sequences between aa382 and 429 failed to identify a smaller binding site, suggesting that either CGI-58 binds to multiple sequences spread throughout the region, or the intact 48aa sequence is required to fold into a conformation that exposes a smaller binding interface. The data obtained from coimmunoprecipitation experiments were mostly consistent with cell-based experiments; however, a notable difference was the coprecipitation of CGI-58 with perilipin B. Since perilipin B contains the sequence from aa382 to 405, the results suggest that the position or conformation of a partial docking site for CGI-58 may be altered by the unique 17-aa sequence of perilipin B (406–422) when perilipin is associated with LD, but exposed when cells are lysed, and the proteins are solubilized away from LD.

Interestingly, CGI-58 translocates off of adipocyte LD and disperses throughout the cytosol when lipolysis is stimulated, suggesting that CGI-58 may play a role in lipid metabolism either when it is bound to LD under basal conditions, or during its movement away from LD following activation of PKA. While the phosphorylation of PKA sites 1 and 2 of perilipin A is unnecessary for the displacement of CGI-58 from LD, mutations altering PKA sites 4, 5, and 6 attenuate dispersion. Since CGI-58 contains at least one PKA consensus site, it is likely that the phosphorylation of serines in PKA consensus sites of both perilipin A and CGI-58 are required for the full dispersion of CGI-58 into the cytoplasm. Thus, the perilipin-dependent binding of CGI-58 to LD is modulated by the activation of PKA. It was hypothesized that perilipins form a scaffold at the surfaces of adipocyte LD that serves as an organizing center for lipid metabolic enzymes and transporters that is altered by metabolic signals. While proteins including CGI-58

bind to perilipin-coated LD under basal conditions, other proteins, such as HSL, are recruited to LD when perilipins have been phosphorylated by PKA. Under the latter conditions, protein components of basal LD may be displaced to accommodate association of the lipolytic machinery.

The role of CGI-58 in lipid metabolism remains to be elucidated. CGI-58 is a member of the α/β-hydrolase fold subfamily of lipases, esterases, and thioesterases. Mutations of human CGI-58 are responsible for excessive TAG storage in many types of cells. Studies of TAG metabolism in fibroblasts from NLSD patients show that CGI-58 is required for normal rates of TAG turnover. However, TAG lipase activity in NLSD cell lysates was comparable to that of control cells. Additionally, the rate of TAG clearance increased in NLSD cells incubated with triacsin C, an inhibitor of acyl-CoA synthetases, although not quite to the higher rates observed in control cells. These observations suggest that lipolysis occurs in NLSD cells, but that TAG clearance is blunted by rapid reesterification. Thus, CGI-58 is a factor that is required to assist TAG clearance, but may not be a lipase.

CGI-58 shows a subcellular localization pattern that is paradoxically opposite to that of HSL. CGI-58 disperses off LD when HSL translocates onto the LD, and the rate of lipolysis becomes elevated. Interestingly, basal rates of lipolysis are relatively normal in adipocytes isolated from HSL null mice, suggesting that as yet uncharacterized mechanisms catalyze TAG turnover under basal conditions. Thus, CGI-58 may interact with perilipin-coated LD to play a role in basal TAG hydrolysis. Alternatively, CGI-58 may function to transport products of lipolysis away from LD following the activation of PKA and the dispersion of CGI-58 into the cytosol. Since adipose TAG metabolism appears not to be severely compromised in NLSD patients, it is likely that adipocytes have redundant mechanisms to avoid the detrimental effects of mutations in CGI-58. Thus, despite much lower levels of expression, CGI-58 may play a more critical role in TAG catabolism in nonadipose tissues.

Other reports have described CGI-58 as a component of LD isolated from oleic acid-treated Chinese hamster ovary cells and cultured human epithelial cells, cells that lack perilipins but instead, coat LD with adipophilin. Furthermore, CGI-58 has been identified as a perilipin-binding protein by yeast two-hybrid assay using the N-terminal sequence of perilipin from aa 1 to 250 as bait. Direct binding between recombinant CGI-58 and recombinant truncated perilipin A that included aa 1–416 was demonstrated. In contrast, CGI-58 binding to LD in intact cells requires sequences in the C terminus of perilipin A, but not the N terminus. Interaction between CGI-58 and adipophilin by yeast two-hybrid and GST pull-down assays using recombinant proteins was also reported. In contrast, significant localization of CGI-58 to lipid droplets in 3T3-L1 preadipocytes was not found. Furthermore, the PAT family of proteins (perilipin, ADRP, TIP47) is highly conserved within N-terminal sequences, but structurally divergent in the C termini, where a binding site for CGI-58 on perilipin A has been identified.

Adipophilin Adipophilin (ADPH) is a prominent LD-associated protein found in many mammalian cell types, including hepatocytes, adipocytes, muscle cells, and mammary epithelial cells, either during development or in the mature functioning cell. ADPH has proposed functions in LD formation, FA transport, and milk lipid

secretion. Although it can be detected at the plasma membrane in mammary epithelial cells as a result of milk globule secretion, the weight of evidence suggests that ADPH specifically targets LD. However, little is known about the structural and biochemical properties involved in its association with LD or how it accomplishes its biological functions. Genetic analysis has demonstrated that ADPH is related to the family of LD-associated proteins that include perilipin (see above) and the mannose-6-phosphate receptor targeting protein TIP47, through a conserved region in their amino-termini, called the ''PAT'' domain (perilipin, ADPH, TIP47). The lack of significant sequence conservation outside this region indicated that it is an important determinant in the association of these proteins with LD. However, a recent study revealed that neither the PAT domain nor the carboxy-terminal half of ADPH is required for efficient targeting to or biogenesis of LD, but that, nevertheless, specific regions located elsewhere within ADPH are responsible for LD targeting. Previous work indicates that secretion of LD from mammary epithelial cells during lactation involves the formation of a tripartite complex between ADPH, the mammary-specific transmembrane protein, butyrophilin, and xanthine oxidoreductase. As formation of such a complex probably involves regions of ADPH distinct from those involved in LD targeting, the PAT domain or the carboxy-terminal half of ADPH may represent candidate regions for interaction with butyrophilin and/or xanthine oxidoreductase to trigger LD secretion.

Caveolins In primary and cultured adipose cells, caveolin-1 and caveolin-2 constitute a framework of caveolae that represent bulb-shaped plasma membrane invaginations (50–100 nm in size) enriched in cholesterol, (glyco)sphingolipids (sphingomyelin) as well as glycolipids (gangliosides, GPI lipids) and harboring a special set of (dually acylated) signaling proteins, glycosyl-phosphatidylinositol-anchored (GPI) proteins and the caveolae structural and marker proteins, caveolin 1–3. Based purely on ultrastructural comparisons and tissue expression profiles, the adipocyte seems to have the highest concentrations of caveolae and the highest levels of caveolin-1 and -2, that is, more than any other cell type. Indeed, electron micrographs of adipocytes dating back to 1963 show that caveolae account for up to 30% of the surface area of the adipocyte plasma membrane. Furthermore, in 3T3-L1 adipocytes, a widely used model system for studying adipogenesis, the number of caveolae increases 9-fold, and caveolin-1 and -2 expression increases 20-fold during differentiation from fibroblasts to the adipocyte state.

Caveolins are supposed to anchor to the plasma, Golgi, and ER membranes by the central hydrophobic domain with both amino- and carboxy-termini exposed to the cytoplasm. Caveolae fulfil important functions in protein and lipid/cholesterol transport (endocytosis, potocytosis, transcytosis, polarized transport) as well as in signal transduction. Caveolin-2, especially its ß-isoform, has been shown being targeted to the surface of LD, by immunofluorescence and immunoelectron microscopy, and by subcellular fractionation. Brefeldin A-treatment induced further accumulation of caveolin-2 along with caveolin-1 in LD. Analysis of mouse caveolin-2 deletion mutants revealed that the central hydrophobic domain (aa 87–119) and the amino-terminal (aa 70–86) and carboxy-terminal (aa 120–150) hydrophilic domains are all

necessary for the localization in LD. The amino- and carboxy-terminal domains appeared to be related to membrane binding to and exit from ER, respectively. This implies that caveolin-2, which is synthesized on cytosolic ribosomes and then incorporated into the ER membrane in posttranslational fashion, is transported to LD as a membrane protein. Thus, caveolin-2 seems to differ from the hitherto reported LD proteins, such as the perilipins, in that it exists as an integral membrane protein in the ER and plasma membrane. As anticaveolin-2 antibody, recognizing the N-terminal segment, decorated only the P face of LD in a freeze-fracture replica, caveolin-2 may take the same orientation on the LD surface as in the membrane. This is consistent with the hypothesis that the LD surface is a half-membrane, or a phospholipid monolayer, with amphiphilic lipid molecules with their hydrophilic and hydrophobic portions oriented toward the cytoplasm and the LD content, respectively. No labeling for caveolin-2 was seen in the LD surface, but was found in small clusters both in cryosections and in freeze-fracture replicas. The labeling for adipophilin shows the same pattern at the LD surface. These results suggest that the whole LD surface may not be homogeneous and that some segregation may occur in the half membrane. Interestingly, a recent study revealed unesterified cholesterol in LD. Furthermore, LD of eosinophils contain proteins typical for DIGs related to intracellular signaling, such as MAPK (mitogen-activated protein kinases) and Lyn. Together, these results suggest, intriguingly, that LD might be a novel membrane domain where caveolins may functionally regulate signaling proteins.

The recruitment of caveolin-1 to LD in BFA-treated cells may also be due to the hydrophobic domain shared by all caveolins. However, caveolin-1 does not appear to have the same degree of affinity for LD as caveolin-2. First, in cells expressing caveolin-1 alone, its redistribution to LD after BFA-treatment occurred slowly and only in some cells. Second, without the BFA-treatment, caveolin-1 was not found in LD even when overexpressed. The LD localization signal of caveolin-1 is likely to be less effective than that of caveolin-2. Endogenous caveolin-2 was not detected in LD under normal culture conditions. This may be because caveolin-2α, expressed predominantly in most cells, is less efficient than caveolin-2ß in LD targeting. But the accumulation of caveolin-2 in LD is transient, so that its distribution in LD can only be detected when the protein is expressed abundantly or when its trafficking is perturbed. The apparent morphological continuity of ER and LD and the persistence of LD labeling in BFA-treated cells indicate that caveolin-2 goes directly from ER to LD. Whether LD exists independently from the ER-Golgi pathway, or LD is an intermediate compartment between ER and Golgi, is not known. The results of BFA experiments may simply indicate that an excess of caveolin-2 in ER overflowed to LD. However, BFA might also block other pathways (e.g. from LD to the Golgi) and have caused LD retention. The two pathways are not mutually exclusive and need further studies for definition. Trafficking of caveolins to LD is important because it may be linked to that of TAG molecules. A testable question is whether the TAG composition of LD is changed by the presence of caveolins and/or by BFA-treatment. Also, if and how is LD related to the reported trafficking routes of caveolin-1? Interestingly, overexpression of a mutant caveolin-3 in BHK cells leads to its association with the

surface of large LD containing TAG and endogenous caveolins 1 to 3. Fluorescence, electron, and video microscopy observations are consistent with formation of the LD by maturation of subdomains of the ER. The mutant caveolin caused the intracellular accumulation of free cholesterol in late endosomes, a decrease in surface cholesterol, and a decrease in cholesterol efflux and synthesis. Incubation of the cells with oleic acid induced a significant accumulation of wild-type caveolins in the enlarged LD. Taken together, the available data hint at a role of caveolins in LD biogenesis.

2.2.2.3 **Biogenesis of LD.**

Role of Caveolins LD biogenesis is incompletely understood. The observations presented above suggest that although the caveolins are not normally associated with internal lipid compartments and particles, such as LD, they can certainly traffic to these locations under certain conditions. As such the caveolins represent the first known integral membrane protein components of LD. This characteristic may also explain the initially surprising finding that caveolin-1 can behave as a soluble protein. Immunogold labeling first detected soluble caveolin-1 in the lumen of the ER after cells were exposed to cholesterol oxidase for conversion of cholesterol at the outer leaflet of the plasma membrane into cholesterone. However, it remained a mystery how caveolin-1 as an integral membrane protein firmly embedded in the cytoplasmic leaflet of the (ER) membrane can move to the luminal leaflet for subsequent release into the lumen. Subsequently, a small pool of soluble caveolin-1 was found in the cytosol of fibroblasts in a complex with chaperones. Finally, the analysis of caveolin-1 distribution in different cell types revealed targeting of caveolin-1 to the cytosol (skeletal muscle cells and keratinocytes), and to the lumen of secretory vesicles (serous cells of the pancreas, fundic stomach, and salivary gland). Both the secreted and the cytosolic caveolin-1 exhibited characteristics for incorporation in lipoprotein-like particles, which may explain their apparent solubility. Several groups provided additional evidence that the cytosol of many cells contains a pool of apparently ''soluble'' and ''lipoprotein-like'' caveolin-1. This caveolin-1 is associated with cholesterol and behaves like a protein that is embedded in a particle with the size and buoyant density of HDL. Interestingly, caveolin-1 is secreted by exocrine secretory cells in HDL-like particles that contain apoA-1, raising the possibility that caveolin-rich lipid particles in the cytoplasm are involved in the assembly of secreted lipoproteins.

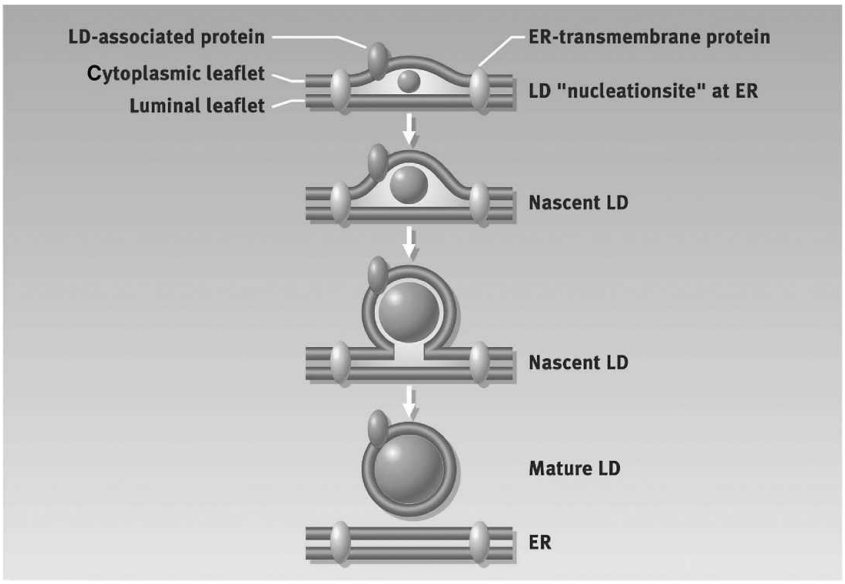
On the basis of the structure of caveolins, with their long stretch of hydrophobic amino acids acting as membrane-anchoring domain, it is unlikely that they can switch the ''membraneous'' into a true ''soluble'' conformation compatible with the aqueous milieu of the cytosol. Rather, the involvement of caveolins in the biogenesis of various lipid particles by budding from either the cytoplasmic or the luminal leaflets of the ER membrane may explain their cell type–specific localization either in the cytosol (as LD or as precursor particles for milk lipid granules destined for budding from the plasma membrane) or in the lumen of the ER and secretory vesicles (as nascent lipoproteins destined for movement along and release by the secretory pathway), respectively. This unifying concept for the biogenesis of apparently ''soluble'' and ''membraneous'' caveolin-containing structures requires a ''flip-flop'' mechanism for translocation of caveolins

from the cytoplasmic ER membrane leaflet (with amino- and carboxy termini exposed to the cytoplasm) to the luminal ER membrane leaflet (both termini exposed to the lumen), which may be induced during cholesterol depletion (e.g. by cholesterol oxidase). In conclusion, caveolin-1 can be integrated in (one leaflet of) various cellular membranes (plasma membrane, Golgi, ER, caveolae) or in (the phospholipid monolayer of) various cytosolic and secreted lipoprotein-like particles (LD, milk lipid granules, lipoproteins) and in each case may regulate the accessibility of these structures toward degradation by (phospho)lipases in a way similar to that now commonly accepted for perilipins.

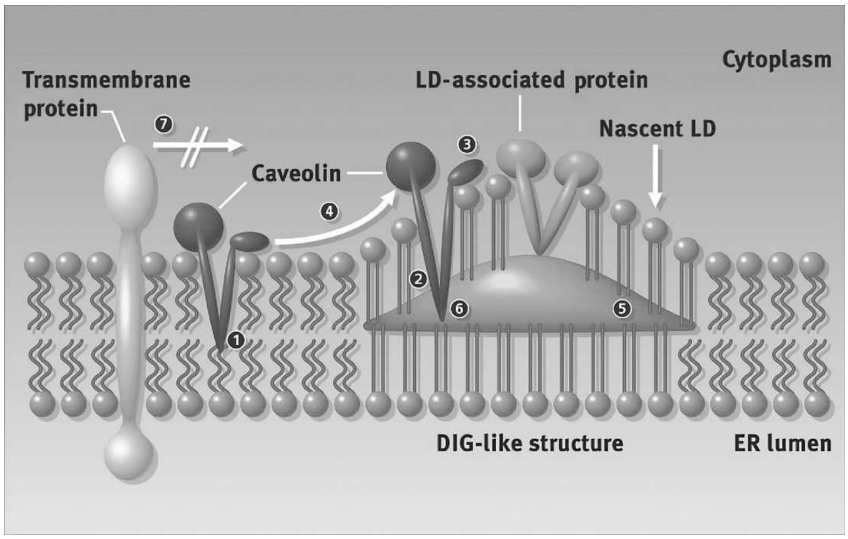
Taken together, the prevailing model for LD biogenesis rationalizes that caveolins (but not most other membrane proteins) might be able to enter the LD (Fig. 3). Since LD are surrounded by a phospholipid monolayer and are thought to be derived from the ER, where TAG and cholesterylesters are synthesized (see above), it is tempting to speculate that TAG accumulate in the hydrophobic core of the bilayer, forming a bulge that eventually buds from the ER membrane to form free LD (Fig. 3a). Accumulation of TAG in the bilayer core would initially force opposite leaflets of the bilayer apart, increasing bilayer thickness. Such a thickened bilayer could not accommodate transmembrane proteins that have hydrophilic domains on both sides of the membrane and these proteins would be excluded from the forming LD (Fig. 3b). Caveolins, by contrast, lack luminal hydrophilic domains, and could diffuse freely between the ER membrane and the monolayer surrounding the nascent LD. Thus, caveolins would not need to dissociate from the ER membrane and expose their hydrophobic domains to the cytosol to enter the LD (Fig. 4, steps 1 and 2). This model suggests that caveolins can enter LD only while they are forming and are still in contact with the ER. Consequently, accumulation of caveolins in the ER would trigger their targeting to LD and concomitantly LD biogenesis. Alternatively, transport of caveolins from the plasma membrane and/or Golgi apparatus to the ER via a retrograde pathway might somehow lead to LD targeting. If caveolins normally pass through LD during biosynthetic transport or intracellular cycling, they must exit the LD rapidly as they are not normally (i.e. absence of BFA, wild-type caveolin) detected there.

Although it is unclear how ER accumulation of caveolins might lead to an apparent concentration of the proteins in LD, several possible explanations can be imagined. First, caveolins might have a high affinity for LD, either through specific binding to a protein or (phospho)lipid of the LD, or through preference of caveolin for the physical state of the LD phospholipid monolayer or TAG core leading to its spontaneous partitioning. Efficient packaging of caveolins into transport vesicles might normally prevent entry into the LD. Accumulation in the ER might saturate some component of the transport machinery, possibly a specific cargo receptor, giving the protein time to access the LD. Alternatively, accumulation of caveolins in the ER might change the properties of the ER membrane. The altered properties might increase the affinity of caveolins for LD, either by changing the physical properties of the membrane or by inducing a conformational change in caveolins.

Role of Perilipins In LD, accumulation of perilipins and TAG occurs roughly in parallel. When FA synthesis was inhibited, the concentration of TAG decreased by 90% and correspondingly the amount



(a)



(b)

Fig. 3 ''Budding'' model for the biogenesis of intracellular LD. (a) LD formation is initiated by accumulation of TAG between the leaflets of the ER membrane. During budding of the forming LD, typical transmembrane proteins with hydrophilic domains protruding into the ER lumen and cytoplasm are segregated from membrane proteins, anchored in the outer leaflet, only, such as caveolin. After detachment of the matured LD from the ER membrane, the TAG core of the LD is surrounded by a phospholipid monolayer with embedded caveolin having both its amino- and carboxy-terminus exposed to the cytoplasm. (b) The topology and segregation of transmembrane proteins and caveolin are shown in greater detail. See text for detail.

of perilipin dropped. The availability of only a small amount of TAG may cause formation of small LD with insufficient surface space for the association of perilipin. Decreased synthesis of FA resulting in liberation of FA from TAG may lead to subsequent detaching of perilipin from the surface of the shrinking LD and subsequent degradation of the protein. Undifferentiated 3T3-L1 fibroblasts transfected with constructs that encode perilipin A accumulate numerous small LD that are associated with perilipin A. These results indicate that appropriate targeting of perilipins is not restricted to adipocytes or steroidogenic cells, and further suggests that perilipins may serve as nucleation sites for TAG deposition (Fig. 2). As nearly all cells can synthesize TAG, the formation of LD in the transfected fibroblasts may reflect trapping of TAG in perilipin-bound structures. This is compatible with the observed consequences of introducing perilipin A into other cells that do not normally express this protein. It remains to be demonstrated, however, whether perilipins are directed toward LD, or *vice versa* LD are transported to perilipin aggregates, or association of both components occurs in parallel (Fig. 4).

Growth Adipocyte differentiation in WAT involves the coalescence of small nascent LD to form the one or more large LD found in mature cells. By contrast, most other cell types contain numerous smaller LD (see above). In adipocytes, cytoskeletal intermediate filament proteins, particularly vimentin, form cages around small LD and thereby prevent the latter from fusing (Fig. 4, step 3). Indeed, a vimentin network is seen near LD in newly

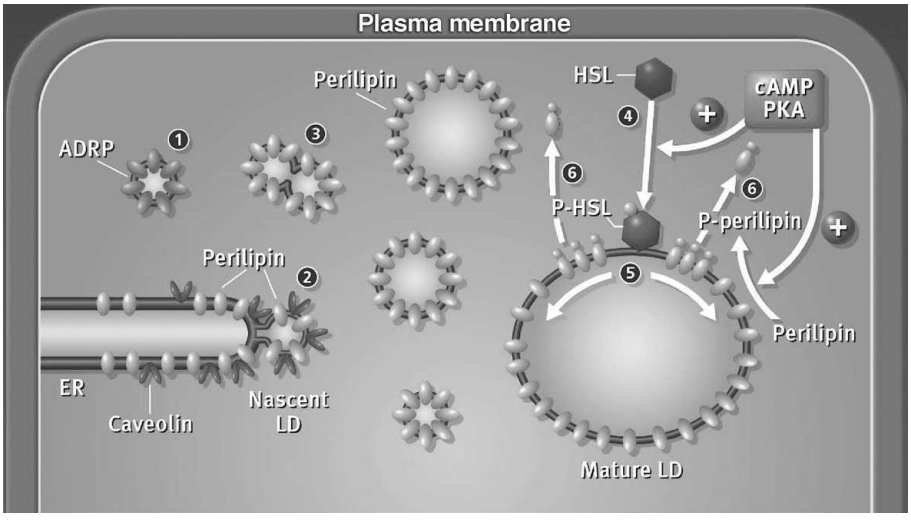


Fig. 4 Hypothetical model for integration of the major mechanisms of TAG storage and mobilization: (1) conversion of fibroblasts/preadipocytes into adipocytes, (2) biogenesis of forming LD at the ER membrane, (3) fusion of smaller LD to mature LD, (4) translocation of HSL from the cytosol to the surface of LD, (5) disassembly and reorganization at the LD surface of perilipin and (6) its translocation from LD to the cytosol. Both processes may contribute to relieve the barrier that prevents HSL from gaining access to the LD. PKA-dependent phosphorylation is depicted as filled circles. See text for details.

differentiating adipocytes. As the cells mature, a decrease in the number of vimentin fibers coincides with, and might play a role in, LD coalescence. In fact, in 3T3-L1 fibroblasts, expression of a dominant-negative vimentin reduces the formation of LD. However, the involvement of vimentin in LD biogenesis came under debate when knockout mice lacking vimentin were shown to exhibit normal biosynthesis of adipocyte LD, even though no compensatory formation of other intermediate-filament proteins could be demonstrated. Nevertheless, coalescence of adipocyte LD must be highly regulated – given the 1000-fold difference in the volume of LD in white and brown adipose tissue – but the mechanism of adipocyte LD maturation remains to be elucidated.

Cell-Free System Very recently, a microsome-based, cell-free system containing substrates for TAG synthesis and a phospholipase D-activating protein was introduced that assembles newly formed TAG into spherical LD. These LD were recovered in the low-density fraction by gradient ultracentrifugation and were similar in size and appearance to those isolated from rat adipocytes and 3T3-L1 fibroblasts. Caveolin-1 and -2, vimentin, ADRP, and the 78-kDa glucose–regulated protein, GRP-78, were associated with LD from this cell-free system. The caveolin was soluble in 1% TX-100, as was the caveolin on LD from 3T3-L1 cells. These data suggest that caveolin is released from the microsomes along with LD, indicating that caveolin may help sort newly formed TAG from the ER into a cytosolic form in a budding process of LD from the ER membrane. The ADRP on the LD was also derived from the microsome-associated pool, suggesting that it can be targeted to the ER membrane. ADRP can be acylated and these acyl moieties may participate in the interaction between ADRP and the membrane, since covalently linked FA are involved in the membrane targeting of other proteins (e.g. ADP ribosylation factor-1). Thus, ADRP binds to the microsomal membrane and participates in the budding of the small LD. Perilipins were not expressed in the 3T3-L1 fibroblasts used to prepare the microsomes and consequently were not present in the partially purified cytosolic phospholipase D activator preparation. Therefore, perilipins were not present on the LD assembled in the cell-free system. Consequently, small LD can be assembled in the absence of perilipins. GRP-78 is a chaperon protein that contains a KDEL sequence and is therefore restricted to the ER/Golgi region of the secretory pathway. GRP-78 appeared to be present on the cytosolic side of the surface layer of LD, suggesting that the surface layer is derived from the membrane of the ER. This agrees with the model proposed for the assembly of LD (see above), according to which the TAG will, during the biosynthesis, ''oil-out'' between the leaflets of the ER bilayers (Fig. 3). The LD formed by complete budding from the ER would be covered by a phospholipid monolayer and proteins originally bound to both the luminal and cytosolic surface of the ER membrane.

The LD from the cell-free system, like those from 3T3-L1 cells, contained TAG, DAG, phosphatidylcholine, phosphatidylethanolamine, and phosphatidylserine. The assembly of these LD-like structures depended on the rate of TAG biosynthesis and required an activator present in the high-speed supernatant from homogenized rat adipocytes. The activator-induced phospholipase D activity, and its effect on the release of the LD from the microsomes, was inhibited by butan-1-ol or 2,3-diphosphoglycerate.

The activator could be replaced by a constitutively active phospholipase D or its product, phosphatidic acid. In conclusion, LD seem to be formed from regions of the microsomal membrane that contain caveolin, vimentin, and ADRP in a process that depends on DGAT activity and is driven by the activity of a phospholipase D and the formation of phosphatidic acid. Phosphatidic acid acts as an intracellular messenger or as cone-shaped lipid that alters the curvature of the membrane. Its formation seems to be important for the fission of transport vesicles. Recent data suggest that it plays a role in (regulation of) the budding step within the biogenesis of LD, as has previously been proposed for the assembly of VLDL in the ER lumen.

Targeting Mechanism Three studies have addressed the question of how LD-associated proteins accumulate at the monolayer surface of LD during their biogenesis. Amino-terminal truncation mutants of caveolin-1, -2, -3, among them Cav-3DGV, are targeted to LD (and the early Golgi). Overexpressed caveolin-2 was found to be associated with LD (and the Golgi). Caveolin-1 with an ER retention signal fused to its carboxy terminus, such as Cav-1KKSL, as well as an internal-deletion mutant of caveolin-1, are highly concentrated in LD (and the ER and Golgi, respectively). Furthermore, blockade of the anterograde transport along the secretory pathway by Brefeldin A leads to increased expression of endogenous caveolin at the surface of LD. Consequently, (transient) accumulation of caveolins at the ER as a result of overexpression or impaired release into the secretory pathway during a folding defect caused by the mutation or by Brefeldin A-treatment may be sufficient for their efficient partitioning from the cytoplasmic membrane leaflet of the ER to the phospholipid monolayer of LD. According to this view, the association of caveolins with LD under physiological conditions, rather than the unusual experimental conditions of inefficient transport, has still to be demonstrated.

The LD-associated proteins described so far can be classified on the basis of their biosynthesis and topology: ADRP, perilipins, and HSL are translated on free ribosomes and recruited to the LD from the cytosol as a type of peripheral membrane protein, the latter two shuttling between the LD and the cytosol in reversible fashion in response to the nutritional state of the adipocyte (see below). Caveolins are cotranslationally inserted into the ER in a signal-recognition-particle-dependent fashion, with their central hydrophobic domain penetrating into the ER cytoplasmic membrane leaflet and the two flanking hydrophilic domains extending into the cytoplasm (Fig. 3b, step 1). Maintaining this topology the caveolins would diffuse laterally from the bulk ER to the surface phospholipid monolayer of nascent LD still attached to the ER without exposing their hydrophobic domains to the cytosol, whereas transmembrane proteins would be excluded from the LD (Fig. 3b, step 4). However, the apparent concentration of proteins at LD requires additional specific targeting information and deciphering mechanisms, albeit a consensus sequence for LD targeting has not been identified. The proteins could interact directly with phospholipids located at the LD surface (Fig. 3b, step 2) or with TAG deposited in the LD core (step 6) or with other LD proteins (step 3). Since LD probably arise (also) *de novo* (in contrast to the biogenesis of membranes) in the absence of preformed structures that could function as nucleation or docking sites for the incorporation of newly synthesized

LD proteins, some LD proteins have to come into direct contact with phospholipids/TAG of the LD and discriminate them from those of the ER. Caveolins represent candidates for LD proteins triggering the initial biogenetic steps of LD assembly on the basis of their high affinity for DIGs, which are characterized by tight packing and a high degree of order of their (saturated) lipid acyl chains (see above). The apparent affinity of caveolins for LD may well rely on their affinity for DIGs, which is supported by the finding that the LD-targeted Cav-3DGV mutant resists solubilization by cold nonionic detergent, as is true for typical DIG-associated proteins. Consequently, a physical state of the LD surface monolayer distinct from the ER cytoplasmic leaflet and more ''DIG-like'' may attract typical LD proteins, such as caveolins (Fig. 3b, step 7). However, putative targeting information encoded by the ''DIG milieu'' of nascent LD is not compatible with a recent more detailed analysis of the phospholipids contained in LD and DIGs, which did not reveal close similarity with regard to length and saturation of the constituent FA (see above). Alternatively, contact of the TAG molecules in the LD core with the phospholipids of the LD surface (Fig. 3b, step 5) might trigger a tight packing of the latter, creating a special lipidic environment that causes the selective recruitment of certain phospholipids and proteins to nascent LD.

3 Mechanism and Regulation of TAG Mobilization

3.1 HSL

HSL activity was first identified in 1964 as an epinephrine-sensitive lipolytic activity in adipose tissue. It was named according to its property of being activated by hormones such as catecholamines, ACTH, and glucagon. In 1981, the isolation of a relatively pure and biologically active HSL from rat adipocytes was reported. First cDNA clones were isolated for both rat and human HSL in 1988 and the structure of the gene for human HSL was elucidated in 1993. The rat and human cDNAs predict 768 and 775 amino acids, respectively, which is in good agreement with the molecular mass of 84 000. Despite 82% identity between the amino acid sequence of rat and human HSL and their similar molecular masses, human HSL migrates exhibit slightly lower electrophoretic mobility during SDS-PAGE compared to rat HSL, that is, 88 versus 84 kDa. HSL has a uniquely broad substrate specificity, hydrolyzing with varying efficacy tri-, di- and monoacylglycerols, as well as cholesteryl, steroid fatty acyl, retinyl and *p*-nitrophenyl esters. However, HSL lacks detectable phospholipase activity. HSL prefers cleavage of DAG (10- and 5-fold vs. TAG and MAG, respectively) and the 1- or 3-ester bond of its acylglycerol substrate (4-fold vs. 2-ester bond) esterified to polyunsaturated and shorter versus saturated and longer FA. Phosphorylation under standard *in vitro* assay conditions leads to moderate increases in activity against TAG and cholesterylesters, but not against DAG and MAG. It remains to be clarified whether phosphorylation of HSL provokes differential effects on its activity also *in vivo*. Rat adipocyte HSL was recognized to exist as a dimer in solution according to gel chromatography and sucrose gradient centrifugation. This finding was then confirmed using the human recombinant HSL and sedimentation equilibrium analysis. Kinetic studies finally revealed that the HSL functional dimer is characterized

by greater maximal activity with no difference in substrate affinity compared to its monomeric subunits.

Reflecting on its unique catalytic and regulatory properties, HSL exhibits only minimal sequence similarity with enzymes of the lipase gene family. On the basis of inhibition of HSL activity by diisopropylphosphofluoridate and the covalent linkage of this inhibitor to the HSL protein, HSL has been categorized as a serine esterase. The Gly-X-Ser-X-Gly motif contains the catalytic serine in most lipases, and HSL contains this consensus pentapeptide (Gly-Asp-Ser-Asp-Gly). Site-directed mutagenesis has confirmed that the serine of this pentapeptide is within the catalytic site of HSL. Human HSL also exhibits a region of similarity with lipase 2 of *Moraxella* TA144, an antarctic bacterium that hydrolyzes lipids at low temperature. Strikingly, HSL also manages to cleave TAG with higher efficacy at reduced temperatures compared to other mammalian lipases. The higher order domain structure of HSL could not be derived from the amino acid sequence. Two different functional domains – the catalytic domain and the regulatory domain – are encoded by different exons of the human gene suggesting the mosaic nature of the HSL protein. However, the overall lack of homology with other lipases precludes assignment of specific functions to different regions of the protein. Other lipases with little primary sequence homology display highly similar structural features based on crystal structure, but the crystal structure of HSL is urgently needed to gain further information. Detailed biochemical studies have provided evidence for the existence of a distinct lipid-binding domain that is separate from the catalytic region. Mild proteolysis of HSL with trypsin almost completely destroyed its activity against trioleoylglycerol with only marginal reductions against water-soluble *p*-nitrophenylbutyrate, indicating that HSL contains a lipid-binding domain. As trypsin treatment generates a stable 17.6-kDa fragment, it is reasonable to assume that HSL is composed of separately folded protease-resistant domains joined by short protease-sensitive linker regions. Studies on interfacial activation, that is, enhancement of lipolytic activity by the presence of a lipid-water interface, provided additional evidence for the existence of a separate lipid-binding domain. Intact HSL is activated by the presence of phospholipid vesicles or emulsified trioleoylglycerol, but these lipids have no effect on activity of the 17.6-kDa fragment on the water-soluble substrate, strongly suggesting that proteolysis has separated the lipid-binding domain from the catalytic domain. A more stable peptide comprising aa 1–323 can be generated by prolonged incubation of HSL with endoproteinase Lys-C suggesting that this fragment represents a separate structural domain. Circular dichroism and fluorescence spectroscopy analyzes during denaturation with guanidine hydrochloride and heat revealed two major steps of unfolding, which is in agreement with the existence of two distinct structural domains.

The amino-terminal 323-aa domain of possibly globular structure is encoded by exons 1–4 and has no primary or secondary structural similarity with known proteins, but interacts with the adipocyte lipid-binding protein, ALBP. The carboxy-terminal portion of HSL is similar to acetylcholinesterase, bile salt-stimulated lipase and several fungal lipases, and is composed of $\alpha/ß$-hydrolase folds that constitute the catalytic site. The secondary

structure elements that constitute this scaffold are expected to be within regions formed by amino acids 332–535 and 688–766 (rat). Despite lack of significant primary sequence homology, the organization of the secondary structure predicted for the carboxy-terminal 450-aa of HSL is similar to the secondary structure of two fungal lipases from *Geotrichum candidum* and *Candida rugosa*. Secondary structure prediction in this region allowed the identification of the central elements of these α/ß-hydrolase folds according to which a three-dimensional model for this domain was proposed. Elucidation of the crystal structure for the Brefeldin A esterase from *Bacillus subtilis*, a protein with significant homology to HSL, confirmed the usefulness of this approach. On the basis of molecular modeling, it was proposed and later confirmed by site-directed mutagenesis, that Ser423, Asp703, and His733 (rat) constitute the catalytic triad for HSL and are found within this carboxy-terminal region. This portion is interrupted by the 150-aa regulatory module, which according to secondary structure prediction, does not contain α-helices and ß-sheets but harbors the known phosphorylation sites for PKA, AMPK, and ERKs and therefore has been assigned a regulatory function.

3.2 cAMP

TAG mobilization by lipolysis as a strictly regulated process has been known since the early 1960s, when it was established that fast-acting hormones such as ACTH and epinephrine increased lipolysis, and that insulin counteracted this activation. It was soon recognized that cAMP was involved in the regulation of the catecholamine-sensitive lipolytic activity in adipose tissue. Catecholamines can either stimulate lipolysis via three subtypes of ß-AR, which are positively coupled to cAMP-synthesizing AC (adenylate cyclase) by G_s proteins, or inhibit lipolysis via α_2-AR, negatively coupled to the AC by G_i proteins (Fig. 2). Concerning the functional significance of adrenoceptor-mediated increases in cAMP levels, two points should be emphasized. First, lipolytic agents generally increase the levels of cAMP far above the concentration required for maximal activation of PKA. Second, considerable species and tissue specificity exists with regard to the distribution of adrenoceptor subtypes. In humans, for instance, the interplay between α_2- and ß-AR is important in modulating cAMP levels in adipocytes. It is now generally accepted that lipolytic response of fat cells is controlled mainly by the sympathetic nervous system and by plasma insulin levels and depends on the balance between stimulatory and inhibitory pathways. cAMP activates PKA and this kinase then phosphorylates the two main targets involved in the control of lipolysis in the adipocyte, HSL and the perilipins (Fig. 2). Phosphorylation of these proteins dramatically increases lipolysis (see below). Insulin is the physiologically most important antilipolytic hormone. The ability of insulin to antagonize hormone-induced lipolysis can largely be explained by its ability to lower cAMP levels and thereby PKA activity, leading to a decrease in the phosphorylation state of HSL and perilipin.

3.3 Phosphorylation of HSL

Phosphorylation of partially purified HSL by PKA, leading to a moderate activation of its activity *in vitro*, was described in the early 1970s and later confirmed.

Subsequent phosphopeptide mapping and phosphoamino acid analysis suggested that HSL was phosphorylated on a single serine residue, named the regulatory site. Partial amino acid sequencing of phosphopeptides generated from bovine HSL, together with determination of the primary structure of rat HSL, allowed identification of Ser563 as the regulatory site. However, more recent data have dramatically challenged this view on the short-term regulation of HSL. The finding that mutation of Ser563 did not abolish PKA-induced activation of HSL led to the identification of two novel PKA sites, Ser659 and Ser660, that seem to be responsible in intact primary adipocytes for the activation of HSL in response to isoproterenol stimulation. The role of phosphorylation of Ser563 remains elusive (Fig. 5).

Apart from three PKA phosphorylation sites described above, HSL is phosphorylated *in vivo* in hormonally quiescent cells at a site named the *basal site*, corresponding to Ser565 in rat HSL, that is, two residues carboxy-terminal to Ser563. Glycogen synthase kinase-4, Ca^{2+}/calmodulin-dependent kinase II, and AMP-activated protein kinase (AMPK) phosphorylate Ser565 *in vitro* without any direct effect on enzyme activity (Fig. 5). AMPK has been proposed to be the physiologically relevant kinase, based on its involvement in other aspects of lipid metabolism and on its proposed role as fuel gauge. Furthermore, because phosphorylation by AMPK prevented subsequent phosphorylation of Ser563, and *vice versa*, it was proposed that phosphorylation of Ser565 exerts an antilipolytic role. This proposal is supported by experiments showing that preincubation with AICAR an activator of AMPK – causes a moderate reduction of the lipolytic response to catecholamines in primary adipocytes. The data indicating mutually exclusive

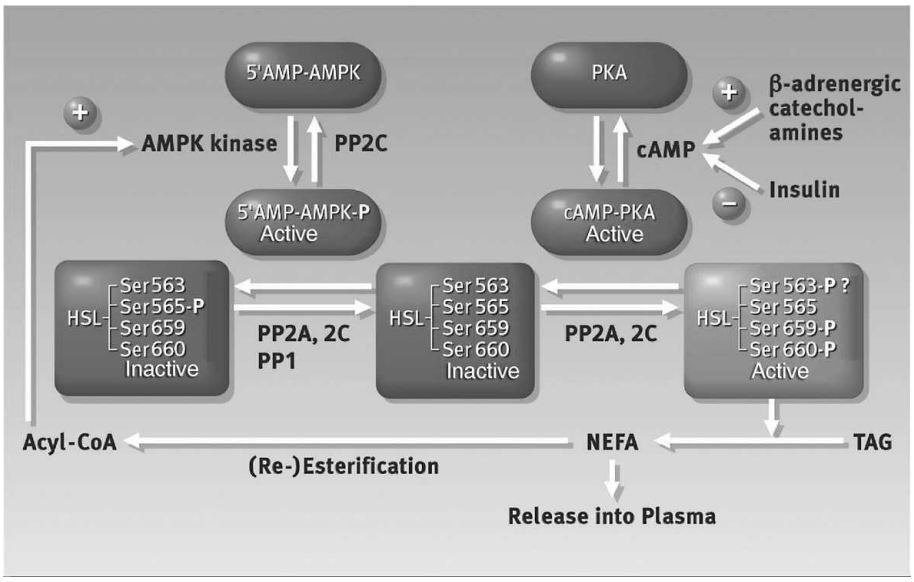

Fig. 5 Working model of the interplay between basal and regulatory phosphorylation sites at HSL, including the kinases and phosphatases involved. See text for details.

phosphorylation at the basal and regulatory sites imply that activation of HSL by PKA has to be preceded by dephosphorylation of the basal site. Whether this dephosphorylation is an important regulatory step or merely a result of a high constitutive protein phosphatase activity in the cell is not clear. Moreover, the recent finding that Ser563 is not essential for HSL activation raises some questions regarding this antilipolytic role of Ser565 phosphorylation. Also, the moderate antilipolytic effect of AICAR should be interpreted with caution because this substance has many cellular effects and has been questioned as a specific AMPK activator.

In fact, recent studies have elucidated completely novel aspects of AMPK physiology as it may be directly involved in the ß-adrenergic regulation of lipolysis. Much experimental evidence has promoted the idea that AMPK acts as an intracellular energy sensor, stimulated by the increased intracellular AMP/ATP ratio when cells are stressed by conditions such as hypoxia/ischemia in the heart and excessive contraction in skeletal muscle. Activated AMPK accelerates ATP-producing pathways, such as FA and glucose oxidation, while reducing ATP consumption, ultimately leading to the preservation or restoration of adequate high-energy phosphates. Whereas the importance of AMPK to control lipid metabolism in liver and muscle is well established, its role in regulating lipolysis in adipose tissue has remained controversial. Previous observations led to the hypothesis that AMPK antagonizes lipolysis in adipocytes (see above), presumably to prevent futile cycling and depletion of ATP during unrestrained simultaneous lipolysis and reesterification. However, subsequent mutational analysis of the PKA phosphorylation sites of HSL raised serious doubts on the negative effect of AMPK phosphorylation on PKA-induced HSL activation, which were then strengthened by the finding that isoproterenol stimulated AMPK phosphorylation and activity in isolated rat adipocytes, in apparent contradiction to an antilipolytic role for AMPK. Confirming and extending the latter study, it was demonstrated recently, that treatment of murine cultured 3T3-L1 adipocytes with isoproterenol or forskolin promoted the phosphorylation of AMPK at a critical activating Thr172 residue in a concentration- and time-dependent fashion. This correlated well with stimulation of AMPK activity as measured in the immune complex. Analogs of cAMP mimicked the effect of isoproterenol and forskolin on AMPK phosphorylation. Treatment of the adipocytes with insulin reduced both basal and forskolin-induced AMPK phosphorylation via a pathway dependent on PI-3K. Overexpression of a dominant-inhibitory mutant of AMPK blocked isoproterenol-induced lipolysis by about 50%. These data indicate that in adipocytes a novel pathway operates through which cAMP can lead to the activation of AMPK, and that this pathway is required for maximal stimulation of lipolysis. However, overexpression of a constitutively active AMPK version had a minimal effect on both basal and isoproterenol-induced lipolysis only, which may indicate that AMPK is required but not sufficient for lipolysis induction (in the absence of elevated cAMP). Moreover, it remains unclear from this study how agents that increase cAMP or the nucleotide itself activate AMPK in intact cells. Thr172, the phosphorylation site on AMPK responsible for most of the increase in AMPK activity, is not a consensus PKA phosphorylation site, suggesting that PKA regulates AMPK activity through

an indirect mechanism, such as phosphorylating and activating an unknown upstream AMPK kinase. Alternatively, the effect of cAMP could be independent of PKA. The other open question is how AMPK regulates lipolysis. As already mentioned, phosphorylation of HSL at Ser563, Ser659, and Ser660 by PKA alone does not account for the maximal activity of HSL as *in vitro* PKA phosphorylation causes a 1.5- to 2.2-fold increase in HSL lipase activity only, while isoproterenol stimulates FA release from adipocytes more than 50-fold. AMPK phosphorylates Ser565, which is located in the regulatory domain of HSL, as are the PKA phosphorylation sites, *in vitro*. Phosphorylation of Ser565 by AMPK might, speculatively, be involved in regulation of the translocation of HSL to the LD (see below). This would explain the recent finding that mutation of this residue abrogated the ability of HSL to translocate to LD. In addition, or alternatively, several other proteins, participation of which in lipolysis has been documented, such as perilipin (see below), may represent direct or indirect targets of AMPK. Taken together, the available experimental evidence hints at a positive modulatory role of AMPK in ß-adrenergic stimulation of lipolysis, during which it undergoes phosphorylation and activation and then possibly phosphorylates HSL at Ser565, leading to its translocation to LD. Physiologically, this putative mechanism nicely fits the commonly accepted role of AMPK as intracellular energy sensor since it guarantees that ATP depletion in adipocytes and in other tissues coordinated via the ß-adrenergic response leads to enhanced lipolysis, resulting in the release of FA that can be oxidized by target tissues to compensate for the increased demand for high energy phosphates.

3.4 Dephosphorylation of HSL

Two major studies devoted to clarifying the action of (protein phosphatases) PP on HSL have demonstrated a several-fold higher activity of PP2A and PP2C than PP1 toward the PKA site (Ser563), even though the source of both HSL and PP differed in each study. The same was true for the basal site, that is, Ser565. Because of their higher abundance in adipose tissue, PP2A and PP1 are the main PP acting on HSL *in vivo*. A role for PP1 in selective dephosphorylation of the basal site has been suggested. This, however, was not supported by another study, which showed a higher preference of PP1 for the PKA sites than for the basal site. The dephosphorylation of the novel PKA sites, Ser659 and Ser660, as well as the possible existence of specific HSL phosphatases, remains to be investigated (Fig. 5).

3.5 Intrinsic HSL Activity

Historically, the major consequence of HSL phosphorylation was thought to be an increase in the catalytic activity of the lipase toward TAG, which thereby triggers lipolysis, but more recent observations indicate that activation of lipolysis involves a more complex and elegant series of reactions. Phosphorylation of HSL *in vitro* leads to a moderate (twofold) increase in activity against emulsified TAG substrates, whereas ß-adrenergic stimulation of adipocytes leads to a >50-fold increase in the hydrolysis of TAG housed within LD. A reasonable explanation for this discrepancy is that (1) cytosolic HSL in unstimulated adipocytes is already highly active but has limited access to its substrate contained within intracellular LD

and; (2) the major consequence of lipolytic stimulation is the migration of HSL toward the LD and a change in the LD surface that provides access of the lipase to its TAG substrate in the LD core. That HSL is present in an active state in unstimulated adipocytes is supported by comparisons of lipolysis in intact control and stimulated cells with the lipolytic activities of homogenates or sonicates derived from these cells. Whereas lipolysis in intact stimulated cells is far greater than in intact control cells, there is little between the measurable lipolytic activities in homogenates or sonicates of these control and stimulated cells. Importantly, high HSL activity is found in sonicates or homogenates of control cells that exhibit only minimal lipolysis before disruption of the cells. The conditions of cell disruption in these studies are unlikely to foster phosphorylation of HSL because both PKA and ATP are diluted, and chelators in the homogenization medium reduce the effective concentration of Mg^{2+}, which is required for PKA activity. Hence, it appears that the non-PKA-phosphorylated HSL in homogenates or sonicates of control adipocytes can hydrolyze TAG at a rate nearly equal to that exhibited by PKA-phosphorylated HSL when acting on exogenous emulsified TAG substrates. The great increase in the lipolytic activity in sonicates of unstimulated adipocytes may result from the large increase in surface area of TAG arising from dispersion of the LD. It has been speculated that the increase was due to destruction of the integrity of the LD surface. Implicit in both explanations is the idea that, in the intact adipocyte, HSL is active but has restricted access to the TAG substrate. As reviewed below, this is compatible with data showing that lipolytic stimulation is accompanied by a migration of HSL to the LD *plus* a dramatic change in the structure of the LD surface.

3.6 Translocation of HSL

3.6.1 Molecular Mechanism

cAMP-stimulated lipolysis in cultured adipocytes is accompanied by redistribution of HSL from the aqueous supernatant of homogenates of unstimulated cells to the particulate fraction and the floating fat cake of homogenates of stimulated cells. These findings were later confirmed by the direct immunological demonstration of HSL movement from the cytosol to the LD, leading to the hypothesis that a major consequence of PKA activation is the translocation of the phosphorylated HSL from the cytosol to the LD. Subsequently, this hypothesis was confirmed by examining the location of HSL in 3T3-L1 adipocytes with the use of immunofluorescence microscopy. In unstimulated cells, the enzyme is disturbed diffusely in the cytosol, but migrates to the LD surface upon stimulation of lipolysis by the ß-AR agonist, isoproterenol. This translocation is reversible since upon addition of the ß-AR antagonist, propranolol, to stimulated cells, HSL resumes a diffuse distribution. Furthermore, HSL leaks from adipocytes into the medium when digitonin is used to permeabilize unstimulated, but not stimulated cells. These data suggest that HSL is freely soluble in the cytosol of unstimulated adipocytes and that its binding to the LD surface in stimulated cells is reasonably avid. Furthermore, HSL remains bound to LD following fractionation of stimulated cells. The temporal kinetics of HSL translocation to and away from the LD parallels the temporal kinetics of the onset and termination of lipolysis. Because the effects of isoproterenol are mimicked

by nonhydrolyzable cAMP analogs, the translocation reaction is downstream of PKA activation. There appears to be no cytoskeletal involvement in the translocation reaction, since translocation is unimpeded by cytoskeletal poisons such as nocodazole, cytochalasin B, and the combination of these two agents. Thus, an important consequence of lipolytic activation of adipocytes is the translocation of HSL from the cytosol to its substrate, that is, the TAG in the core of LD (Fig. 4, step 4).

Meanwhile, HSL translocation seems to be more complex and may be accompanied by and/or trigger a conformational change of HSL, leading to higher affinity for TAG and/or phospholipids of the LD. *In vitro*, even nonphosphorylated HSL binds readily to phospholipid vesicles and mixed phospholipid/DAG monolayers. However, in intact cells, the interaction with the LD only takes place upon lipolytic stimulation and phosphorylation of HSL. Remarkably, a mutant variant in which the newly described phosphorylation sites (Ser659, Ser660) have been replaced by alanines was unable to translocate. Of interest is whether the different sites for PKA phosphorylation on HSL have different roles in promoting cellular lipolysis, that is, in triggering HSL translocation to LD versus increasing intrinsic HSL activity toward TAG in the LD core. HSL translocation proceeds normally when either of these two sites is mutated singly, but is abolished on simultaneous mutation of both sites. By analogy with other lipases, HSL might exist in two conformational states, an active form – corresponding to the ''open'' form exposing a large hydrophobic lid structure as observed for other lipases – and an inactive ''closed'' form. In intact cells, phosphorylation of HSL would be required to trigger the transition from the ''closed'' to the ''open'' form, exposing the hydrophobic lid structure for interaction with TAG. *In vitro*, HSL may be permanently stabilized in the ''open'' form by the nonionic detergent required to keep the enzyme soluble and active in its purified form, thus making phosphorylation unnecessary. This mechanism of stabilization of the ''open'' form by a micelle of tensioactive molecules has been elegantly demonstrated for pancreatic lipase.

Recently, the involvement of multiple mechanisms for hormonal regulation of lipolysis by HSL has convincingly been demonstrated with transgenic mice expressing human HSL in WAT. HSL mRNA levels were increased in WAT threefold versus endogenous HSL. The lipolytic activity against TAG was elevated in WAT of transgenic compared with wild-type mice, which may explain the observed more pronounced reduction of body weight and fat mass in transgenic compared with wild-type mice after a four-day calorie restriction. However, and surprisingly, the cAMP-inducible lipolytic response was lower in adipocytes prepared from transgenic mice. Thus, these data suggest that mechanisms other than phosphorylation, translocation, and intrinsic activity of HSL may become rate limiting for lipolytic degradation of TAG in LD of intact adipocytes, at least under conditions of HSL overexpression, some of which and the components putatively involved are discussed below.

3.6.2 Involvement of Perilipins

Initially it was proposed that the function of perilipin could be to anchor HSL to its TAG substrate as a ''docking protein'' at the surface of LD when phosphorylated. However, attempts to coimmunoprecipitate (PKA-phosphorylated) HSL and perilipin offer no evidence of any direct interaction between these two proteins, nor

does a yeast two-hybrid screen. A salient feature of perilipins A and B is their phosphorylation by PKA. The A isoform has six predicted sites for PKA phosphorylation, three of which are in perilipin B. Most, if not all, of these sites in perilipin A appear to be phosphorylated upon lipolytic activation of adipocytes. The PKA-mediated phosphorylations occur on serine residues. By contrast, in unstimulated cells, one or more threonine residues, as yet not identified, are phosphorylated. Because perilipin A is polyphosphorylated by PKA during lipolytic activation of adipocytes, a role for perilipin in lipolysis has been hypothesized. As cytosolic HSL seems to be in an activated state in the absence of PKA phosphorylation, one must ask why the lipase does not bind to and hydrolyze TAG in unstimulated adipocytes. There are two possible explanations. First, despite the evidence that in intact cells nonphosphorylated HSL behaves like a freely soluble cytosolic protein, this HSL form might be constrained from reaching the LD due to its association with another protein (see below). Secondly, perilipins could serve to block HSL action in unstimulated cells. During the last decade, the common hypothesis has been that non-PKA-phosphorylated perilipins suppress lipolysis by denying HSL access to TAG in the core of the LD (Fig. 4, step 5). Several lines of evidence support this:

Mutational analysis of the three consensus PKA sites in perilipin A that are common to both perilipin A and B (Ser81, Ser222, Ser276) was performed to analyze the role of PKA-mediated hyperphosphorylation of perilipin in regulating lipolysis. When the mutant protein (delta3) was expressed in cells overexpressing acyl-CoA synthase-1 (ACS1) and fatty acid-binding protein-1 (FATP1), like wild-type perilipin A, the mutant one targeted itself to the surface of LD, increased TAG accumulation, and decreased basal lipolysis. However, unlike perilipin A, perilipin-delta3 blocked PKA-stimulated lipolysis in ACS1/FATP1 cells overexpressing HSL. Thus, PKA-stimulated phosphorylation of perilipin A is necessary to abrogate perilipin's A inhibitory action on lipolysis. Because perilipin A and B share the same PKA phosphorylation sites that were mutated, it can be speculated that perilipin B may also modulate PKA-stimulated lipolysis. If perilipins A and B assume similar extended conformations at the LD surface, the greater protection against hydrolysis of the longer splice variant, perilipin A, may be attributed to its greater length and thus greater coverage of the LD surface, that is, it is the extended unique carboxy-terminal tail (12 kDa) of perilipin A that is important in protecting against lipolysis in the unstimulated state. Since perilipins are major substrates of PKA, which polyphosphorylates perilipins on lipolytic stimulation, that is, in parallel to lipid hydrolysis, it follows that phosphorylation of PKA sites in the amino-terminal region induces a conformational change in the carboxy-terminal region that exposes portions of the LD surface to HSL action. Furthermore, expression of native and mutated forms of perilipin A and B in CHO fibroblasts revealed that perilipin A inhibits TAG hydrolysis by 87% when PKA is quiescent but that activation of PKA and phosphorylation of perilipin A provokes a sevenfold lipolytic activation. No HSL was detected by immunoblotting in these cells nor could any PKA-stimulated lipolytic activity in CHO cell homogenates be measured. Thus, the lipase responsible for TAG hydrolysis in CHO cells appears unresponsive to PKA, and PKA

regulation of lipolysis in CHO cells expressing perilipin A is concluded to result solely from the PKA phosphorylation of perilipin, which is supported by the finding that mutation of selected PKA sites eliminated this regulated response. Unlike perilipins, ADRP has no consensus sequences for PKA phosphorylation and thus is unlikely to be phosphorylated in lipolytically stimulated cells.

In agreement with the above findings, perilipin A acts cooperatively with HSL in lipolysis when both proteins are introduced into CHO cells. Thus, the ability of perilipin to regulate lipolysis of TAG in the core of LD appears to be manifested with any lipase that has access to the LD surface. The enhancement of lipolytic activity by perilipin A and the endogenous lipase of CHO cells is clearly time-dependent, requiring at least 30 min after stimulation to become manifest. In contrast, when both HSL and perilipin are introduced into CHO cells, the lipolytic activation occurs with no detectable lag. Phosphorylation of HSL is assumed to foster this immediate reaction, in contrast to the endogenous lipase, which is apparently not a PKA substrate.

Additional support for the barrier hypothesis for perilipin is based on analyzes of the stimulation of adipose cell lipolysis with the cytokine, tumor necrosis factor-α (TNF-α). Several cytokines, including TNF-α, increase lipolysis in adipocytes. Unlike the fast-acting lipolytic hormones, which activate PKA and increase lipolysis within minutes, TNF-α requires at least 6 to 8 h to initiate a lipolytic response. Moreover, TNF-α does not increase PKA activity. However, the cytokine does terminate expression of the perilipin gene, and within 24 h of exposure of the cells to TNF-α the perilipin content of cells is reduced by up to approximately 50%. This reduction in perilipin accounts for the increased lipolysis since adenovirus-mediated expression of perilipins A or B prevents TNF-α-stimulated lipolysis. In contrast to the endogenous perilipin, that produced by the adenovirus construct is not attenuated by the cytokine. Thus, the data indicate that perilipins not phosphorylated by PKA inhibit lipolysis and that phosphorylation of perilipins abrogates this barrier (Fig. 4, step 5).

Most interestingly, increased PKA activity in 3T3-L1 adipocytes is correlated with dramatic and reversible changes at the LD surface. Immunofluorescence staining for perilipin decreased at the periphery of large LD, suggesting that PKA activation lowers the density of the perilipin coat at the LD surface, either by an increase of the total LD surface area leading to ''dilution'' of perilipin or, more likely, loss of perilipin from the LD due to its translocation into the cytosol. The apparent reciprocal translocation of HSL (Fig. 4, step 4) and perilipin (Fig. 4, step 6) between LD and cytosol seems to depend on the ''age'' of the adipocytes. In young male rats (160–200 g), the translocation of HSL in response to isoproterenol closely paralleled the stimulation of lipolysis, but there was no translocation of perilipin from LD to the cytosol. By contrast, upon lipolytic stimulation and perilipin phosphorylation in adipocytes from older rats, there was no translocation of HSL but a significant translocation of perilipin away from the LD. Furthermore, the maximum rate of lipolysis induced by isoproterenol was markedly lower in cells from older rats than in those from younger rats. A similar redistribution of perilipin has also been reported for 3T3-L1 adipocytes. This ''reverse'' perilipin translocation is unlikely to involve a conformational change that allows perilipin to become freely soluble

in the cytosol as it is extremely hydrophobic. Instead, phosphorylation of perilipin and/or some other mechanism may trigger an alteration in the LD surface, rendering LD more susceptible to disruption by fractionation procedures, resulting in the release of apparently ''free'' perilipin in the cytosolic fraction. In conclusion, the results with older rats emphasize that lipolytic stimulation is not due to HSL translocation alone. The current speculation is that this diminution of the perilipin coating may represent one mechanism whereby perilipin contributes to lipolysis in adipocytes. However, it appears that the translocation of perilipin is not essential for the stimulation of lipolysis in all cells, or may not be the only or predominant mechanism as it is not observed in adipocytes from young male rats in which translocation of HSL was apparent upon lipolytic stimulation.

3.6.3 Involvement of ADRP

As already mentioned, perilipin can shield lipid esters in LD from lipase activity. When phosphorylated by PKA upon catecholamine stimulation, perilipin not only downregulates its barrier function, but also promotes translocation of lipases and enables efficient hydrolysis of TAG. On the other hand, ADRP is not likely to function as a shield against lipases, but it binds to NBD-FA and NBD-cholesterol, stimulates uptake of long-chain FA, and increases the cellular content of TAG. These properties suggest the importance of ADRP in the intracellular lipid trafficking, but the whole picture of its physiological function has not been delineated. The function of ADRP was examined by searching for proteins that interact with ADRP. By the yeast two-hybrid screening, ADP-ribosylation factor 1 (ARF1), a GTP-binding protein, was obtained as a candidate, and confirmed that it binds to ADRP both *in vivo* and *in vitro*. Interestingly, the GDP-bound ARF1 showed a higher affinity to ADRP than its GTP-bound form. Consistent with the property, when cells were treated with BFA, a reagent that inhibits ARF guanine nucleotide exchange factors, ADRP was dissociated from LD. The result indicates that an ARF1-dependent mechanism could affect association of ADRP to LD. It also showed that LD is a target of BFA action.

In addition, ARF1 is known to interact with a number of effector proteins, including phospholipase D, phosphatidylinositol 4-phosphate 5-kinase, and clathrin adaptor protein. These effectors interact with ARF1-GTP. Preferential binding to ARF1-GDP was also reported previously for p23, a transmembrane protein, which mediates recruitment of ARF1-GDP to the Golgi membrane. ARF-guanine nucleotide exchange factors also bind to ARF1-GDP. But ADRP does not have apparent sequence similarity to these proteins, and appears to be dissociated from LD upon binding to ARF1-GDP. It is not clear why dissociation of ADRP does not occur in the normal untreated cell, in which ARF1-GDP should exist in the cytosol, but several possibilities can be speculated. First, even though ARF1-GDP continuously dissociates ADRP from LD at a certain rate, it may be at equilibrium with ADRP that is newly synthesized and recruited to LD. Second, although a molecule corresponding to Rab-guanine nucleotide dissociation inhibitor has not been reported for ARF, it might exist, and ARF1 bound with the putative ARF1-guanine nucleotide dissociation inhibitor may not be able to interact with ADRP. Third, most ARF1 may be readily converted to ARF1-GTP by ARF1-guanine nucleotide exchange factors in the normal state, and thus dissociation of ADRP from LD may occur only when

ARF1-GDP increases by some stimulation. A number of ARF-GTPase activating proteins reported to exist in mammalian cells may be involved.

How does binding of ARF1-GDP cause dissociation of ADRP from LD? Previous studies showed that two independent segments, located in the amino and carboxyl termini of ADRP, can target the molecule to LD, whereas the central portion interposed between them is dispensable. It is now clear, that the central segment, 174–282, is involved in binding to ARF1. The relatively hydrophilic profile of the central segment suggests that it does not adhere to LD through hydrophobic interactions and may be able to interact with cytosolic molecules. In this context, it is noteworthy that the corresponding portion of TIP47 constitutes a unique α/β-domain and the first helix of the four-helix bundle, and makes a hydrophobic cleft in between where a lipid molecule may bind. Sequence alignment suggests that the central domain of ADRP takes a similar structure. Binding of ARF1 to critical domains may influence ADRP functionally and/or structurally, and eventually cause its dissociation from LD.

ADRP and perilipin are thought to be translated on free ribosomes, and they resemble each other in that several independent segments are involved in binding to LD. These properties may suggest that ADRP and perilipin adhere to LD by a similar mechanism. However, they are divergent in two important aspects. First, despite the sequence similarity in the amino-terminal PAT-1 domain, binding to LD is mediated by relatively dissimilar domains. Second, phosphorylation/dephosphorylation of perilipin regulates its binding to LD, whereas ADRP is not likely to be phosphorylated *in vivo*. Instead, FA may be involved in binding of ADRP to LD. A recent study showed apparent degradation of ADRP after the BFA-induced dissociation as well as the lack of promoting effect of ARF1-GTP on new LD formation. These findings suggest that ADRP dissociates from LD in an irreversible manner, and that the mechanism of LD binding may be different between ADRP and perilipin. BFA has been used as a reagent to inhibit vesicular transports. In addition, it causes redistribution of caveolins to LD (see above). In untreated cells, caveolins are present in the plasma membrane, endosome, and the Golgi, but after BFA treatment, they become concentrated in LD. This phenomenon has been thought to occur by translational diffusion of caveolins from the ER membrane to the LD surface, that is, due to inhibition of the ER-to-Golgi transport, an excessive amount of caveolins accumulate in the ER membrane and overflow to the LD surface. But in view of the effect of BFA upon ADRP and LD, the mechanism causing the redistribution of caveolins to LD may need to be reconsidered. One possible model is that ADRP normally coats the LD surface and blocks translational influx of ER membrane molecules by diffusion, but that dissociation of ADRP caused by BFA enables influx of ER membrane molecules into LD. As a modified version of this model, it is possible that dissociation of ADRP from LD may not be completed by binding to ARF1-GDP, but may occur only when the incoming ER proteins physically dislocate ADRP. In this case, the effect of BFA on ADRP is both direct and indirect. The latter model could explain the length of time required for the BFA effect on ADRP to become apparent.

It is noteworthy that LD of some cell types contains abundant free cholesterol. Free cholesterol in the LD surface may be important in sequestering a selected set

of proteins including caveolins. Despite the fact that inhibition of the ER-to-Golgi transport by BFA could cause accumulation of caveolins in the ER membrane and the subsequent diffusion to LD, the prominent concentration of caveolins in LD, and their retention even after BFA wash out cannot be explained simply by the overflow model. Dissociation of ADRP, a cholesterol-binding protein, and the resultant availability of free cholesterol may be important for the retention of caveolins in LD. Besides the direct action on ADRP, other ARF1-related pathways may work to cause the observed effect on LD. For example, phospholipase D was shown to be involved in new LD formation *in vitro* (see above). If turnover of LD is rapid in living cells and continuous formation is required to maintain constant LD volume, suppression of phospholipase D by BFA may contribute to reduce the total LD volume in a cell.

3.7 Feedback Inhibition of HSL

HSL is inhibited in a noncompetitive manner by oleoyl-CoA, oleic acid, and 2-monopalmitoylglycerol, with 50% inhibition at 0.1, 0.5, and 500 μM, respectively. Feedback inhibition of HSL by oleoyl-CoA and oleic acid may therefore prevent accumulation of free FA and cholesterol in the cell, whereas 2-monoacylglycerol may act as a feedback inhibitor if the capacity of 2-monoacylglycerol lipase is exceeded. The inhibition of HSL by oleoyl-CoA and oleic acid at concentrations well below their critical micellar concentrations (reported for fatty acyl-CoAs, 30–60 μM; for FA 0.8–1 mM) rules out any detergent effects, implying that inhibition is via binding to a specific site on the enzyme protein [Fig. 6]. FA inhibit AC and therefore cAMP accumulation in the adipocyte. Furthermore, PKA can phosphorylate and thereby stimulate phosphodiesterase, PDE3, directly or possibly indirectly by phosphorylating and activating the postulated PDE3 kinase (PDE3K), which finally leads to cAMP degradation. These mechanisms would reduce HSL activation by phosphorylation. The four inhibitory feedback loops may therefore act together to prevent further accumulation of FA released from lipolysis and therefore possible cell damage via detergent properties inherent in high concentrations of FA (Fig. 6).

The observed inhibition of HSL by 2-monopalmitoylglycerol may also be of significance as a feedback control of lipolysis. As a result of preferential cleavage of 1(3)-ester bonds by HSL, the hydrolysis of TAG and subsequently of DAG yields 2-monoacylglycerol. This is a poor substrate for HSL and therefore a distinct 2-monoacylglycerol lipase is required for the final step of lipolysis to yield free NEFA and glycerol. If the rate of production of 2-monoacylglycerol by HSL exceeds its rate of hydrolysis by the 2-monoacylglycerol lipase, the resultant accumulation of this lipid may prevent its further generation. However, the physiological conditions under which this might occur are unknown, as 2-monoacylglycerol lipase is reported to be present in adipocytes in sufficient quantity and is not rate limiting, even during hormonally stimulated lipolysis.

The two key enzymes in FA synthesis and cholesterol synthesis, ACC1, and HMG-CoA reductase, are also inhibited by oleic acid and oleoyl-CoA in a noncompetitive manner and over similar concentration ranges as for HSL. All three enzymes are phosphorylated by the AMPK. Phosphorylation of ACC1 and HMG-CoA reductase results in direct inhibition of

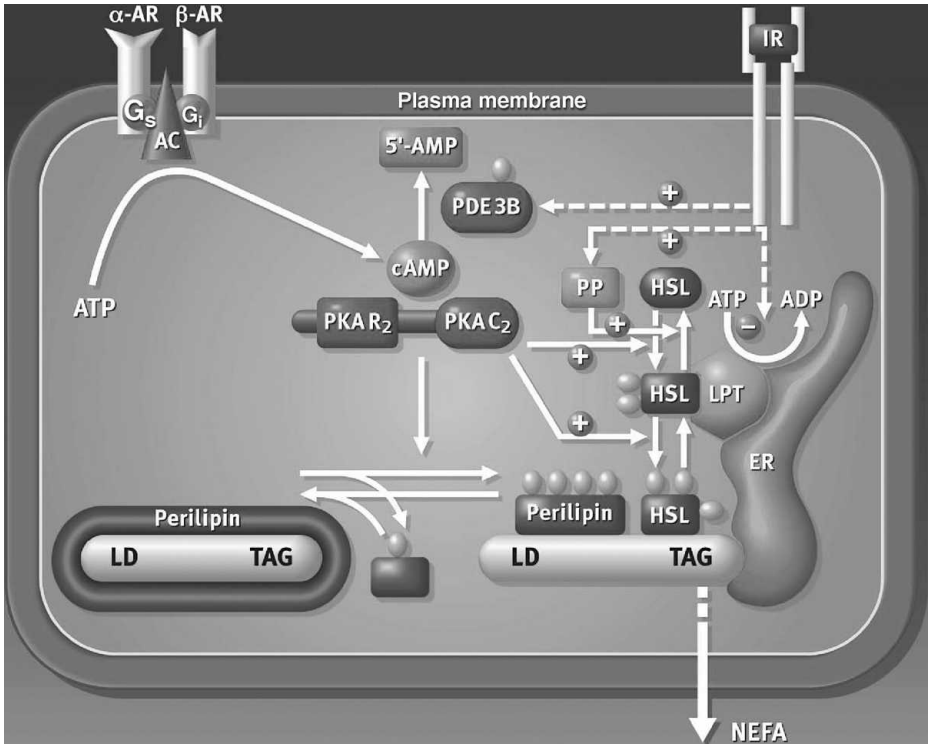

Fig. 6 (Hormonal) regulation of TAG mobilization in adipocytes by translocation of HSL and perilipin as well as the molecular mechanisms involved (phosphorylation by PKA, dephosphorylation by protein phosphatases PP and interaction with lipotransin, LPT, near the ER and LD; the role of lipotransin in HSL translocation reported by one group so far, only, remains to be confirmed and analyzed in greater detail). Phosphorylation is depicted as filled circles. See text for details.

these enzymes. AMPK is itself activated by nanomolar concentrations of fatty acyl-CoA. Thus, a coordinated feedback mechanism may exist whereby elevated levels of FA or fatty acyl-CoAs regulate the levels of free cholesterol and FA in the cell via inhibition of their *de novo* synthesis and mobilization from their stores through lipolysis.

Utilizing an yeast two-hybrid screen of a rat adipose tissue library, it was demonstrated that HSL specifically interacts with adipocyte lipid-binding protein (ALBP or aP2) and the amino-terminal 300 aa of HSL has been identified as the region responsible for this interaction. This adipose-specific fatty acid-binding protein is expressed during adipocyte differentiation and makes up to 6% of cytosolic protein in mature fat cells. Fatty acid-binding proteins (FABP) are abundant low-molecular-weight cytoplasmic proteins that are involved in intracellular trafficking and targeting as well as metabolism of FA. ALBP binds FA, retinoids, and other hydrophobic ligands and is postulated to shuttle FA within the aqueous cytosol toward the membranes of

the relevant intracellular organelles that are involved in TAG synthesis and oxidation. This transfer is believed to occur via a collision mechanism that depends on the interaction of organelle membrane phospholipids with basic residues of ALBP, resulting in partitioning of FA to organelles for metabolic utilization. It has been proposed that intracellular FABP function to sequester FA, thus serving as an intracellular buffer. Because HSL and ALBP interact, it was also hypothesized that ALBP might prevent direct feedback inhibition of HSL by high local concentrations of NEFA released at the site of hydrolysis (see above). Consistent with this view, adipocytes from ALBP-null mice exhibit markedly reduced basal and stimulated lipolysis both *in situ* and *in vivo*, but show few phenotypic changes when fed a standard low-fat diet, with the exception of slightly lower plasma glucose and TAG concentrations in the fasted state. This may be based on increased expression of keratinocyte fatty acid-binding protein in ALBP-null mice, normally expressed at low levels in adipose tissue. However, in contrast to wild-type controls, high-fat feeding did not lead to hyperinsulinemia and insulin resistance in ALBP-null mice, despite similarly elevated body weights. No major abnormalities in adipocyte TAG synthesis were observed in ALBP-null mice with compensation by keratinocyte FABP. Therefore, deficiency of ALBP was associated with partial protection from mild insulin resistance resulting from short-term high-fat feeding, possibly by relieving HSL from feedback inhibition by NEFA. In the opposite concept for the function of ALBP, it delivers FA to HSL, thereby mediating the inhibition of its catalytic activity by FA. Evidence has accumulated that the interaction of ALBP and HSL constitutes an additional mechanism whereby the hydrolytic activity of HSL is regulated (Fig. 7). Thus, incubation of ALBP with purified recombinant HSL *in vitro* led to an increase in TAG hydrolysis. This ALBP-induced increase in hydrolytic activity was due to at least two components. First, a small nonspecific effect of added ALBP, perhaps altering the surface tension of the TAG substrate and thereby leading to interfacial activation of HSL, and, second, a specific effect. The specific effect of the ALPB-induced increase in HSL hydrolytic activity appeared to be based primarily on the ability of ALBP to interact with HSL. The ability of ALBP to bind FA did not seem to be required for this effect since an FA-binding mutant of ALBP, which binds normally to HSL, displayed a similar capacity to increase activity as wild-type ALBP. There was no evidence that the ALBP-induced increase in HSL activity was due to changes in the dimerization of HSL, which has been reported previously. Furthermore, the ability of ALBP to increase HSL hydrolytic activity was also demonstrated *in situ* in cells cotransfected with HSL and ALBP as compared with HSL and vector alone. Importantly, the ability of FA to inhibit HSL hydrolytic activity was attenuated by coincubation with ALBP. Here, the specific effect of ALBP to protect HSL from FA-induced inhibition appeared to depend in part on the ability of ALBP both to interact with HSL and to bind FA since the ALBP FA-binding mutant did not preserve HSL activity as effectively as native ALBP when exposed to higher concentrations of FA. The level of ALBP *in vivo* is, notably, extremely high (estimated to be 250–400 μM), suggesting that, within the cellular context, ALBP can relieve product inhibition by sequestration of FA to a much greater degree than measured *in vitro* or *in situ*. On the basis of the amount of FA released from isolated adipocytes and the

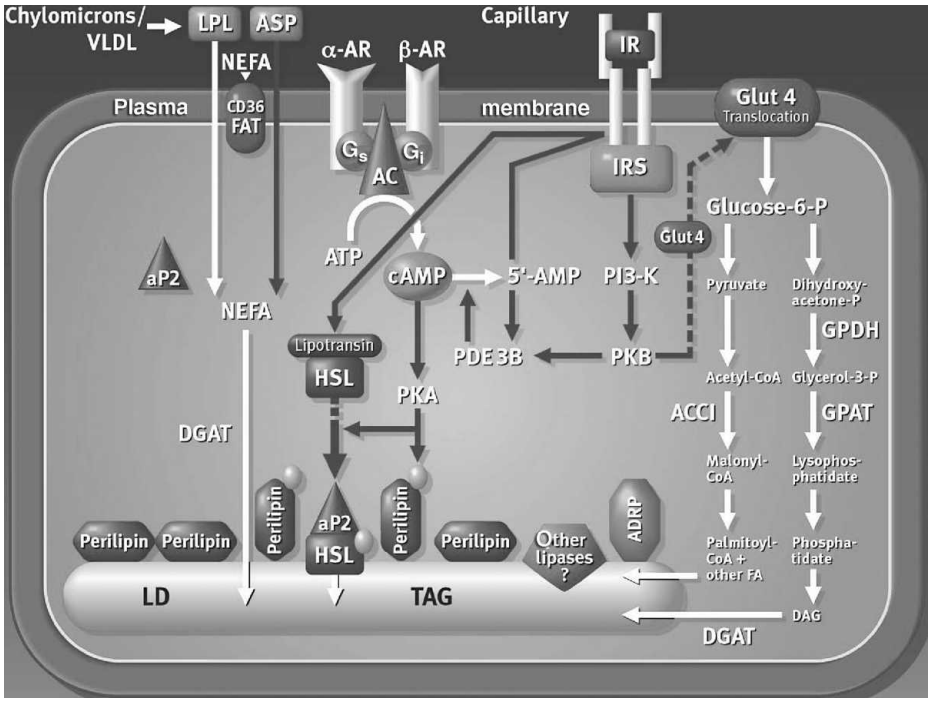

Fig. 7 Working model for the short-term inhibition of HSL activity/phosphorylation by insulin, including mechanisms of feedback inhibition by lipolytic end products and positive antilipolytic cross-talk to the insulin signaling cascade in adipocytes. Operation of a putative PDE3K downstream of PKB as well as direct phosphorylation/activation of PDE3B by the insulin receptor (IR) and/or PI3K is indicated. See text for details.

estimated water volume of an adipocyte, the intracellular concentration of FA is estimated to be 600 ± 74 μM. The near 1 : 1 stoichiometry of the total FA pool with ALBP and the high affinity of FA for this protein, measured by a combination of titration calorimetry and fluorescence displacement assays, suggest that FA in the adipose cell are largely, if not exclusively, protein-bound.

By analysis of a series of deletional mutants of HSL in GST pull-down experiments, the region of HSL interacting with ALBP was localized to aa 192–200. In particular, site-directed mutagenesis of His194 or Glu199 eliminated the ability of HSL to interact with ALBP. Thus, these two residues, either directly or indirectly, are critical for mediating the interaction of HSL with ALBP. Interestingly, HSL mutants H194L and E199A, each of which retained normal basal hydrolytic activity but were unable to bind ALBP, failed to display an increase in hydrolytic activity when cotransfected with wild-type ALBP. The retention of normal basal hydrolytic activity by these mutants argues against mutations at these sites affecting HSL dimerization, since monomeric HSL displays only 1/40 the activity of the dimer. Moreover, this is consistent with the finding that no apparent increase in HSL dimerization occurred upon incubation with ALBP. Consequently, the capacity

of ALBP to increase the hydrolytic activity of HSL is, apparently, not due solely to the ability of ALBP to bind and sequester FA, but also appears to depend on the physical interaction of ALBP with HSL. This suggests that the binding of ALBP to HSL might either alter its conformation, allowing TAG to access the catalytic site more efficiently or preventing FA from inhibiting HSL through a conformational change or steric inhibition. Experiments with ALBP-null mice indicate that these functional consequences of the interaction of ALBP with HSL occur *in vivo*. Thus, the current observations are consistent with the proposal that ALBP (aP2) and HSL constitute a lipolytic complex (Fig. 7). This complex functionally results in an increase in the hydrolytic activity of HSL brought about by the physical interaction of HSL with ALBP and by the ability of ALBP to bind and sequester FA. Thereby, lipolysis and intracellular trafficking of FA are controlled in an organized fashion.

3.8 Expression of HSL

Existing adipocyte-like cell lines, such as 3T3-L1, 3T3-F442A, and BFC-1, together with primary adipocyte cultures, have been used to investigate the effects of different nutritional and hormonal factors on HSL expression. cAMP and phorbol esters decrease HSL expression in mature 3T3-F442A and BFC-1 adipocytes via two apparently distinct mechanisms. Insulin, growth hormone, and retinoic acid and oleic acid reportedly had no effect on HSL expression in mature 3T3-F442A adipocytes. In a study on isolated rat adipocytes in culture, dexamethasone increased HSL mRNA fourfold, whereas adrenaline and growth hormone had no effect.

The expression of HSL protein and mRNA levels are lower in subcutaneous fat stores compared with internal (visceral, omental) fat depots in the rat, suggesting a possible basis for the differences in the rate of lipolysis among various fat depots. In contrast, subcutaneous fat in humans has a higher HSL mRNA expression and HSL activity than omental fat. Human subcutaneous fat cells are larger and there is a positive correlation between fat cell size and HSL expression. When controlled for adipocyte cell size, the amount of HSL protein and HSL mRNA levels in subcutaneous adipocytes show a strong correlation with maximum lipolytic activity.

3.9 Non-HSL Lipases

Until recently, HSL was considered to be the principle or the only mediator of lipolysis in WAT. However, gene-targeted HSL-deficient mice with no detectable HSL show active HSL-independent lipolysis. Although $HSL^{-/-}$ mice have a severely blunted response to adrenergic stimulation, the basal lipolytic rate of isolated adipocytes was somewhat greater in $HSL^{-/-}$ cells than in normal cells. In $HSL^{-/-}$ mouse embryonic fibroblasts, the basal lipolytic rate is equal in $HSL^{-/-}$ cells and controls. In homogenates of WAT and of embryonic fibroblasts from $HSL^{-/-}$ mice, total TAG hydrolase (lipase) activity is 40 to 45% of that of normal mice. Therefore, HSL appears to be responsible for hormone-stimulated lipolysis, but the enzyme(s) mediating basal lipolysis remained unknown until the recent use of functional proteomics to detect non-HSL lipase(s) in mouse WAT.

After cell fractionation of intraabdominal WAT, most non-HSL neutral lipase

activity is localized in the 100 000 × *g* infranatant and fat cake fractions. By oleic acid-linked agarose chromatography of infranatant followed by elution in a CHAPS gradient, two peaks of esterase activity were identified using *p*-nitrophenyl butyrate as a substrate. One of the peaks contained most of the lipase activity. In the corresponding fractions, gel permeation chromatography and SDS-PAGE, followed by tandem mass spectrometric analysis of excised Coomassie Blue–stained peptides, revealed carboxylesterase 3 (TAG hydrolase [TGH]). TGH is also the principle lipase of WAT fat cake extracts. Partially purified WAT TGH had lipase activity as well as lesser but detectable neutral cholesterylester hydrolase activity. Western blotting of subcellular fractions of WAT and confocal microscopy of fibroblasts following *in vitro* adipocytic differentiation are consistent with a distribution of TGH to ER, cytosol, and the LD. TGH is responsible for a major part of non-HSL lipase activity in WAT *in vitro* and may mediate some or all HSL-independent lipolysis in adipocytes.

Both subcellular fractionation and confocal immunofluorescence microscopy suggest that TGH is present in the cytosol, in the ER, and also on the LD surface. TGH has previously been isolated from pig liver microsomes and from rat liver cytosol. In WAT, the distribution of TGH with that of the ER luminal enzyme, α-glucosidase II was compared. A greater fraction of TGH than of α-glucosidase II was present in the cytosol, suggesting that the presence of TGH in this compartment may not be due simply to spillage. Other possibilities cannot be eliminated, such as nonhomogeneous distribution of enzymes within adipocyte ER and selective disruption of TGH-enriched ER during preparation. Of note, the microsomal proteins TGH, calnexin, and α-glucosidase II were all present in fat cake. Part of this may be artifactual, due to nonspecific hydrophobic affinity of these proteins for the LD during subcellular fractionation. On confocal microscopy, some TGH immunofluorescence is in immediate proximity to the LD surface, and some merge with that of perilipin. These observations are consistent with a true *in vivo* relationship between the LD surface and ER. This has previously been suggested by electron microscopic data showing proximity of some ER cisternae with the LD surface and by reports that LD may arise from the ER and of the presence of other ER proteins on the LD surface (see above). Given that TGH, a microsomal protein, accounts for most non-HSL intracellular lipase activity in WAT at neutral pH *in vitro*, the possibility that ER may be directly involved in adipocyte lipolysis merits further experimentation.

3.10 Release of FFA

While liberated FA from adipocytes was believed to be transported by simple diffusion, recent studies have identified several membrane proteins that transport NEFA across the adipocyte plasma membrane. These include the FA transport protein, FATP, plasma membrane fatty acid-binding protein and fatty acid translocase, which are expressed in tissues with a high metabolic capacity for FA, such as WAT, skeletal muscle, and heart. Protein-mediated FA transport is assumed to occur via facilitated diffusion along the concentration gradient formed between the intracellular and plasma NEFA concentrations. Thus, during starvation the release of NEFA from adipose tissue into

the plasma is determined by the adipocyte lipolytic state, the coronary flow and the peripheral removal of NEFA. CD36 is a class B scavenger receptor that binds multiple ligands, including FA, and has been proposed to function as the predominant transporter of long-chain NEFA, acting as a gatekeeper. Adipose cells of CD36 null mice show a decreased capacity to incorporate long-chain NEFA into TAG. Although neither the effects of CD36 deficiency on adipose mass, adipocyte size, or insulinemia have been reported, an approximately 30% reduction in plasma glucose concentrations has been observed. Transgenic mice overexpressing CD36 in skeletal muscle showed increased glucose and insulin concentrations together with decreased plasma concentrations of NEFA and TAG at the same time as having increased FA oxidation in muscle. FATP expression is augmented by fasting and damped by insulin.

A number of studies in recent years have implicated changes in circulating FA and FA metabolism with impaired insulin sensitivity in skeletal muscle. A recent study demonstrates for the first time that in muscle from obese subjects and NIDDM patients, rates of FA transport are increased. This was associated with the increased plasmalemmal content of CD36. This greater influx of FA contributes to the excess accumulation of intramyocellular TAG, since the rates of long-chain FA esterification are increased in skeletal muscle from obese subjects. Although there has been some debate as to whether long-chain FA traverses the plasma membrane via unregulated diffusion or protein-mediated processes, molecular evidence indicates that both processes occur. Using animal models, translocation of CD36 from an intracellular depot to the plasma membrane by muscle contraction and by insulin has been demonstrated, and this increase in plasmalemmal CD36 increases FA uptake into muscle tissue. Interestingly, in human muscle of obese and NIDDM patients, the skeletal muscle FA transport rates and plasmalemmal CD36 were significantly increased, while the total available pool of CD36 (plasmalemmal + intracellular) was not altered, which parallels previous observations in muscle from obese Zucker rats. Changes in plasmalemmal FABP were not observed in either insulin-resistant animal muscle or human muscle from obese and NIDDM patients. The impairment of CD36 cycling between subcellular compartments is reminiscent of a similar disturbance in the insulin-responsive glucose transport system. It is well known that GLUT4 cycling between the cell surface and intracellular depots is impaired in skeletal muscle in obesity and NIDDM despite similar levels of total GLUT4. Thus, the impairment in CD36 and GLUT4 cycling are juxtaposed. In obesity and NIDDM, CD36 is retained at the cell surface while GLUT4 is retained within the intracellular depots. Given the strong association between FA transport and intracellular TAG, a marker of insulin resistance (see above), it is tempting to speculate about a cross talk between CD36 and GLUT4 signaling pathways.

The increase in rates of long-chain FA esterification and the positive association between FA transport and TAG concentration in skeletal muscle strongly suggests that the increased long-chain FA transported into muscle contributes to the accumulation of intramyocellular TAG. It has been proposed that the TAG concentrations in obesity and NIDDM are increased owing to an increase in plasmalemmal CD36. This increase then serves to increase the rate of FA transport into the muscle cell, where the excess long-chain

FA that are taken up are primarily stored as TAG. Excess intramyocellular TAG accumulation has been associated with impairments in insulin signaling in human obesity and NIDDM, although TAG depots are most likely to be a surrogate measure of other FA metabolites that interfere with insulin signaling in muscle (see above). Taken together, the increase in the FA transport rate is another disturbance in lipid handling that can occur in skeletal muscle in humans. The key mechanism accounting for this increase is not altered expression of FA transporters, but rather subcellular relocation of CD36, indicating that CD36 cycling between the plasma membrane and its intracellular compartment has been altered in obesity and NIDDM. The increased influx of FA, along with their increased rate of esterification, contributes to the increased intramuscular accumulation of TAG. Thus, the increased rate of FA transport may be a critical step in the long-chain FA-mediated development of insulin resistance.

4
Physiological, Pharmacological, and Genetic Modulation of TAG Mobilization and Storage

4.1
Muscle Contraction

Acute muscular contraction increases HSL activity in mouse soleus. In agreement with this finding, muscle contraction, independent of hormonal influence, increases intramyocellular TAG utilization. The mechanism underlying the contraction-induced increase in HSL activity is unknown. Furthermore, whether intramyocellular HSL activity can be hormonally regulated during muscular contraction is also unclear. The regulation of HSL in skeletal muscle by external hormonal signals during exercise is thought to be unlikely, inasmuch as calcium and metabolites related to the energy status of the cell are expected to be the dominant regulators. However, this may not be the case, since, surprisingly, insulin has been found to play a pivotal role in the regulation of FA oxidation and TAG utilization during intense muscular contraction, when the role of calcium and metabolites would be expected to exert a strong influence. This suggests that the well-known early decline in insulin during exercise may be a major factor in permitting increased TAG mobilization and utilization by muscle. The role of epinephrine in regulating intramyocellular lipolysis during contraction is also relatively unexamined. Infusion of various physiological concentrations of epinephrine during low-intensity cycling (25% peak oxygen uptake) enhances whole-body lipolysis but actually reduces whole-body lipid oxidation. Furthermore, increasing the exercise intensity to 45% peak oxygen uptake blunts the lipolytic action of epinephrine. Thus, the most important hormonal signal early in exercise that permits enhanced lipid utilization by muscle may be the decline in insulin, rather than the increase in epinephrine. The contraction-induced activation of HSL suggests the involvement of calcium in lipolysis control, possibly via Ca^{2+}/calmodulin-dependent kinase(s). Although early observations pointed to a role of calcium at different levels of the adipocyte lipolytic cascade, this has been contradicted by recent reports suggesting that an increase in intracellular calcium concentrations inhibits lipolysis. However, tissue-specific mechanisms may well exist for lipolysis control.

HSL of 84-kDa size has been reported to be expressed in cardiac muscle and skeletal muscle. In skeletal muscle, the expression of HSL is higher in oxidative than glycolytic muscle, and HSL expression is reduced in the muscle of 24-month-old rats, perhaps contributing to the increase in muscle TAG content observed with aging. HSL activity in muscle is stimulated by catecholamines acting via β-AR and cAMP and by contraction acting independently of sympathetic tone or catecholamines. Exercise training does not affect the expression of HSL protein in muscle, but decreases the sensitivity of stimulation of muscle HSL activity by epinephrine. Heart-specific transgenic overexpression of HSL prevents the accumulation of cardiac TAG normally seen in fasted rodents. In addition, heart-specific overexpression of HSL alters the expression of cardiac genes for FA oxidation, transcription factors, signaling molecules, cytoskeletal proteins, and histocompatibility antigens. Thus, HSL in cardiac and skeletal muscle plays a role in controlling the accumulation of LD as well as the mobilization of TAG dependent on the working load. At present there is no experimental evidence for a direct inhibition of HSL by insulin in skeletal muscle.

4.2 Glucose

Glucose deprivation of primary cultured adipocytes results in a slight decline in HSL expression, whereas incubation with high glucose and insulin maintains HSL expression and leads to an increase in basal and stimulated lipolysis. Recently, a glucose-responsive region was mapped within the proximal promoter of human HSL and the involvement of upstream stimulatory factor-1 and -2 binding to a consensus E-box within this region was shown to be responsible for transcriptional regulation in response to glucose metabolism between glucose-6-phosphate and triose phosphates. Glucose deprivation also reduces HSL mRNA levels by a factor of 2.5 to 3 in 3T3-F442A cells. The physiological significance of the glucose/insulin effects on HSL expression remains to be determined, but it may reflect an adaptation to nutritional changes.

Glucose oversupply has been associated with an increase in muscle TAG and malonyl-CoA. Muscular TAG content is strongly related to insulin resistance (see above), and malonyl-CoA is known to inhibit carnitine palmitoyltransferase 1 (CPT-1), which is responsible for the transport of long-chain acyl-CoA into mitochondria. Intramuscular levels of both long-chain acyl-CoA and malonyl-CoA are increased after chronic glucose infusion in rats. These changes correlate with the chronic activation of PKC-ε. However, *de novo* lipogenesis is not assumed to take place in human skeletal muscles to a significant extent. Interestingly, even if glucose is not involved in lipid accumulation, it has been reported to have a negative effect on insulin signaling mediated by PKC isoforms in several cell systems.

Chronic exposure of cultured skeletal muscle cells to high glucose concentrations caused the accumulation of TAG and increased DGAT-1 activity. These changes were accompanied by reduced basal and insulin-stimulated glucose uptake and glycogen synthesis. The conversion of labeled glucose into lipids indicates that *de novo* lipogenesis can take place in skeletal muscle cells, and suggests that the lipid accumulation caused by hyperglycemia is a result of increased lipogenesis. Surprisingly, the elevated lipid synthesis stimulated by glucose was accompanied by reduced palmitate uptake, whereas glycogen

content and expression of GLUT1 and GLUT4 were unchanged. This suggests that chronic hyperglycemia stimulates lipogenesis in myotubes rather than glycogen accumulation. Previous studies have shown that in rats chronically infused with glucose, intramyocellular TAG content is doubled and insulin sensitivity in muscle is decreased. However, hyperglycemia and hyperinsulinemia occur in parallel with metabolic and hormonal changes *in vivo*, and confounding effects of liver and adipose tissue cannot be excluded. Chronic incubation with 20-mM glucose increased intramyocellular TAG content in the absence of exogenously supplied FA and increased the incorporation of glucose into TAG. The increased conversion of [^{14}C]glucose into FFA and complex lipids also implies an effect on lipogenesis. *De novo* lipogenesis is low in skeletal muscle (about 5% of the [^{14}C]glucose incubated was recovered as cellular lipids), but apparently lipogenesis is stimulated under certain conditions (e.g. when glucose is the only source of energy supplied). Interestingly, hyperglycemia increases the activity of DGAT-1. Studies have recently focused on the role of DGAT-1 in obesity and insulin resistance. Mice lacking DGAT-1 have reduced levels of tissue TAG and increased sensitivity to insulin and leptin. Although TAG formation is increased by DGAT-1 after hyperglycemia in human myotubes, DGAT-1 mRNA expression is not elevated. The mechanism by which DGAT-1 activity is increased remains to be elucidated.

The metabolic changes induced by hyperglycemia most likely occur upstream of the Krebs cycle, since glucose oxidation to CO_2 was not altered. One possible explanation could be that glucose oversupply increases the production of the substrates acetyl-CoA and malonyl-CoA for FA biosynthesis. However, an increase in malonyl-CoA would be expected to inhibit CPT-1 and FA oxidation. Hyperglycemia does not alter the oxidation of oleic and palmitic acid. The increase in FFA from labeled glucose suggests that malonyl-CoA and long-chain acyl-CoA may be increased, although possibly not to levels sufficient to inhibit CPT-1. Alternatively, there could be multiple pools of malonyl-CoA in muscle: a cytosolic pool involved in FA synthesis and a pool localized to mitochondria that is involved in the regulation of FA oxidation. The long-chain acyl-CoA or other related lipid products formed might activate one or more PKC isozymes. In line with this fact is the activation of several PKC isoforms in the skeletal muscle of glucose-infused rats.

FA uptake and oxidation are often regulated in concert. Cellular uptake of palmitic acid was decreased after glucose oversupply, while uptake of oleic acid was not and FA oxidation was unaffected. These findings suggest that FA uptake and oxidation can be regulated separately. In agreement, high carbohydrate availability was found to be associated with an increase in palmitate uptake in perfused rat muscle. However, this may be due to the fact that a more acute exposure to a high glucose concentration has been used, where rat muscles were perfused for up to 40 min. The mechanism of reduced uptake of palmitic acid in myotubes is currently unknown, but is apparently specific. There may be a link between increased lipogenesis and the uptake and metabolism of exogenously added palmitic acid.

4.3 Insulin

4.3.1 Molecular Mechanism

Insulin, the most important physiological inhibitor of catecholamine-induced

lipolysis, induces phosphorylation and activation of a phosphodiesterase (PDE), leading to a decrease in cAMP levels and concomitant decrease of PKA activity (Fig. 7). The decrease in cAMP is mainly the result of an insulin-mediated activation of PDE3. By catalyzing the hydrolysis of cAMP and cGMP, PDEs regulate intracellular concentrations and biological responses of these second messengers. PDEs constitute a group of structurally related enzymes that belong to at least nine related gene families (PDE1-9), which differ in their primary structures, affinities for cAMP and cGMP, responses to specific effectors, and sensitivity for inhibitors and regulatory mechanisms. Two PDEs (PDE3 and PDE4) have high affinity for cAMP and are present in fat cells. PDE3 can be distinguished from PDE4 by its high affinity for both cAMP (low K_m) and cGMP (which downregulates PDE3 activity) and is associated with the ER membrane. Activation of PDE3 but not PDE4 plays a role in the antilipolytic effect of insulin *in vivo* in human fat tissue. Two distinct PDE3 subfamilies, PDE3A and PDE3B, products of distinct but related genes, have been identified, of which PDE3B is expressed in adipocytes. The importance of PDE3 as an upstream regulator of HSL activity in insulin's antilipolytic pathway has been shown with the use of specific and cell-permeable PDE3 inhibitors. Specific inhibition of PDE3 in intact cells completely blocks the antilipolytic action of insulin. Activation of PDE3 is associated with phosphorylation of serine-302 in intact cells. This site is also phosphorylated in response to cAMP-increasing hormones, leading to feedback regulation of the cAMP level. In the presence of both hormones, that is, the physiological condition during which insulin exerts its antilipolytic action, there is more than additive phosphorylation of serine-302 associated with a more than additive activation of PDE3, suggesting positive cross talk between the pathways upstream of PDE3. Thus, the regulation of cAMP content, PKA activity, and thereby the activity of HSL is very complex and includes feedback loops as well as cross talk between different pathways.

Upstream regulation of PDE3B can be summarized as follows (Fig. 7): The insulin-stimulated PDE3 kinase (PDE3K), apparently a serine kinase activity, may be identical to that intrinsically associated with the insulin receptor. PDE3B may thus represent the first substrate of the insulin receptor kinase, which is phosphorylated at serine leading to its activation (Fig. 7). However, other experimental evidence argues for the dual specificity protein/lipid kinase, PI3K, consisting of a regulatory and catalytic subunit, as the major upstream regulator of PDE3B and, consequently HSL, since treatment of the cells with the PI3K inhibitor wortmannin completely blocks activation of PDE3K, phosphorylation/activation of PDE3B, and finally the antilipolytic action of insulin (Fig. 7). Upon insulin stimulation, PI3K binds to specific tyrosine-phosphorylated motifs on the insulin receptor substrate protein-1 (IRS-1), the major substrate for the insulin receptor tyrosine kinase (IR). The signal transduction between PI3K and PDE3K is not yet known, but probably involves protein kinase B (PKB; Fig. 7). The well-known insulin-stimulated serine kinases, MAPK or p70S6 kinases, apparently are not involved in the antilipolytic pathway of insulin.

In addition to the short-term insulin regulation of cAMP degradation, long-term effects of insulin on HSL have been reported. HSL activity, immunoreactive protein, and mRNA levels in adipose tissue were increased in response to

streptozotocin-induced insulin deficiency in the rat, whereas acute treatment with insulin returned HSL activity to normal without altering the increased amounts of HSL immunoreactive protein and mRNA. Increased HSL activity after prolonged exposure of isolated adipocytes to insulin has been reported in one study, whereas others did not reveal an effect of insulin at the mRNA expression level of HSL. Thus, long-term insulin regulation of HSL and the involvement of pretranslational mechanisms remain under debate, while short-term treatment with insulin controls HSL by posttranslational mechanisms.

4.3.2 Desensitization

Long-term exposure of 3T3-L1 adipocytes to insulin at or near physiological concentrations results in increased basal glycerol release in the medium without a concomitant rise in NEFA release. These conditions also altered β-adrenergic-stimulated lipolysis, exaggerating glycerol but preventing NEFA release. Stimulation of lipolysis by long-term insulin treatment, as measured by glycerol release is an unexpected finding given the short-term antilipolytic action of insulin. This finding, however, agrees with previous studies that showed increased glycerol release after prolonged insulin treatment of isolated rat adipocytes. One of these studies showed that the effect of long-term insulin depends on the presence of high glucose concentrations in the medium. Yet, the role of the hexosamine pathway in mediating this effect of long-term insulin treatment seems unlikely as increased glycerol release occurred irrespective of the presence of glutamine in the medium. In this study, long-term exposure to insulin was done in culture medium, which contained 25-mM glucose. Yet, at the end of the incubation period, glycerol was collected for 1 h in a buffer without glucose. Thus, it seems that extracellular glucose could be necessary as a priming factor, particularly under high glucose conditions, but is not required for the actual metabolic flux responsible for glycerol generation. Collectively, these studies demonstrate the ability of insulin, even at subnanomolar concentrations, to stimulate glycerol release upon prolonged exposure as opposed to its short-term inhibitory effect on lipolysis.

In contrast to the effect on glycerol release, long-term exposure to insulin was not associated with increased NEFA concentrations in the medium. Despite being the two end products of TAG breakdown, glycerol and NEFA released from adipocytes rarely reach the expected 1 : 3 molar ratio. Short-term insulin stimulation rapidly inhibits NEFA release from adipose tissue, through a combined inhibitory action on HSL and a stimulatory effect on NEFA reesterification. Recent findings support the possibility that although long-term insulin stimulates glycerol release, the short-term insulin stimulatory effect on NEFA reesterification is maintained under prolonged treatment. Because the antilipolytic effect of insulin and the stimulation of NEFA reesterification have been shown to involve PI3K, the two pathways seem to diverge downstream of PI3K. These seemingly independent pathways to affect glycerol and NEFA release from adipocytes also respond to leptin, which was shown to stimulate glycerol but not NEFA release from isolated adipocytes (see below). A role for leptin in mediating the effects of long-term insulin on glycerol and NEFA release from adipose tissue is an intriguing possibility. In conclusion, long-term treatment with insulin apparently leads to desensitization of the signaling pathway downregulating HSL activity without

concomitant negative interference with stimulation of the reesterification pathway. The physiological role of long-term insulin regulation of HSL activity remains unclear.

4.4 Leptin

Studies with rodents have demonstrated that leptin induces lipolysis both *in vitro* and *in vivo*. The effect was absent in animals lacking a functional leptin receptor, that is, db/db mice and in Zucker rats. Intriguingly, FA release does not accompany glycerol release in leptin-induced lipolysis, which suggests simultaneous induction of FA oxidation. In these studies, effects on HSL expression were not investigated. Thus, it is not known whether the lipolytic effect of leptin is mediated via phosphorylation-induced activation of HSL, an induction of HSL expression, a combination of both, or some other mechanism. In another study, however, long-term treatment of mice with leptin increased HSL mRNA expression by 30% in WAT, whereas no effect was seen in brown adipose tissue. The leptin signal is presumably transduced via the JAK/STAT pathway. Leptin was also shown to directly activate the TAG/FA substrate cycle, lipolysis, and FA oxidation, shifting fuel preference from carbohydrate to FA oxidation. In particular, studies with isolated rat adipocytes in primary culture demonstrated that leptin impairs insulin inhibition of isoproterenol-induced lipolysis and PKA activation. These insulin effects were reduced by leptin (2 nM) with a half-life of 8 h. Leptin concentrations below 1 nM led to a rightward shift of the corresponding insulin concentration–response curves. At leptin concentrations above 30 nM, the responsiveness was diminished, and also resulted in nearly complete relief of lipolysis from insulin control. The IC_{50} for leptin was about 3 nM after 15 h of preincubation of the primary adipocytes. The natural splice variant des-Gln49-leptin exhibited a significantly lower potency. Adipocytes regained full sensitivity for insulin's antilipolytic action within a few hours after leptin removal. Consequently, in ob/ob mice, the loss of leptin stimulation of uncoupling and TAG/FA substrate cycling triggered, at least in part, by leptin blockade of the antilipolytic activity of insulin will simultaneously contribute to the decrease in TAG mobilization and utilization as well as to the increase in TAG synthesis and storage. In conclusion, accelerated TAG/FA substrate cycling in adipose tissue provides a new mechanism by which leptin triggers increased metabolic rate and energy expenditure.

4.5 Growth Hormone

Growth hormone is another hormone signaling *via* the JAK/STAT pathway and with documented lipolytic effects, albeit with variable efficiency, depending on species and experimental system. Using primary rat adipocytes, growth hormone was found to increase HSL activity, that is, lipolysis, without causing an increase in HSL mRNA levels, supporting a role for posttranslational mechanisms in controlling lipolysis. In agreement, cGMP levels appear to be elevated moderately upon challenge with growth hormone. cGMP has been shown to mimic cAMP as an activator of lipolysis. This is supported by *in vitro* studies showing that cGMP-dependent protein kinase phosphorylates

and activates HSL. cGMP-dependent protein kinase is present at very low levels in adipose tissue, and the physiological role of this kinase and cGMP for activation of lipolysis, if any, is not known. Recently, nitric oxide was shown to exert modulatory actions on lipolysis in adipose tissue via cGMP-independent mechanisms. The effects were complex, with different redox forms acting either stimulatory or inhibitory.

4.6 Glucagon-like Peptide-1

Inhibition of lipolysis in rat islets by orlistat has been shown to inhibit the incretin action of glucagon-like peptide-1 (GLP-1). It was therefore a surprise that GLP-1 was able to rescue the loss of GSIS in isolated islets from fasted male $HSL^{-/-}$ mice. Hence, HSL is not essential for the incretin action of GLP-1. Although it is possible that GLP-1 was able to overcome the effect of FA deprivation via signaling pathways independent of FA metabolism, the findings could also be consistent with the action of GLP-1 to stimulate an alternative lipase (see above). The failure of GLP-1 to significantly alter glycerol release does not rule out this possibility. Given that FA deprivation has previously been shown to block insulin secretion to both fuel and nonfuel secretagogues like GLP-1, the latter possibility seems to be more likely. Clearly, the characteristics of other islet ß-cell lipase activities, including their responsiveness to PKA activators, such as GLP-1, warrant further investigation. Of relevance, isoproterenol, a ß-agonist believed to promote lipolysis through HSL, has been shown to stimulate lipolysis in adipocytes from $HSL^{-/-}$ mice. This supports the notion of another cAMP-mediated lipase in adipose tissue and perhaps in the ß-cell as well.

4.7 TNF-α

Of the various factors suggested to play a part in impaired adipocyte function in insulin resistance and NIDDM, increased TNF-α expression and production have attracted interest. TNF-α is produced and secreted from adipose tissue in obesity and thus acts in an autocrine fashion to alter adipocyte function during obesity-linked insulin resistance. Long-term exposure (>6 h) to TNF-α has been shown to stimulate lipolysis in adipocytes, despite inducing reduced HSL expression. An early study showed a downregulation of HSL gene expression upon TNF-α treatment of 3T3-L1 cells, as measured by Northern blot analysis and enzyme activity measurements. A similar effect, although much more moderate, was seen more recently at the protein level. In a study with primary rat adipocytes, however, no alteration of the levels of HSL protein occurred upon treatment with TNF-α. Studies using human adipose tissue have now shown that TNF-α inhibits LPL activity by downregulating its protein expression. Increased TNF-α mRNA levels are correlated with decreased LPL activity in human subcutaneous adipose tissue. In addition, TNF-α reduces the expression of FA transporters in adipose tissue of the Syrian hamster, and decreases the expression of enzymes involved in lipogenesis, such as acetyl-CoA carboxylase, FA synthase, and acyl-CoA synthase. TNF-α could thus impair the synthesis and entry of FA into the adipocyte, curtailing an increase in the intracellular TAG pool size.

TNF-α has also been found to promote lipolysis. Indirectly, the downregulation

of HSL observed in 3T3-L1 cells may reflect the known dedifferentiating effect of TNF-α in these cells, whereas, directly, the lipolytic effect of TNF-α could be explained by the decrease in LPL activity and intracellular reesterification and/or downregulation of G_i and perilipin expression. The latter effect of TNF-α, as well as the activation of lipolysis, was prevented by thiazolidinediones, a class of insulin-sensitizing antidiabetic agents. The mechanisms involved in regulation of lipolysis by TNF-α remain unclear. A study with human subcutaneous adipocytes demonstrated that, concomitant with an increase in lipolysis induced by TNF-α, there is activation of ERK1/2, leading to a decrease in the expression of PDE3B, together with an elevation in intracellular cAMP and hence activation of PKA. Since these two pathways are classically not coupled, the significance of changes in both is unclear in relation to an increase in lipolysis. Interestingly, TNF-α stimulated the three mammalian MAPK, p42/44 (ERK2/1), JNK, and p38 in time- and concentration-dependent manners in parallel to induction of lipolysis (3-fold at maximal dose). Lipolysis was completely abrogated by inhibitors specific for p42/44 and JNK but was not affected by a p38 inhibitor. These data suggest involvement of p42/44 and JNK in the TNF-α upregulation of lipolysis in human preadipocytes. The close association between the expression of enzymes involved in lipolysis and lipogenesis with adipogenesis has made it difficult to tease out process-specific actions of TNF-α. TNF-α can thus act on the adipocyte to shift lipid metabolism away from lipid accumulation and toward a reduction in the TAG pool, which could represent one mechanism by which TNF-α can reduce total adipose tissue weight.

Severe weight loss or cachexia is the detrimental end point of several diseases, including cancer, infection, and congestive heart failure. Unlike starvation, cachexia results from a severe loss of lean body mass (mostly skeletal muscle) and the depletion of the fat depots. The pathogenesis of this weight loss is multifactorial, but evidence suggests that cytokines are key players. The predominant reason for the loss of adipose tissue is the fall in the activity of LPL and an increase in the activity of HSL. Since TNF-α promotes lipolysis and inhibits lipogenesis, it represents an ideal player in the depletion of adipose tissue mass seen with cachexia. An elevation in plasma levels of TNF-α, as opposed to adipose tissue-derived TNF-α, is suggested to be responsible for the metabolic alterations in adipose tissue with cachexia.

4.8 Acylation-stimulating Protein

Acylation-stimulating protein (ASP) is identical to C3adesArg, a cleavage product of complement C3. Cleavage of complement C3 is mediated through the alternate complement pathway via the interaction of C3, factor B, and adipsin that generates C3a. Rapid cleavage of the carboxy-terminal arginine of C3a by carboxypeptidase N generates ASP. Adipocytes are one of the few cells capable of producing all three factors (factor B, adipsin, and C3) that are required for the production of ASP. ASP production increases consequent to adipocyte differentiation, and plasma ASP levels are elevated in obesity. Chylomicrons *in vitro* stimulate ASP production by adipocytes. *In vivo* arterial–venous gradients across a subcutaneous adipose tissue bed in humans demonstrate direct postprandial production of ASP. The postprandial increase

in ASP is adipose tissue–specific and is not observed in the general circulation. Altogether, these data suggest that ASP and TAG storage are metabolically intertwined. ASP acts as an adipocyte autocrine factor and has been proposed to play a central role in the metabolism of adipose tissue by increasing the efficiency of TAG storage in adipocytes, an action that results in more rapid postprandial TAG clearance. This is based on stimulation of both glucose uptake and NEFA storage in human adipose tissue via translocation of glucose transporters (GLUT1, GLUT3, and GLUT4) from intracellular sites to the cell surface and an increase in DGAT activity. In addition, ASP has been shown to inhibit HSL in adipocytes, independently and additively to insulin.

The pathways distal to PI3K that are involved in the effect of insulin on FFA reesterification and in the action of ASP on FFA reesterification and lipolysis were unknown until now. PKC blockers could not counteract the effects of ASP or insulin on fractional NEFA reesterification or lipolysis, suggesting that the actions of the two hormones on NEFA release are not mediated by PKC. This is in contrast to earlier results on the action of ASP on TAG synthesis and glucose transport in human fibroblasts, which was counteracted by PKC blockers. The PI3K blocker wortmannin counteracted the effect of insulin on NEFA release by reversing the effect of insulin on both fractional NEFA reesterification and lipolysis. The effects of ASP, however, were not affected by wortmannin. Thus, the pathway mediating the effect of ASP on NEFA release does not involve PI3K. This strongly supports the hypothesis that ASP and insulin follow different pathways in their action on NEFA release. Because the ASP receptor protein(s) has not been identified, further research in this area is difficult at present. The question whether a more distal pathway could be common for the actions of insulin and ASP on NEFA metabolism was addressed. Interest was focused on PDE, which previously was found to mediate not only the antilipolytic effect of insulin (see above) but also contributes to the stimulatory effect of the hormone on glucose transport in human fat cells. A nonselective PDE inhibitor that does not interact with the antilipolytic effects of adenosine, counteracted the actions of both ASP and insulin on NEFA release by reversing their effects on fractional NEFA reesterification and lipolysis. The selective PDE3 blocker OPC3911 could also counteract these effects of ASP and insulin. The selective PDE4 blocker rolipram could not counteract the effect of insulin on fractional NEFA reesterification and lipolysis. Rolipram did not alter the effect of ASP on lipolysis either, but it counteracted slightly the effect of ASP on fractional NEFA reesterification. These results agree with those obtained with direct measurements of PDE activity. PDE3 activity in fat cells was stimulated with both ASP and insulin in a concentration-dependent manner, whereas PDE4 activity was only slightly stimulated with ASP. Thus, the effects of both ASP and insulin on NEFA release appear to be mediated predominantly by PDE3. PDE4 seems to be involved in the action of ASP as well, although to a lesser extent than PDE3.

4.9 Acipimox, Nicotinic Acid, and Niacin

Acipimox (5-methylpyrazine carboxylic acid-4-oxide) is a newer, well-tolerated derivative of nicotinic acid (NA) which shows lipid-lowering properties in patients

with types II and IV hyperlipidemia. The fall in plasma TAG is associated with a decrease in total and LDL cholesterol and an increase in HDL cholesterol. NA has long been used in the treatment of dyslipidemia, producing a very desirable modification of multiple cardiovascular risk factors, increasing HDL, TAG, and lipoprotein(a), which results in a reduction in mortality. NA is an effective therapeutic agent. However, it has to be administered at high doses and has a characteristic side effect profile defined by intense, but transient, prostaglandin-mediated cutaneous vasodilation (''flushing'') that affects patient compliance. Despite their long history of clinical use, the precise mechanism of action of acipimox and NA was unknown until recently, although inhibition of adipocyte lipolysis via the activation of a G_i-coupled receptor is believed to contribute. It has been postulated that a reduction in NEFA liberated from adipose tissue results in reduced influx of NEFA into the liver and hepatic reesterification of NEFA and thereby diminishes the production rate of hepatic TAG available for VLDL and LDL synthesis, which in part explains the hypolipidemic effects observed during NA and acipimox therapy.

Whereas most studies have focused on the effects of NA on lipid metabolism, the action of NA on carbohydrate metabolism is less well understood. After acute NA administration, glucose concentrations have been reported to decrease, rise or remain unaltered in rats and humans. Results of glucose tolerance tests after acute NA intake have also been inconsistent. Chronic administration of NA has consistently resulted in deterioration of glucose tolerance and elevation of fasting blood glucose concentrations in normal humans and impairment of glycemic control in NIDDM patients. These effects are contrary to expectations based on the glucose-FA cycle. If reduction of lipolysis and NEFA availability reduces oxidation of fat in tissues and availability of gluconeogenic precursors in the liver, insulin sensitivity should improve and glucose concentrations fall, as observed with inhibitors of mitochondrial FA oxidation. It is unclear whether this failure of NA to act as an antidiabetic drug is caused by its unfavorable pharmacokinetic profile (short half-life time) and/or its mode of action as inhibitor of adipocyte lipolysis.

Niacin is an effective, unique lipid-regulating agent that beneficially reduces plasma TAG, cholesterol, and atherogenic apolipoprotein B (apoB)-containing lipoproteins (VLDL, LDL, and lipoprotein [a]) and increases antiatherogenic apoA-I-containing HDL levels. Several clinical trials have demonstrated that treatment with niacin significantly reduces total mortality and coronary events and retards the progression or induces the regression of coronary atherosclerosis. Despite its wide usage as a broad-spectrum lipid-regulating agent, the cellular and molecular mechanisms by which niacin modulates the hepatic lipid metabolism and the production of VLDL and LDL particles are incompletely understood. Using HepG2 cells as an *in vitro* model system, it has previously been shown that niacin inhibits the incorporation of radiolabeled oleic acid or glycerol into TAG, suggesting decreased *de novo* synthesis of TAG by niacin. Additionally, niacin may also increase intracellular apoB degradation in HepG2 cells. Because the synthesis and availability of TAG play a critical role in intracellular apoB processing and secretion of apoB-containing lipoproteins; previous studies suggested that niacin, by inhibiting TAG synthesis, increased intracellular apoB degradation,

resulting in reduced secretion of apoB-containing particles. In support of these *in vitro* studies, earlier turnover studies in humans suggested that niacin decreased the production (transport) rate of TAG from radiolabeled FA, thus decreasing TAG-rich lipoproteins (e.g. VLDL) and their product LDL.

4.9.1 Physiological Mode of Action

The effect of acipimox on adipose tissue lipolysis has been examined under three experimental conditions. Firstly, in the presence of high levels of the nonselective ß-AR agonist isoproterenol, secondly in the presence of low levels of adenosine deaminase (ADA), which when used alone has a minimal effect on basal lipolysis, yet when combined with submaximal concentrations of isoproterenol, substantially facilitate the lipolytic response. Thirdly, acipimox was examined in the presence of high levels of ADA. Fat cells produce adenosine from cAMP via consecutive action of PDE and 5′-nucleotidase, which, upon release into the medium, act at specific AR to inhibit AC, this inhibitory effect being mediated by the GTP-dependent, pertussis toxin-sensitive regulatory protein, G_i. High levels of ADA, by converting the endogenous adenosine into inosine, relieve the inhibition of AC, which results in the observed increase in basal lipolysis. The data show that acipimox has only a minor, if any, antilipolytic effect on lipolysis stimulated by isoproterenol alone. In contrast, when the lipolytic rate is increased by a lower concentration of isoproterenol in combination with ADA, acipimox becomes a potent antilipolytic agent. Wieser and Fain reported similar results for NA, with the addition of ADA increasing the sensitivity to catecholamine-induced lipolysis toward inhibition by NA. The dependence of acipimox upon removal of adenosine suggests that the antilipolytic mechanisms downstream of the AR and the putative acipimox receptor (see below) and upstream of AC are identical for adenosine and acipimox, respectively.

These results show that acipimox acts to inhibit cAMP-stimulated lipolysis through suppression of intracellular cAMP levels, with subsequent decrease in PKA activity. The antilipolytic activity of acipimox is associated with a quantitative shift of HSL from the LD to the cytosol in rat adipocytes, suggesting that, by decreasing intracellular cAMP levels, acipimox can reduce the association of HSL with TAG substrate of the LD. Pharmacokinetic studies show that the plasma concentration of acipimox in man after a single 250 mg oral dose reaches 33 µM, and remains above 7 µM for 6 to 8 h. In comparison, acipimox is a potent antilipolytic agent at a concentration of 10 µM and above, in human adipose tissue stimulated maximally and submaximally by isoproterenol. Thus, plasma acipimox levels correlate well with its *in vitro* effect on lipolysis and cAMP synthesis in adipocytes.

Work on NA showed that it also decreased intracellular cAMP levels through inhibition of AC. The conditions were identical to those required to inhibit the enzyme by the antilipolytic hormonal factors, prostaglandin E_2, adrenaline, and the adenosine analog, PIA. These findings indicated that NA inhibits AC via a receptor-mediated process in a hormone-like manner, which indicates the involvement of the regulatory protein, G_i. This was confirmed by the discovery that the antilipolytic effects of prostaglandin E_2, PIA, and NA were abolished by the pretreatment of adipocytes with pertussis toxin, to inactivate G_i. Use of the AR antagonist, 3-isobutyl-1-methylxanthine demonstrated that NA and adenosine act through

separate receptors to inhibit adipocyte AC activity. Since NA shares its ability to inhibit lipolysis via a G_i-dependent mechanism with acipimox, and since the drugs are structurally related, it seemed possible that acipimox suppresses intracellular cAMP levels through binding to the same G_i-linked receptor (see below).

4.9.2 Molecular Mechanism

G-protein activation by NA and derivatives was recently assessed as stimulation of guanosine 5′-(γ-[^{35}S]-thio)triphosphate binding, and [^{3}H]NA was used to specifically label binding sites. NA (EC_{50} 1 μM) stimulated [^{35}S]GTPγS binding in membranes from rat adipocytes and spleen, but not from other tissues. G-protein activation in adipocyte membranes in the presence of maximally activating concentrations of a selective A_1 AR agonist, 2-chloro-N^6-cyclopentyl-adenosine, and NA was almost additive, indicating that G-proteins of mostly distinct pools were activated by these agonists. G-protein activation by NA and related substances in spleen and adipocytes revealed identical pharmacological profiles. [^{3}H]NA specifically detected guanine nucleotide-sensitive binding sites of identical pharmacology in adipocyte and spleen membranes. These data indicate that NA most probably acts on a specific G-protein-coupled receptor (GPCR).

To identify the G_i-linked GPCR for NA, orphan receptors were selected on the basis of their tissue expression profiles for a rational screening. Subsequently, a subset of 10 orphan GPCR, which by mRNA distribution analysis exhibited significant expression levels in both adipose tissue and spleen, were expressed in an appropriate mammalian cell line to allow measurement of functional $GTP_\gamma S$ binding following NA treatment. Thereby, HM74 was identified as a low-affinity receptor for NA, which represents an orphan GPCR previously cloned from a cDNA library derived from human monocytes. The half-maximal effector concentration for NA with 1 mM at HM74 was 1000-fold higher than that previously reported in membranes produced from rat adipose tissue or spleen. Subsequent identification of a novel paralog of HM74, termed HM74A, by a molecular biology approach and its expression in various test systems revealed that HM74A acts as a high-affinity receptor for NA. The activity and affinity of NA was in good agreement with that previously reported. In the [^{3}H]NA displacement assay, both the absolute potency and the rank order of potency of various HM74A ligands was the same, whether tested against the stable CHO cell line expressing recombinant human HM74A or human adipocytes. These data strongly suggest that HM74A is the G_i-linked GPCR for NA on human adipocytes. Compatible with this conclusion, nicotinamide, which unlike NA produces no alteration in lipoprotein profiles, acted only as a very weak agonist at HM74A with 1000-fold lower potency than NA. In contrast, acipimox has also been identified as a full high-affinity agonist for HM74A. Thus, activation of HM74A seems to account for the inhibition of lipolysis observed with NA and acipimox. Therefore, of the NA derivatives tested in man, it appears that potency at HM74A is linked with their efficacy in normalizing lipoprotein profiles.

Using HepG2 cells, the effect of niacin on the mRNA expression and microsomal activity of DGAT1 and DGAT2, the last committed but distinctly different enzymes for TAG synthesis was examined. Addition of niacin to the DGAT assay reaction mixture dose-dependently (0–3 mM) inhibited DGAT activity by 35 to 50%,

and the IC_{50} was found to be 0.1 mM. Enzyme kinetic studies showed apparent K_m values of 8.3 and 100 μM using [^{14}C]oleoyl-CoA and *sn*-1,2-dioleoylglycerol as substrates, respectively. A decrease in apparent V_{max} was observed with niacin, whereas the apparent K_m remained constant. A Lineweaver–Burk plot of DGAT inhibition by niacin showed a noncompetitive type of inhibition. Niacin selectively inhibited DGAT2 but not DGAT1 activity. Niacin inhibited overt DGAT activity. Niacin had no effect on the expression of DGAT1 and DGAT2 mRNA. These data suggest that niacin directly and noncompetitively inhibits DGAT2 but not DGAT1, resulting in decreased TAG synthesis and hepatic atherogenic lipoprotein secretion, thus indicating a major target site for its mechanism of action.

The inhibitory effects of niacin on FA synthesis and inhibition of peripheral lipolysis (e.g. adipose tissue) and decreased FA mobilization may be additional mechanisms of action to explain TAG reduction by niacin. In the absence of other regulatory events, niacin-mediated inhibition in adipocyte FA mobilization over prolonged steady state conditions would result in excessive synthesis of TAG and obesity. However, this mechanism is unlikely because niacin is not known to affect body weight clinically. On the basis of observations in hepatocytes, it is likely that niacin may also inhibit DGAT2 activity in adipocytes. This may provide a regulatory mechanism to limit excessive adipocyte TAG synthesis and related obesity events in the face of the effect of niacin on adipocyte FA mobilization. Although the biological actions of niacin are not clearly known to be mediated by receptor-mediated events, recent reports indicate that the orphan G-protein-coupled receptor mouse PUMA-G and human HM74 act as cellular receptors for niacin (see above). PUMA-G and its human ortholog HM74 are highly expressed in white and brown adipose tissue and are also detected in various other tissues, including lung, adrenal gland, and spleen. However, PUMA-G and HM74 were not detected in liver tissue. Using PUMA-G-deficient mice, it has been demonstrated that PUMA-G mediates the niacin-induced inhibition of FFA release from isolated adipocytes. Because of the lack of PUMA-G and/or HM74 in liver tissue, it is very unlikely that PUMA-G/HM74 mediates the effect of niacin on DGAT activity and TAG synthesis in hepatocytes.

In conclusion, inhibition of DGAT2 activity in liver by niacin may result in a decreased rate of TAG synthesis and its reduced availability for intracellular apoB lipidation and translocation across the ER membrane, resulting in observed effects of increased apoB degradation. Thus, these results suggest DGAT2 as a major site of action of niacin to inhibit TAG synthesis, resulting in decreased secretion of apoB-containing atherogenic lipoproteins. Niacin may represent a new therapeutic class of drugs that regulate atherogenic apoB-containing lipoprotein (e.g. VLDL and LDL) secretion by specifically targeting DGAT2.

4.9.3 Desensitization

The established phenomenon that exposure of a cell to an agonist can cause desensitization, so that a second exposure to the agonist is less effective than the first, has been studied extensively and various mechanisms have been described. First, short-term exposure to a ligand (minutes) can induce a change in the receptor. For example, ß-AR can become phosphorylated by a specific kinase (ß-AR kinase) after exposure to an agonist. Second, after

more prolonged exposure to an agonist, the number of receptors on the cell surface can decrease by a process termed *downregulation*. Downregulation is generally considered to occur in two steps. Initial rapid sequestration of receptors from the cell surface through endocytosis is followed by a slower loss of total cellular receptors involving intracellular degradation, although at least a portion is often recycled back to the cell surface, as has been demonstrated for the insulin receptor. In addition to increased degradation of receptors, recent studies for ß-AR have suggested that alterations in receptor mRNA turnover, that is, decreased transcription and/or increased mRNA degradation, may also play a role. These phenomena can readily explain homologous desensitization, where exposure of a cell to a hormone results in subsequent insensitivity to that hormone. Another commonly reported phenomenon is known as heterologous desensitization, in which treatment of a cell with a hormone subsequently can make the cell less sensitive to another hormone that operates through a different receptor. Heterologous desensitization has been described for many signaling systems, including GPCRs coupled to AC and to phospholipase C. Mechanisms of heterologous desensitization, however, are relatively poorly understood.

A_1-AR can, reportedly, be downregulated in rat adipocytes following prolonged incubation with the nonmetabolizable adenosine analog and agonist, PIA. Although there are two major classes of AR, known as A_1 and A_2 receptors, adipocytes primarily possess receptors of the A_1 class. These receptors are inhibitory toward AC, and their action is thought to be mediated via a pertussis toxin-sensitive G-protein known as G_i, of which three subtypes 1–3 have been identified in rat adipocytes. Prolonged incubation of adipocytes with PIA leads to a marked downregulation of A_1-AR. In addition, an approximately 50% decrease in G_i, as measured by pertussis-catalyzed ADP-ribosylation, has been found. This observation suggested that G_i was downregulated along with the AR. Subsequently, a series of specific antisera was used to demonstrate that PIA causes a marked (ca. 90%) loss of G_i1 and G_i3 with a more modest (50%) loss of G_i2. When PIA is washed away, G_i downregulation was reversed, suggesting that it is a real regulatory phenomenon rather than a simple toxic effect. Furthermore, Stiles and coworkers reported similar findings in adipocytes derived from rats after chronic infusion of PIA. More recent studies suggest that G-protein downregulation is a common phenomenon resulting from chronic exposure to agonists. Since several agonists can presumably couple through a single G-protein, it is clear that this phenomenon of G-protein downregulation could account for heterologous desensitization.

In addition to impairment of signal transduction activity at the level of G-proteins, heterologous desensitization of GPCR regulation of lipolysis can be caused by changes at the level of cell surface expression of GPCRs or signaling activity of signaling components, such as AC, PDE, and PKA (catalytic activity), as well as function of the lipolytic end effectors (e.g. HSL/perilipin translocation apparatus). Interestingly, prolonged incubation of rat adipocytes in primary culture with NA at concentrations up to 1 mM had no effect on the levels of $G_i1–3$ as well as AC. However, pretreatment of the cells with 1 mM NA for four days decreased their sensitivity for subsequent acute inhibition of β-adrenergic stimulation of lipolysis and

AC activity by NA by 1 order of magnitude (but had no effect on the sensitivity of the cells toward PIA). The molecular mechanism of the homologous desensitization of lipolysis by NA, which may form the molecular basis for this observed loss of efficacy of NA and acipimox treatment during chronic antihyperlipidemic therapy, remains to be elucidated.

4.10 Glimepiride and Phosphoinositolglycans

Recent studies have identified two completely different exogenous stimuli, which mimic the antilipolytic activity of insulin in insulin target cells. They bypass activation of the insulin receptor, and rather act by triggering redistribution of signaling components between DIGs of different lipid and protein composition at the target cell plasma membrane. (1) Phosphoinositolglycan-(-peptides) (PIG[-P]) prepared by chemical synthesis or isolation from natural sources reduce isoproterenol-stimulated lipolysis in concentration-dependent fashion to almost basal levels in primary and cultured adipocytes. PIG(-P) are derived from the polar core glycan head group of glycosylphosphatidylinositol (GPI) anchored proteins consisting of 2′,3′-cyclic phospho-*myo*-inositol coupled to five sugar moieties in typical glycosidic linkages (PIG portion) and, optionally, contain an additional terminal ethanolamine-linked tripeptide residue (P portion); (2) The hypoglycemic sulfonylurea, glimepiride, which in NIDDM patients exerts an insulin-independent blood glucose-decreasing activity in addition to its insulin-releasing potency blocks isoproterenol-stimulated lipolysis in adipocytes from insulin-resistant Zucker fatty rats or in adipocytes made insulin-resistant *in vitro* by incubation in primary culture in the presence of high concentrations of insulin and glucose.

Interestingly, hydrophilic PIG-P and lipophilic glimepiride, albeit differing completely in structure, have in common part of the signaling pathway that cross talks to the insulin signal transduction cascade and thereby negatively regulates HSL activity and lipolysis in adipocytes. The available data support the following model for their molecular mode of action. PIG(-P) bind as agonists/antagonists to the receptor, p115, a transmembrane protein that is anchored at the cell surface within DIGs. Upon binding, PIG(-P) displace endogenous GPI proteins from binding to p115 by competition with their GPI head groups and thereby reduce their concentration at DIGs. In contrast, glimepiride is not recognized by a proteinaceous receptor of the adipocyte plasma membrane but spontaneously inserts into DIGs via direct hydrophobic interactions in nonsaturatable fashion with GPI lipids thereby altering the structural organization of DIGs. Both events induce the redistribution of lipid-modified signaling protein, which are known to reside within DIGs on the basis of their acylation/glypiation and/or direct binding to caveolin. In particular, GPI proteins and palmitoylated nonreceptor tyrosine kinases of the src class, such as pp^{59}Lyn, translocate from DIGs of lower buoyant density (higher cholesterol content) to those of higher buoyant density (lower cholesterol content) accompanied by dissociation of pp^{59}Lyn from the DIG resident protein, caveolin. This relieves pp^{59}Lyn from inhibition by caveolin, interaction of which with various signaling proteins downregulates their signaling activity. In turn, activated pp^{59}Lyn phosphorylates IRS-1 at tyrosine residues, presumably at the same sites used by

the insulin receptor. In consequence, activation of the PI3K pathway leads to upregulation of PDE3B and downregulation of HSL activity via the same series of events engaged by insulin (see above). Very recent experiments revealed a possible explanation for the molecular link between the interaction of glimepiride with DIGs and the resulting reorganization and redistribution of structural (GPI proteins) and signaling (nonreceptor tyrosine kinases) components within the DIGs. The binding of glimepiride to GPI lipids triggers the activation of a DIG-associated GPI-specific phospholipase that cleaves GPI proteins and GPI lipids. PIG(-P) thereby generated may bind to the p115 at the DIGs and subsequently induce redistribution of signaling proteins from DIGs and the same downstream series of events, as recently demonstrated for exogenously added synthetic or natural PIG(-P). Alternatively, GPI cleavage may directly affect the structure of DIGs and thereby cause the redistribution of DIG components at both the outer (GPI proteins) and inner (nonreceptor tyrosine kinases) leaflets of the DIG membrane, accumulation of which critically depends on the presence of glycolipids. The latter possibility seems more likely since p115 is apparently not involved in mediating the antilipolytic activity of glimepiride. It seems plausible that the loss of long-chain FA from the outer leaflet of DIGs caused by redistribution of GPI proteins or cleavage of GPI lipids within DIGs simultaneously triggers the alteration of the FA composition of the DIG inner leaflet. This ''adjustment to a common FA milieu'' across the leaflets of DIGs may facilitate the redistribution of pp^{59}Lyn. Interestingly, the GPI-specific phospholipase stimulated by glimepiride in cultured and primary adipocytes is reportedly activated also by insulin in the presence of glucose.

4.11 Differences in Regulation of TAG Storage and Mobilization between Visceral and Subcutaneous Adipocytes

Individuals with peripheral obesity possess fat distribution subcutaneously in gluteofemoral areas and the lower part of the abdomen, and are at little risk of metabolic complications, such as NIDDM. Conversely, individuals with upper-body obesity accumulate fat in subcutaneous and visceral deposits and are more susceptible to metabolic problems, in particular when visceral fat deposits are abundant. Visceral fat deposits, located in the body cavity, are composed of the omental and mesenteric fat, and comprise the minor component of total body fat, representing 20% and 5–8% of total body fat in men and women, respectively. In upper-body obesity, fat excess is present not only in the visceral abdominal regions but also in the subcutaneous abdominal regions. There are several explanations but no clear proof why upper-body obesity is more at risk of developing metabolic disease than lower-body obesity. Since the visceral deposit is in direct contact with the liver through the portal circulation and considering the alterations of hormonal control of lipolysis of its adipocytes (insulin vs. catecholamines, see below), the ''portal paradigm'' was postulated on the basis that visceral adipocytes, through enhancement of lipolysis due to both reduced insulin-induced antilipolysis and enhanced catecholamine-induced lipolysis, will release portal NEFA that disturb liver metabolism. Chronic NEFA excess will in turn lead to glucose intolerance, hyperinsulinemia, insulin resistance, and dyslipidemia. However, experimental evidence is accumulating that nonvisceral upper-body fat rather than visceral fat

deposits is the predominant source of excess postprandial systemic NEFA availability in upper-body obese women and NIDDM patients. This raises the question as to whether the extent of visceral fat just represents another marker of ectopic fat distribution (i.e. fat present at the wrong place in tissues such as muscle, heart, liver, and pancreatic ß-cells). Alternatively, visceral adipocytes may possess properties that could be the origin of metabolic disturbances. In fact, striking adipose location–related differences have been reported in adipocyte responsiveness to insulin and catecholamines. Moreover, differences have been described in the characteristics of various biochemical pathways regulating TAG storage and mobilization between subcutaneous and visceral fat deposits.

In detail, adipocytes from visceral adipose tissue are more resistant to insulin-induced antilipolysis and reesterification of NEFA than those from leg and nonvisceral body fat both *in vitro* and *in vivo*. Various functional differences in these cells have been identified at the level of the insulin receptor and the postreceptor insulin-signaling cascade. PDE3B involved in lipolysis regulation by insulin (see above, Fig. 7) and protein tyrosine phosphatases dephosphorylating the insulin receptor, such as PTP1b, could be affected in differential fashion in visceral versus subcutaneous adipocytes. This concurs with the endogenous PTP1b activity found to be elevated in visceral adipose tissue and might contribute to the relative insulin resistance of this fat deposit. Exacerbating the impairment of insulin inhibition of lipolysis, the lipolytic response toward catecholamines is more pronounced in isolated adipocytes from visceral adipose tissue than from subcutaneous gluteal, femoral, and abdominal adipose tissue. This higher lipolytic activity can be explained by altered expression or function of HSL (increase) and/or proteins interacting with either HSL, such as ALBP (increase), or the LD, such as perilipin (decrease) (see above, Fig. 7). An enhanced α_2-adrenoceptor responsiveness associated with a concomitant decrease in ß-adrenoceptor responsiveness explains the lower lipolytic effect of catecholamines in gluteal and femoral adipocytes of normal and obese women and abdominal adipocytes of obese men compared with visceral adipocytes. Conversely, visceral adipocytes exhibit the highest $ß_{1,2}$-adrenoceptor-mediated and the weakest α_2-adrenoceptor-mediated lipolytic and antilipolytic responsiveness, respectively, to catecholamines, which seems to correlate with decreased expression of α_2-adrenoceptors and concomitantly increased expression of ß-adrenoceptors. In obese subjects, unrestrained lipolysis leads to excessive NEFA release from visceral hypertrophied adipocytes and may prevent their further enlargement in contrast to subcutaneous adipocytes, which actually represent the largest ones. The search for adipose tissue-specific local differences in the expression of genes that regulate the differentiation and expansion of adipose tissue as well as the regulation of TAG storage and mobilization is under way using genomic and proteomic approaches.

5 Up-/Downregulation of Components of TAG Storage and Mobilization

5.1 HSL

Recently, the functional significance of HSL in adipose tissue metabolism has

begun to be clarified in studies using HSL null mice. These mice showed normal growth rates and body weights. While the epididymal retroperitoneal and femoral WAT depots of HSL null mice remained unchanged, they displayed a 65% increase in brown adipose tissue mass compared with wild-type control mice. Inactivation of HSL resulted in the complete absence of neutral cholesterylester hydrolase activity in adipose tissue (both white and brown). However, TAG lipase activity in WAT was reduced by only 40% and TAG lipase activity in brown adipose tissue was similar to wild-type mice. Basal lipolysis, that is, glycerol release, was reduced in isolated adipose cells from HSL null mice in one study, but was unaffected and seemingly increased in another. Nonetheless, there was a marked defect or complete absence of catecholamine-stimulated glycerol release in adipose cells from HSL null mice, whereas catecholamine-stimulated NEFA release was still observed, but attenuated. This apparent discrepancy in the release of glycerol and NEFA from adipose cells of HSL null mice has been clarified by the observation that the basal and catecholamine-induced DAG content increased markedly in white and brown adipose tissue of HSL null mice. Therefore, the studies with HSL null mice appear to substantiate that HSL is the rate-limiting enzyme for DAG hydrolysis in adipose tissue and is essential for hormone-stimulated lipolysis. Remarkably, the absence of HSL was not associated with the development of obesity. However, adipose cells from HSL null mice, while displaying size heterogeneity, tended to be hypertrophic. Moreover, due to defective lipolysis during fasting, there was a reduction in circulating NEFA and a decreased hepatic production of VLDL secondary to the diminished release of NEFA from adipose tissue. This was associated with an induction of LPL in WAT, as well as in skeletal and cardiac muscle, but a decrease of LPL in brown adipose tissue. It remains to be determined whether operation of the TAG lipase in HSL null mice is a consequence of its compensatory upregulation in HSL-deficient adipocytes, only, or is indicative for expression of a second TAG-specific HSL-like lipase in wild-type adipocytes, too. Taken together, the findings on the lack of obesity and mild adipocyte hypertrophy observed in HSL null mice suggest that other lipases could also play a role in TAG mobilization.

Interestingly, in HSL null mice after prolonged fasting, plasma NEFA and TAG levels as well as hepatic TAG stores were reported to be significantly lower than with wild-type mice. This low hepatic TAG content was associated with improved hepatic insulin sensitivity since insulin caused a greater reduction in endogenous hepatic glucose production in HSL null mice (by 71%) than in wild-type mice (by 31%). This increase in hepatic insulin sensitivity was associated with elevated insulin receptor protein levels and activation of components of the insulin-signaling cascade, such as phosphorylation of PKB and activity of PI3K. The low hepatic TAG content in HSL null mice can be explained by their low plasma NEFA levels, since liver-specific NEFA uptake is commonly regarded to be a concentration-driven process facilitated by specific membrane transporters (see above). The inverse relationship between insulin sensitivity and hepatic TAG content may be explained by alterations in gene expression during activation of nuclear transcription factors such as peroxisome proliferator-activated receptors by intracellular TAG and/or fatty acyl derivatives. Furthermore, the diminished plasma NEFA levels *per se* cannot be excluded from being, at least partly,

responsible for the increased hepatic insulin sensitivity, since plasma NEFA concentrations are inversely correlated with insulin sensitivity (see above). Strikingly, in HSL null mice, no differences were observed in insulin-mediated whole-body glucose uptake compared with wild-type mice as revealed during hyperinsulinemic euglycemic clamp studies. The lack of improvement of whole-body insulin sensitivity may be explained by the reported absence of significant differences in muscle TAG content in combination with unchanged insulin-induced PKB phosphorylation in HSL null compared with wild-type mice despite lower plasma NEFA levels.

Recently, HSL null mice have been shown to have impaired insulin secretion, a 2- to 2.5-fold increase in islet TAG content, and elevated basal insulin secretion from isolated islets that fails to rise further upon challenge with glucose. Comparison of the gene expression profile between islets isolated from wild-type and HSL null mice using microarray chip technology and Taqman quantitative PCR for selected genes revealed changes in genes that are involved in lipid metabolism (methyl sterol oxidase, short chain acyl-CoA dehydrogenase), insulin response (insulin-induced growth response protein) and cytoskeleton (profilin, cofilin). In particular, the mRNAs for UCP-2, SREBP-1c, and PPAR-γ were upregulated in islets from HSL null mice as compared with wild-type mice. The transcriptional upregulation of UCP-2, which is regulated by SREBP-1c and PPAR-γ, was associated with elevated NEFA and correlated with impaired glucose-stimulated insulin secretion. Finally, C/EBPα, which is involved in cytokine-regulated apoptosis of pancreatic ß-cells, was also upregulated. Collectively, these findings suggest that HSL is important in maintaining lipid homeostasis in ß-cells by directly and indirectly controlling gene expressing for multiple metabolic and signaling pathways and hence in the regulation of glucose-stimulated insulin secretion.

A recent study using transgenic mice overexpressing HSL specifically in ß-cells provided novel and important insights with regard to the role of HSL in the development of lipotoxicity. These transgenic mice were characterized by impaired glucose and severely blunted glucose-stimulated insulin secretion upon challenge with a high-fat diet. Their islets displayed both elevated HSL activity and forskolin-induced lipolysis compared with wild-type islets, which resulted in significantly reduced TAG levels in transgenic compared with wild-type islets provided the mice have been fed a high-fat diet. Thus, the rate of influx of NEFA into TAG of the islet LD and the capacity to mobilize this TAG pool seem to determine the emergence of islet lipotoxicity. This is in accord with the recently reported inverse correlation between apoptosis and TAG accumulation in cultured ß-cells, suggesting a cytoprotective function of TAG in cytoplasmic LD formed by normal ß-cells against NEFA-induced islet dysfunction. Moreover, prolonged high-fat feeding of mice is accompanied by downregulation of the expression of islet HSL. Consequently, physiological downregulation of HSL or pharmacological inhibition of HSL and possibly of other as yet unknown TAG lipases in ß-cells could be interpreted in terms of the operation of a defense mechanism against the emergence of NEFA-induced islet cell dysfunction.

In conclusion, HSL degrading TAG of LD in islets seems to exert at least three different functions in the regulation of insulin secretion and its coupling to external stimuli. (1) In the short-term,

upon challenge of ß-cells with an insulin secretagogue, HSL is phosphorylated and activated via (glucagon-like peptide 1 and gastric inhibitory polypeptide) receptor/cAMP-dependent mechanisms lipolytically releasing NEFA and/or NEFA derivatives from islet TAG. These may act as acute stimulus (glucose)-secretion coupling factors for the exocytosis of insulin-containing secretory vesicles. (2) In the long-term diet-induced NIDDM and the increased influx of NEFA derived from plasma lipoproteins through the action of LPL and plasma NEFA into ß-cells lead to the accumulation of TAG in LD of ß-cells, which apparently exceeds the degradation capacity of the basal HSL. Thus, the low activity state of HSL under these conditions guarantees the storage of NEFA (derivatives), which potentially compromise the insulin secretory mechanism and induce ß-cell apoptosis. (3) Long-lasting aberrations in the regulation of lipolytic activity, such as overexpression of HSL, failure to downregulate HSL during prolonged high-fat feeding or the mass effect of TAG overstorage *per se* leading to incremental lipolytic release of NEFA even at low constitutive HSL activity, may result in exceeding a certain threshold level of NEFA flux. This triggers the lipotoxic pathway, presumably involving binding of NEFA (derivatives) as ligands to transcription factors, such as PPAR, and other mechanisms. The resulting alterations in the expression of genes regulating insulin secretory vesicle biogenesis and exocytosis finally lead to dampening of glucose-induced insulin secretion.

5.2 ALBP

In the absence of ALBP, intracellular concentrations of NEFA unbound to protein were increased in adipose cells, and basal as well as isoproterenol-stimulated lipolysis is decreased by 40%. These ALBP-deficient rodents showed a normal growth rate, body weight, and body composition compared with wild-type littermates due to functional compensation by the keratinocyte-type FABP. However, when exposed to a high-fat diet, ALBP-null mice developed diet-induced obesity, reaching a greater total weight gain than the control mice as a consequence of an increased fat pad weight. Both lean and obese ALBP-null mice displayed normoglycemia and normoinsulinemia, providing evidence for an uncoupling of obesity from insulin resistance through ALBP deficiency.

5.3 Perilipin

Recently, the amount of perilipin protein and lipolysis rates was analyzed in human subcutaneous adipocytes of nonobese and obese women. A polymorphism in intron 6 (rs891460 A/G) in the perilipin gene seems to be associated with a 50% decrease in perilipin expression and increased basal lipolysis (AA vs. GG carriers) in adipocytes of the obese women, which in subjects matched for body mass index and adipocyte volume was inversely correlated with the plasma concentrations of NEFA and glycerol and thus may contribute to the development of insulin resistance. Furthermore, they found two- to fourfold increases in noradrenaline-induced lipolysis. These data also reinforce the role of perilipin for the regulation of lipolysis in human fat cells.

The participation of perilipin in the regulation of TAG storage and mobilization has been addressed by knockout approaches from two different experimental groups.

Perilipin-deficient mice showed an increased metabolic rate together with an increased basal lipolytic rate in adipocytes, which confer resistance to diet-induced obesity. Nonetheless, they were severely impaired in their ability to respond to ß-adrenergic stimulation by an appropriate elevation in circulating NEFA. Although absence of perilipin resulted in leanness and reversal of obesity with an approximately 50% decrease in adipose mass and adipocyte size, which was not reflected in the lean body mass (that even increased slightly), it did not affect glucose tolerance, even with perilipin ablation being able to worsen peripheral glucose disposal. Perhaps most surprising is that mice lacking perilipin are more drastically affected in regard to regulation of FA mobilization than those deficient in HSL (see above). These observations could be explained if perilipin is not only required to maintain adipose cells in the quiescent state but is also involved in the functional lipolytic activation in adipose cells. To test this hypothesis experimentally, HSL translocation has been investigated in adipocytes differentiated *in vitro* from embryonic fibroblasts of wild-type and perilipin-null mice. Strikingly, they found that HSL fails to translocate to LD in cells lacking perilipin. Furthermore, introduction of normal perilipin A but not of an unstimulatable mutant variant (lacking the amino-terminal PKA phosphorylation sites) into CHO fibroblasts significantly stimulated the PKA-induced translocation of HSL. CHO cells expressing both perilipin and HSL were able to elicit a greater and more rapid response to a lipolytic stimulus than when either of these proteins was expressed separately. Thus, the perilipin-null mice emphasize the two major actions of perilipin: (1) to protect TAG against hydrolysis in the basal state and thus permit TAG storage; and (2) to facilitate HSL translocation to LD, leading to hydrolysis of TAG and release of FA in the stimulated state. Interestingly, the perilipin-mediated translocation process does not seem to depend on additional factors unique to adipocytes since it can be reconstituted by expressing both perilipin A and HSL in CHO fibroblasts. Moreover, phosphorylation of perilipin A at its three most amino-terminal PKA sites is apparently required to promote HSL translocation to LD. Recently, it was demonstrated that expression of wild-type perilipin alone, but not of a mutant lacking these PKA sites, in CHO cells increases the sensitivity of lipolysis toward ß-adrenergic stimulation. In contrast, LD coated with ADRP from cells that do not express perilipin (i.e. all with the exception of adipocytes and steroidogenic cells) neither facilitate HSL binding to the LD surface nor respond to elevated PKA activity nor are capable of restraining lipolysis to a minimum. The accelerated lipolytic activity exhibited by perilipin A-coated LD may result from increased accessibility of HSL (or some unknown neutral lipase) to TAG within LD when perilipin is phosphorylated at its three most amino-terminal PKA sites. Importantly, the binding of HSL to LD seems to be based on its direct interaction with the TAG substrate since translocation of HSL is blocked upon mutating the serine residue in its catalytic triad.

Two hypotheses have been proposed that reconcile the present data. Phosphorylated perilipin could directly recruit HSL to the LD surface by direct binding to the enzyme. However, pull-down and two-hybrid experiments have not provided experimental evidence of direct interaction between perilipin and HSL so far. Alternatively, phosphorylated perilipin may modify the

LD surface to indirectly facilitate interaction of HSL with the TAG core within the LD. HSL translocation and initiation of lipolysis occur within minutes. Initially, HSL and perilipin colocalize on LD but then, within a much longer period, perilipin slowly departs from large LD, and is subsequently recovered from dispersed, much smaller, LD (see above). Recent studies indicate that even after the departure of perilipin, HSL remains bound to the larger LD, which now lack perilipin, where it continues to cleave TAG. Taken together, the present data favor the indirect mechanism, although the two hypotheses are not mutually exclusive. In any case, the mechanism underlying the action of phosphorylated perilipin seems to modify the TAG of LD such that it is more effectively presented as a substrate, for example, by triggering dispersion of LD upon contact with phosphorylated perilipin leading to a larger total LD surface area and thereby facilitated access of HSL. It is now generally accepted that protein–phospholipid/cholesterol interactions can modify the shape of the plasma membrane and this mechanism seems to form the molecular basis for the biogenesis of caveolae (see above), for instance. The operation of similar mechanisms for neutral lipids seems to be more speculative.

5.4 PKA

PKA is a heterotrimer consisting of two regulatory cAMP-binding and two catalytic subunits. Four regulatory isoforms (RIα, RIβ, RIIα, and RIIβ) and two catalytic isoforms (Cα and Cβ) are expressed in the mouse, and each is encoded by a separate gene. The RIIβ subunit is expressed principally in three tissues known to regulate energy homeostasis: brown adipose tissue, WAT, and brain. It has been suggested that the induction of PKA in certain tissues may decrease obesity. For example, activation of the adipose-specific ß-AR, which signals via PKA, decreased obesity in both genetically obese (ob/ob) and diet-induced obese mice, suggesting that signaling mechanisms through this pathway are important in preventing obesity.

Studies in mice lacking RIIβ have revealed an unexpected role for this protein in regulating energy balance. These animals remained remarkably lean even when challenged with a high-fat diet and had increased metabolic activity, manifested by increases in body temperature, uncoupling protein-1 concentration, and lipolysis. Biochemical studies have shown that loss of RIIβ was compensated by increased expression of RIα, which is more sensitive to cAMP activation, resulting in a net increase in basal PKA activity, but markedly impaired cAMP-induced activation of HSL in mutant WAT, yet left cAMP-regulated gene expression relatively unperturbed. The disruption of lipolytic stimulation was seen both *in vitro* and *in vivo* and occurred equally for signaling from the ß$_3$-receptor-specific agonist CL316.243 and a nonspecific ß-agonist, isoproterenol. It is unlikely that the signaling defect in RIIβ mutant WAT was caused by decreased expression of either ß-AR or HSL, given that mRNA levels for these genes were unaffected. Conceivably, impairment of lipolytic hormonal response could be a consequence of the chronic stimulation of basal lipolysis seen in RIIβ null mice due to increased basal PKA activity. However, adipocytes from knockout mice deficient in the G-protein subunit, $G_i\alpha_2$, showed a threefold increase in basal cAMP levels and an elevated basal

rate of lipolysis but retained normal maximal response to ß-AR agonists. These studies suggest that increasing basal PKA activity in adipose tissue and brain ameliorates obesity.

In a recent study, wild-type and RIIβ null mice maintained on the C57BL/6 genetic background strain were fed a high-fat, high-carbohydrate diet, which is known to induce obesity and diabetes in C57BL/6 mice. RIIβ null mice were resistant to weight gain and hyperinsulinemia. *In vivo* insulin sensitivity and glucose disposal were dramatically improved in the RIIβ null mice, as were plasma lipid profiles. When mice were corrected for differences in body weight, improved insulin-mediated glucose disposal was still observed in the RIIβ null mice, suggesting an obesity-independent effect of RIIβ on promoting insulin resistance. This suggests that PKA activity in both adipose tissue and brain is important for determining body composition, food intake, and diabetogenic parameters.

It has been speculated that at least some of the elements mediating lipolytic stimulation (e.g. ß-AR, AC, PKA, HSL) be colocalized within adipocytes to facilitate efficient signal transduction, and that lipolytic stimulation is impaired in RIIβ-deficient rodents because RIIβ participates specifically in the formation of this complex. Previous studies suggest a compartmentalized apparatus that mediates lipolytic stimulation as follows: (1) At any given intracellular cAMP concentration, the lipolytic response toward catecholamines is greater than toward forskolin, a nonspecific AC activator. Hence, low concentrations of isoproterenol (~10 nM) can stimulate lipolysis without measurably altering overall cAMP levels, whereas low concentrations of forskolin (0.1–1.0 µM) increase intracellular cAMP without affecting lipolysis. (2) The concentration of isoproterenol or $ß_3$-specific agonists required for half-maximal activation of AC activity in adipocyte membranes is 80-fold greater than the concentration required to activate lipolysis in intact adipocytes. (3) A signaling complex including $ß_2$-AR, PKA, and phosphatases has been isolated that appears to be assembled by the scaffold protein, gravin. In summary, catecholamines stimulate lipolysis more potently than they increase overall intracellular cAMP, suggesting a preferential association of ß-AR, PKA, and perhaps its substrate, HSL, in a ''lipolytic'' complex.

5.5 ASP

Since mice lacking complement C3 cannot produce ASP, C3 gene knockout mice are consequently ASP-null animals. ASP null mice show a reduced WAT weight, distributed evenly through all depots in females while primarily affecting gonadal and perirenal localizations in males, as well as reduced body fat. In addition, male mice have delayed TAG clearance. The reduced adipose mass was accompanied by hypoleptinemia with a modest increase in food intake. When fed on either a low-fat or high-fat diet, male ASP null mice showed no differences in body weight compared with wild-type animals. Female ASP null mice, however, had a decreased body weight compared with their wild-type counterparts. The relatively mild phenotype of these mice suggests a minor role of ASP in TAG storage and mobilization control or the existence of compensatory mechanisms rescuing part of the physiological function of ASP.

Very recently, the effect of ASP deficiency has been examined in ob/ob mice, which are leptin-deficient. The ob/ob mice have been used to test for protection from obesity in several double-knockout models. In most cases, the decrease in body weight, which was evident in the single knockout, was enhanced when examined on the background of the ob/ob obese mouse model. Compared with age-matched ob/ob mice, ob/ob C3 null mice had delayed postprandial TAG and FA clearance, associated with decreased body weight and according to the homeostasis model assessment index increased insulin sensitivity. By contrast, food intake in the double-knockout mice was slightly elevated compared with ob/ob mice. The hyperphagia/leanness was balanced by a significant increase in energy expenditure and oxygen consumption. These results suggest that the ASP regulation of energy storage may influence energy expenditure and dynamic metabolic balance.

Since ASP increases TAG synthesis and reesterification and decreases intracellular TAG mobilization, such as norepinephrine-stimulated NEFA release from fat cells as well, the effect of ASP, at least in adipose tissue, is to effectively decrease substrate cycling and increase TAG storage. ASP deficiency could possibly release the brake on this cycling process, allowing for increased substrate cycling and augmenting energy expenditure. This pattern is different to that observed for insulin, which had marked effects on both lipolysis and fractional NEFA reesterification. When fat cells were incubated with maximally effective concentrations of each protein, ASP inhibited NEFA release during lipolysis to a lesser degree than insulin, whereas it stimulated fractional NEFA reesterification to the same, or even greater, extent as insulin.

5.6 Caveolin

Caveolin null mice shed additional light onto the proposed new roles of caveolin and caveolae in TAG storage and mobilization (see above). Caveolin-1 null mice were found to store less TAG in WAT than control mice. This defect led to resistance to diet-induced obesity and to increased blood concentrations of NEFA and TAG. Because caveolin can be recovered with LD, at least under certain experimental conditions (see above), it is tempting to speculate that the lack of caveolin interferes with normal LD biogenesis or enables HSL to gain access to TAG in the LD core. Alternatively, in the absence of caveolin-1 adipocytes lack functional caveolae and this could lead to diminished FA uptake. As the flux of FA into primary adipocytes and 3T3-L1 adipocytes follows saturatable kinetics, facilitated membrane transport has been proposed as the uptake mechanism. Interestingly, labeling of membrane proteins with photoreactive long-chain FA identified caveolin-1 as the major FA-binding protein in adipocytes. Together with the demonstrated association of the caveolins with LD (see above), it is possible that caveolae and the caveolins act as portals for the uptake and transport of FA to LD. However, it cannot be excluded that the negative effect of missing caveolin-1 on TAG storage is secondary to impairment of insulin signaling to the glucose transport system and the resulting reduction of glucose uptake and FA esterification. Caveolae and lipid rafts (DIGs) act as scaffolding platform for the so-called Cbl-CAP pathway that is required for insulin stimulation of glucose transport in addition to the IRS-PI3K pathway.

Keywords

Aggregate
Accumulation of proteinaceous and/or ribonucleic acid material into a structure that is visible in a cell at the light microscope level.

Anticipation
Worsening severity of a disease phenotype as the causal (typically dominant) genetic mutation is transmitted from one generation to the next in a family segregating the disease of interest.

Gain of function
Refers to a type of mutation that imparts a novel activity or action to the gene product containing the mutation.

Loss of function
Refers to a type of mutation that eliminates the action of the gene product encoded by the gene within which the mutation resides.

Repeat Expansion
An elongation of a repeat to a larger size that no longer falls within the size distribution range typically seen in the normal population; this process is now recognized as a mechanism of human genetic mutation.

Trinucleotide
Three DNA base pairs of specific sequence composition (e.g. cytosine-adenine-guanine).

The repeat expansion disorders are a group of human diseases that are caused by the elongation of a DNA repeat sequence. In this chapter, we provide an overview of the discovery of repeat expansion as an important cause of human disease, and we summarize the molecular genetics and mechanistic basis of 27 microsatellite repeat disorders. Comparison of the many repeat expansion disorders reveals distinct categories of repeat diseases, allowing us to propose a classification of the repeat expansion disorders based upon mutation sequence and pathogenic mechanism. The four types of repeat expansion disorders defined by this approach are the CAG/polyglutamine repeat diseases; the loss-of-function repeat diseases; the RNA gain-of-function repeat diseases; and the polyalanine diseases. Although the genetic basis for most of these diseases was determined less than a decade or so ago, considerable advances have been made in our understanding of how ''dynamic mutations'' produce molecular pathology and human disease.

1
A Novel Mechanism of Genetic Mutation Emerges

1.1
Repeat Sequences of All Types and Sizes

Long before the sequencing of the human genome was undertaken, the discovery of bacterial enzymes that recognize specific DNA sequences (''recognition sites'') and cleaved them, yielded a new methodology for differentiating individuals (''molecular fingerprinting''). This methodology also found application in the mapping of inherited genetic diseases, taking advantage of human variation in the form of so-called restriction fragment length polymorphisms (RFLP's). In the search for even more informative genetic markers, investigators uncovered a variety of very

short repeat sequences (''short tandem repeats'' – STR's; ''simple sequence length polymorphisms'' – SSLP's) that were highly dispersed throughout the human genome. These latter repeat sequences came to be known as ''microsatellites'' to differentiate them from the ''minisatellites'' that were being used for molecular fingerprinting. Minisatellites were originally defined as tandem arrays of 14–100 bp repeating sequences. In the case of minisatellites, the repeat sequence was in essence a ''consensus'' as deviations from the exact repeat sequence were common. Microsatellites, however, were typically pure perfect repeats of less than 13 bp, the most common microsatellites being dinucleotide repeats, trinucleotide repeats, or tetranucleotide repeats. The discovery of minisatellites and microsatellites yielded a virtual bonanza of reagents for molecular fingerprinting and genetic linkage mapping, while also providing evolutionary biologists and population geneticists with intriguing material to attempt to reconstruct evolutionary relationships and inter- or intraspecies relationships. Although human geneticists and evolutionary biologists were applying microsatellites in different ways for their own studies, they shared the commonly held belief that such repeats were neutral and therefore unlikely to be of much functional consequence, let alone play a role in causing human disease. Of course, all that would soon change in the last decade of the twentieth century.

1.2 Trinucleotide Repeat Expansion as a Cause of Disease: Unique Features Explain Unusual Genetics

In 1991, two groups working on seemingly unrelated inherited genetic diseases independently made paradigm-shifting discoveries. In one case, a CAG trinucleotide repeat expansion within the first coding exon of the androgen receptor (*AR*) gene was found to be the cause of an X-linked neuromuscular disorder known as spinal and bulbar muscular atrophy (SBMA or Kennedy's disease). CAG encodes the amino acid glutamine; thus, elongation of a polyglutamine tract within the AR protein was hypothesized to be the molecular basis for the motor neuron degeneration in SBMA. In the other case, a disorder known as the fragile X syndrome of mental retardation (FRAXA), also X-linked but much more common, was reported to result from expansion of a CGG repeat. In the latter case, although originally envisioned to encode a polyarginine tract, the CGG repeat turned out to be in the 5′ untranslated region of a novel gene, the so-called *FMR-1* gene (for ''fragile X mental retardation-1'').

The identification of triplet repeat expansions as the cause of two inherited diseases was an exciting turning point in the field of human molecular genetics not only because of the novel nature of these findings, but also because of the unusual genetic characteristics of this new type of mutation. Analysis of families segregating FRAXA revealed the existence of three distinct allele categories defined by the length of the pure CGG repeat: a normal size range; a disease size range; and an intermediate, ''premutation'' size range. As discussed below, individuals carrying premutation-sized CGG repeats never develop the mental retardation phenotype, but instead are at risk for passing on even larger CGG repeats to their children or grandchildren who then display the mental retardation phenotype. An important tenet that emerged from these early studies was that expanded CGG repeats (larger

than the normal size range) displayed an exceptionally high rate of further mutation. This observation reversed a commonly held view of the genetic material – the notion that any single nucleotide in the human genome displayed a mutation rate of $\sim 1 \times 10^{-5}$. In the case of expanded CGG repeats in premutation carriers, the rate approached unity (10^0)! Besides displaying this high mutation rate, there were other unusual features: (1) the CGG repeats showed a marked tendency to further expansion, suggesting that repeat mutation was a polar process; and (2) the sex of the individual transmitting the premutation-sized CGG allele determined whether a large expansion into the disease range would be possible. For FRAXA, expansion into the disease range could only occur if the premutation allele was transmitted by a female carrier. All of these unusual aspects of FRAXA CGG repeat genetics thoroughly accounted for the bizarre non-Mendelian inheritance patterns described in FRAXA families as the ''Sherman paradox.''

The recognition of repeat expansion as the cause of the neurodegenerative disorder SBMA and as an explanation for the puzzling genetics of FRAXA set the stage for further discoveries in the field of neurogenetics (the study of inherited neurological disorders). One disorder known as *myotonic dystrophy* (DM), the most common of all muscular dystrophies, had been the center of a genetic controversy that had gone on for nearly a century. The controversy involved the debate over whether the clinical phenomenon of anticipation truly existed or was simply an artifact of clinical study (Anticipation may be defined as a progressively earlier age of disease onset with increasing disease severity in successive generations of a family segregating an inherited disorder). Although anticipation was initially proposed as a defining feature of DM in 1918, a number of leading geneticists, among them Penrose, L.S., dismissed its authenticity, claiming that it was a product of ascertainment bias due to better clinically defining the profound variable expressitivity in this disorder. This view persisted from its promulgation in the 1950s, reinforced by the concept that the genetic material is seldom subject to alteration or modification that could be heritable. However, with the discovery that expanded trinucleotide repeats could further expand, and that indeed the expansion process was a prerequisite for the FRAXA disease phenotype – accounting for maternal inheritance and greater percentages of affected individuals in more recent generations – a role for repeats in diseases displaying anticipation was entertained. Consequently, the third repeat mutation disorder to be identified – just one year after the SBMA and FRAXA discoveries – was DM. Studies of the causal CTG repeat expansion in DM demonstrated a strong correlation between disease severity (i.e. age of onset and rate of progression) and the length of the CTG repeat. In this way, it became clear that anticipation was a genuine phenomenon and that expanded repeat mutational instability was its long awaited molecular explanation. The mutational instability characteristics of expanded repeats have led to their designation as so-called ''dynamic mutations.''

2
Repeat Diseases and Their Classification

2.1
Summary of Repeat Diseases

The list of diseases caused by microsatellite repeat expansions (involving repeats of

3–12 bp) now includes more than 25 disorders (Table 1). Certain aspects of the list of repeat diseases deserve emphasis. Twenty of the repeat diseases either principally or exclusively affect the neuraxis – that is, anywhere from the brain to the cerebellum/brainstem, to the spinal cord, to the peripheral nerve or muscle – and are degenerative disorders. Almost all of these inherited neurological disorders are caused by large expanded repeats that display the property of pronounced genetic instability (dynamic mutation). On the other hand, the developmental malformation syndromes for which repeat expansion mutations have been implicated all involve modestly sized disease repeats by comparison, and these repeats do not exhibit such dynamic mutation genetic instability.

2.2 Differences in Repeat Sequence Composition and Location within Gene

When faced with the task of categorizing the various repeat expansion diseases into different classes, a number of approaches are possible. We have found that consideration of the sequence of the repeat and its location within the gene are the most useful characteristics to apply for grouping the different repeat diseases. As shown in Table 1, there are many different types of repeats varying in length and sequence composition. However, among the recurrent sequence types are CAG trinucleotide repeats, CTG trinucleotide repeats, and GCG trinucleotide repeats. The rest of the repeat sequences are unique in composition and differ widely in size, ranging from 3 to 12 bp as noted above. Comparison of the location of a repeat within the gene it is affecting also yields different types of repeats. The largest single-repeat location category is within the coding region of a gene, which applies to both CAG (glutamine) and GCG (alanine) repeats, and has been proposed but not yet demonstrated for CTG (leucine) repeats. The rest of the locations defined for repeats vary widely, ranging from the gene's promoter to its 5′ untranslated region to an intron to the 3′ untranslated region, and no more than two to three repeat expansions can be placed in each of these categories at this time.

2.3 Classification Based upon Mechanism of Pathogenesis and Nature of Mutation

To allow us to reconstruct how the different repeat expansion mutations cause molecular pathology in the various disorders that they cause, we have chosen to categorize the 25 repeat disorders into four classes (Table 2). The first class of disorders, the Type 1 repeat diseases, are the ''CAG-polyglutamine disorders.'' This class of repeat diseases includes nine inherited neurodegenerative disorders (SBMA, Huntington's disease, dentatorubral pallidoluysian atrophy, and six forms of spinocerebellar ataxia) that all share the common feature of being caused by a CAG repeat located within the coding region of a gene. Upon CAG repeat expansion, a mutant protein with an extended polyglutamine tract is produced, making the protein then adopt an abnormal conformation and misfold to initiate the pathogenic cascade. The resultant pathology is believed to primarily stem from a gain of function of the mutant protein imparted by the expanded polyglutamine tract. As discussed below, much effort has gone into trying to define what the gain-of-function effect is for each polyglutamine disease protein and into determining if

shared pathways of toxicity are initiated in the different diseases. At least one, and perhaps a greater number of these disorders may principally involve a simultaneous dominant-negative partial loss of the normal function of the disease protein. The next class of disorders, the Type 2 repeat diseases, are a much more disparate group of repeat disorders. The Type 2 repeat diseases are the ''Loss-of-function repeat disorders.'' These disorders include different repeats that vary in sequence composition and gene location, but share a final common pathway of disease pathogenesis – a loss of function of the disease gene within which they occur. This group includes various classic trinucleotide repeat disorders such as the two fragile X syndromes of mental retardation (FRAXA and FRAXE) and Friedreich's ataxia – but also encompasses the dodecamer repeat expansion in progressive myoclonic epilepsy type 1, and possibly the CAG repeat expansion in Huntington's disease like-2 (*HDL2*) gene. Strong evidence for a loss-of-function pathway in the form of nonrepeat loss-of-function mutations supports many of these classifications. The third group of repeat diseases, the Type 3 disorders, comprise a shared class because all of them have been proposed to involve the production of a toxic RNA species. This category of repeat diseases is thus called the *RNA gain-of-function disorders*. Included among these disorders are two closely related forms of DM, the common and classic myotonic dystrophy type 1 (DM1) and its uncommon phenocopy, myotonic dystrophy type 2 (DM2). Another member of this group is the recently described fragile X tremor-ataxia syndrome (FXTAS) in male premutation carriers – a fascinating example of two different disease pathways operating upon the same expanded repeat mutation based upon size range differences. One form of spinocerebellar ataxia (SCA8) with an unclear mechanism of pathogenesis has also been provisionally placed into this category, based upon current working models of how its repeat causes disease. The last class of repeat disease, the Type 4 disorders, are the ''GCG-polyalanine disorders'' that are grouped together because all involve short GCG repeat tracts falling within the coding regions of unrelated genes that become expanded to moderately sized GCG repeats. With the exception of oculopharyngeal muscular dystrophy, all are developmental malformation syndromes, and while gain-of-function polyalanine toxicity has been proposed for a number of these disorders, loss of function due to the polyalanine expansion seems more likely for others. Finally, a number of repeat disorders, spinocerebellar ataxia type 10 (SCA10), spinocerebellar ataxia type 12 (SCA12), and Huntington's disease like 2 (HDL2), currently defy classification because very little is known about their molecular basis. These diseases will be considered in the final section of this chapter.

3
Type 1: The CAG/Polyglutamine Repeat Diseases

3.1
Spinal and Bulbar Muscular Atrophy

Spinal and bulbar muscular atrophy (SBMA; Kennedy's disease) is a late-onset neurodegenerative disease with an inheritance pattern resembling X-linked recessive. It has a prevalence of about 1 in 50 000 males. Patients suffer a late-onset, progressive degeneration of primarily lower motor neurons in the anterior horn of the spinal cord and in the bulbar region of the

brainstem; however, variable involvement of sensory neurons in the dorsal root ganglia also occurs. SBMA typically presents with cramps, followed by proximal muscle weakness and atrophy. Patients often exhibit dysarthria, dysphagia, and fasciculations of the tongue and lips. Affected individuals have symptoms of mild androgen insensitivity, such as gynecomastia, reduced fertility, and testicular atrophy.

SBMA is caused by a polymorphic (CAG)*n* repeat in the first exon of the *AR* gene, which is expressed as a glutamine tract. Unaffected individuals carry 5 to 34 triplet repeats, while affected individuals carry 37 to 70 repeats. SBMA exhibits a paternal expansion bias. The disease does not appear to involve a simple loss-of-function mechanism, as complete loss of AR does not result in motor neuron degeneration.

AR is widely expressed in males and females, and is a member of the steroid receptor–thyroid receptor superfamily with a highly conserved DNA binding domain, ligand binding domain and transactivation domain (Fig. 1). In its inactive state, it forms an apo-receptor complex with heat-shock proteins (HSPs) 70 and 90, and resides in the cytoplasm. Upon binding androgen, it dissociates from these HSP chaperone proteins and translocates to the nucleus. Once in the nucleus, AR dimers transactivate certain genes, many of which are responsible for generating and maintaining male characteristics. Although the glutamine expansion does not affect the binding of its ligand, androgen (testosterone), the glutamine tract is in the major transactivation domain, and may affect transactivation competence. However, the effect of the polyglutamine expansion upon AR transactivation competence remains controversial.

Many lines of evidence suggest that AR must translocate to the nucleus to exert its toxicity. Nuclear inclusions (NIs) are present in motor neurons of the spinal cord and brainstem in SBMA patients. In a Drosophila model of SBMA, retinal expression of mutant AR only yielded a degenerative phenotype in the presence of ligand. As in humans, androgen binding causes the nuclear translocation of AR in mice. Transgenic male SBMA mice produce testosterone and will only

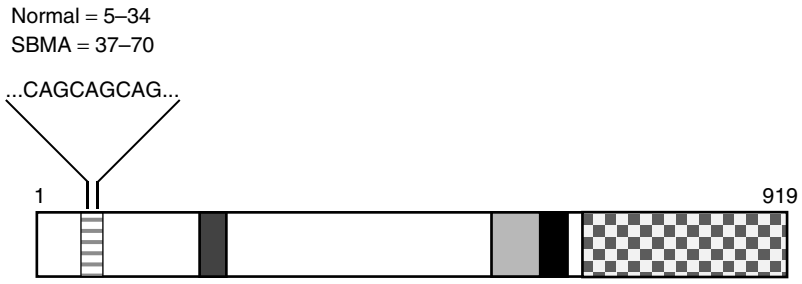

Fig. 1 Diagram of the androgen receptor. The androgen receptor is a member of the steroid receptor-thyroid hormone receptor superfamily, and consequently displays a stereotypical architecture. The CAG repeat – polyglutamine tract (striped box) resides within the amino-terminal domain, which mediates transcription activation through an ''activation function'' domain (charcoal gray box). Additional conserved domains include the DNA binding domain (light gray box), nuclear localization signal (black box), and the ligand binding domain (checkered box). Expansion of the CAG repeat to alleles of $\geq$37 triplets is the cause of spinal and bulbar muscular atrophy (SBMA).

develop motor neuron disease if expressing polyglutamine-expanded full-length AR protein, yet when castrated, such SBMA transgenic mice do not develop a phenotype. In the same study, female transgenic mice hemizygous for expanded AR develop motor neuron degeneration when exposed to exogenous androgen. Importantly, even rare human females who are homozygous for an AR CAG repeat expansion mutation do not develop SBMA, despite widespread expression of mutant AR throughout the CNS (central nervous system). Thus, SBMA is not a true X-linked recessive disorder, but rather is classified as a sex-limited disorder, since expression of the disease phenotype is dependent upon male levels of androgen.

A number of studies on SBMA patients and mouse models have characterized the NIs seen in this disease. While NIs are widely distributed in lower motor neurons of the spinal cord and brainstem, NIs also occur in a variety of nonneuronal tissues that appear to function normally. NIs colocalize with components of the proteasome and with molecular chaperones. How this contributes to the phenotype is unknown, although HSP70 overexpression attenuates toxicity in cell culture and in transgenic mouse. The presence of proteasome components and HSPs in NIs may thus be revealing a protective intervention by the cell, or alternatively may be deleterious due to depletion of these important cellular proteins. Interestingly, only antibodies raised to amino-terminal fragments of AR detect NIs, indicating that proteolysis may play a role in the disorder. Caspase-3 has been shown to cleave AR in a polyglutamine tract length-dependent manner *in vitro*, and this may have pathogenic significance, as truncated AR is more toxic than full-length protein in cell culture studies and transgenic mouse models. The phosphorylation of AR is modulated by androgen, and this posttranslational modification appears to enhance caspase-3 cleavage.

One possible mechanism of expanded AR toxicity is through transcription interference. Polyglutamine-expanded AR interacts with the transcription coactivator CREB-binding protein (CBP) in a polyglutamine tract length-dependent manner, colocalizes with CBP in spinal cord NIs from patients, and can interfere with CBP-dependent transcription. CBP is a transcription cofactor that regulates the expression of vascular endothelial growth factor (VEGF), among other genes. VEGF is important in motor neuron health, as deletion of a portion of its promoter called the *hypoxia response element* (HRE) causes motor neuron degeneration even in normoxic mice. Pathologically expanded AR reduces VEGF transcript expression in males, with VEGF165 isoform expression reduced at both the RNA and protein levels. Adding VEGF165 to a motor neuron-like cell line (MN-1) expressing polyglutamine-expanded AR significantly rescues its cell death, again supporting the role of transcription interference in SBMA and suggesting that VEGF165 may serve as a neurotrophic factor for motor neurons.

While no effective treatment for SBMA has yet been validated in human patients, the role of testosterone in SBMA disease progression has received considerable attention. Interestingly, testosterone supplementation was initially used as a treatment for SBMA. Rather than aggravating the disease as one might fear, it was reported to attenuate the phenotype slightly, but did not significantly retard disease progression. Such a beneficial effect of testosterone may be due

to anabolic effects on muscle strength or to a downregulation of AR in response to elevated androgen levels. Still another possibility is that AR-mediated transcription in motor neurons somehow performs a trophic function in the face of damage or injury. Very recent work, however, strongly indicates that elimination of ligand by surgical or pharmacological castration is a very effective treatment in SBMA transgenic mouse models, even showing efficacy when SBMA mice display an advanced phenotype. As ligand binding is associated with nuclear translocation of mutant AR and aberrant effects upon nuclear transcription appear crucial for SBMA disease progression, abrogation of nuclear localization may account for the success of castration. Consistent with this hypothesis are results of studies with flutamide, a drug that appears to block AR-dependent transactivation without preventing its nuclear translocation. While pharmacological castration with leuprolide is highly effective therapeutically, flutamide does not ameliorate symptoms or disease progression in an SBMA mouse model. Attempted translation of these preclinical trial results to human SBMA patients is currently underway.

3.2 Huntington's Disease

Huntington's disease (HD) is an autosomal dominant disorder with a prevalence of 1 per 15 000 persons worldwide. It is a debilitating disease that often presents clinically in the fourth or fifth decade of life with chorea (i.e. spontaneous, involuntary dancelike movements). Personality change and cognitive impairment may precede the clinical onset by years, and ultimately culminate in dementia after onset of the movement disorder. Chorea gives way to bradykinesia and rigidity late in the disease. CNS atrophy occurs most prominently in the striatum, which is reduced to a fraction of its original size (Fig. 2). However, significant neurodegeneration and neuron loss in the cortex is also typical, while cerebellum, brainstem, and spinal cord are relatively spared – except in juvenile-onset cases.

HD is caused by a (CAG)*n* repeat expansion in the *huntingtin* gene (*htt*), which encodes a 350-kDa protein containing 67 exons. Unaffected individuals carry 6 to 35 repeats, while affected individuals carry 39 to 250 repeats. The largest repeats cause juvenile-onset HD and display a paternal transmission bias. The htt protein is ubiquitously expressed in brain tissue,

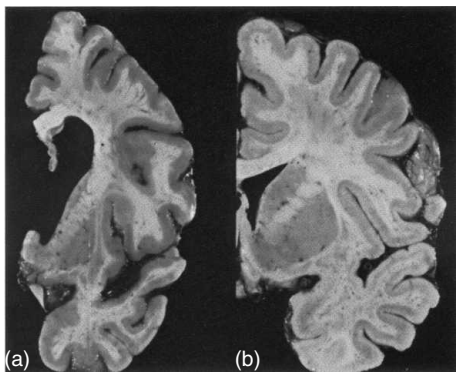

Fig. 2 Huntington's disease (HD) neuropathology. Hemi-coronal sections of postmortem brains from (a) a classic, adult-onset HD patient and (b) a normal control reveal marked degeneration of the striatum (midmedial region) and considerable atrophy of cortical regions. (From Robataille et al. (1997) *Brain pathol.* **7**, 901. Used with permission).

with highest levels in striatal interneurons and cortical pyramidal cells. Two htt mRNA transcripts have been detected: one 10 kb and the other 13 kb in length, expressed most highly in CNS neurons. Ultrastructurally, the wild-type full-length protein is predominantly cytoplasmic and is located in the pre- and postsynaptic regions of dendrites and axons. Htt protein associates with microtubules, vesicles, and organelles.

HD appears to have a predominantly dominant mechanism due to its inheritance pattern, evidence that homozygotes are no more severely affected than heterozygotes, and the observation that heterozygous deletion of huntingtin does not cause HD. The fact that no HD-causing loss-of-function mutations have been documented in the huge *htt* gene further supports a gain-of-function mechanism. However, postnatal elimination of htt expression in regions of the cortex can cause striatal degeneration in mice, so the notion that gain of function fully accounts for the HD phenotype is being reexamined. As htt is a regulator of transcription activation and/or mediator of vesicular brain-derived neurotrophic factor (BDNF) transport up and down axons, many investigators now envision the effects of expanded htt as twofold: simultaneously causing protein misfolding leading to gain-of-function toxicity, and inducing partial loss of an ill-defined normal function.

In 1997, it was first reported that mutant htt forms dense amyloid-type aggregates in the nucleus, perikarya, and neuropil of neurons from a transgenic mouse model and in human patients. The role of aggregation in the polyglutamine diseases and in a wide range of neurodegenerative disorders including Alzheimer's disease, Parkinson's disease, amyotrophic lateral sclerosis, and the prion diseases, thus emerged as an important theme at the end of the last decade. While initially it was thought that the formation of large aggregates is the basis of polyglutamine neurotoxicity, the weight of evidence now suggests little correlation between visible aggregate formation and disease pathology. However, the occurrence of aggregates along with neuropathology suggests that aggregation is inextricably linked to the pathogenicity of polyglutamine disease proteins. We will address the role of polyglutamine aggregation in neurotoxicity in detail in a separate section.

Many theories have been proposed to account for how polyglutamine-expanded htt causes neurotoxicity. A thorough discussion of this literature goes beyond the scope of this chapter, so the reader is referred to the relevant books and reviews in the Bibliography for a more intensive treatment of this topic. Major theories of htt neurotoxicity that will be considered herein include transcription dysregulation, proteasome inhibition, mitochondrial dysfunction/excitotoxicity, and proteolytic cleavage. As multiple independent toxicity events may be occurring concomitantly, these disease pathways are not mutually exclusive.

Expanded htt protein may interfere with transcriptional processes. Many transcription factors, such as CBP, contain glutamine tracts that mediate important protein–protein interactions. CBP interacts directly with htt, and mutant htt toxicity is ameliorated in striatal neurons *in vitro* when CBP lacking the htt interaction domain is overexpressed. CBP mediates the transcription of a number of neuronal survival factors, such as BDNF, and functions by acetylating histones, one aspect of chromatin remodeling that permits transcription to occur. Studies of HD fruit fly and mouse models have highlighted the

potential importance of histone acetylation by demonstrating that histone deacetylase inhibitors (HDAC Is) can successfully rescue degenerative phenotypes in these model organisms. Htt can affect transcription mediated by p53, Sp1, and REST interaction, thereby potentially altering the expression of a large number of genes. Differential expression of survival factors, neurotransmitter receptors, and a number of other genes may thus contribute to HD pathogenesis.

The ubiquitin-proteasome protein degradation pathway has also been implicated in HD. Nuclear inclusions of htt colocalize with ubiquitin, which indicates that the expanded protein has been identified as misfolded and thus targeted for proteasomal degradation. However, polyQ sequences longer than 9 glutamines are impossible for eukaryotic proteasomes to cleave. The proteasomes of htt-transfected cells are consequently less capable of degrading proteins other than htt, as demonstrated by the reduced degradation of GFP-tagged proteins in culture. If proteasome components are clogged with mutant protein and/or sequestered into inclusions, they may be unable to degrade other misfolded or damaged proteins that carry out important functions. Alternatively, accumulation of improperly degraded proteins may interfere with other normal cellular processes, such as autophagy or mitochondrial oxidative phosphorylation.

Perhaps the longest and most thoroughly studied htt toxicity pathway involves metabolic disturbances and excitotoxicity. Glucose metabolism and oxygen consumption are reduced in HD brains as measured by PET. Severe deficits in the activity of complexes II/III and IV of the mitochondrial electron transport chain (ETC) are evident in HD brains. Inhibitors of complex II of the mitochondrial electron transport chain, such as 3-nitropropionic acid (3-NPA), can cause a selective degeneration of the striatum in rat and primate models when injected systemically, since the striatum has among the highest energy demands of all neuronal regions. 3-NPA reduces levels of ATP, resulting in mitochondrial and cellular depolarization with activation of voltage-dependent NMDA receptors. Excitotoxic damage may act in concert with increased production of free radicals to cause selective striatal degeneration in HD. Some of the earliest animal models of HD were thus generated by exposing the striatum or entire brain of rats or primates to metabolic or excitotoxic insults. In 1976, the first such model of HD was created by injection of the glutamate analog and excitotoxin kainic acid into the striatum of rats. Such lesioned rats exhibited a selective degeneration of neurons in the striatum reminiscent of HD. Recent studies have suggested that impaired Ca++ flux due to aberrant interaction of htt with the inositol phosphate-3 receptor (IP3-R) may underlie excitotoxic pathology. Studies of mitochondria from HD patients reveal abnormal mitochondrial Ca++ handling and decreased mitochondrial depolarization thresholds, in support of this hypothesis. One very recent study has found that deletion of peroxisome proliferator-activated receptor (PPAR) gamma coactivator 1 alpha (PGC-1α), a key mediator of mitochondrial biogenesis, yields HD-like striatal degeneration in mice. Thus, metabolic insults and excitotoxicity may be key steps in HD disease pathogenesis.

Another important theory of htt neurotoxicity posits that proteolytic cleavage of htt is a required step in neuronal dysfunction and the degeneration process. As noted above, the htt protein is enormous, with full-length product consisting of >3100 amino acids. Analysis of human

HD material has indicated an absence of midprotein and C-terminal epitopes in htt aggregates. Careful biochemical studies of htt have characterized a variety of putative caspase and calpain cleavage sites. Various studies suggest that the more truncated the polyglutamine-expanded htt protein, the more toxic it is in cell culture and in animal models, and the more likely it is to enter the nucleus and produce toxicity there. In the case of htt, a series of proteolytic cleavage steps culminating with cleavage to an ~100 amino acid peptide fragment by an aspartyl protease has been proposed to yield a final ''toxic fragment.'' As it turns out, the ''toxic fragment hypothesis'' (as it has also been called) may be applicable to a number of polyQ diseases, which will be reviewed later in this section.

3.3 Dentatorubral Pallidoluysian Atrophy

Dentatorubral pallidoluysian atrophy (DRPLA) is a rare, autosomal dominant neurodegenerative disorder most prevalent in Japan. Adult-onset DRPLA typically involves progressive cerebellar ataxia, choreoatheosis, epilepsy, and dementia, while juvenile-onset cases also display myoclonus, epilepsy, and mental retardation. Neuropathological abnormalities include degeneration of the dentate nucleus of the cerebellum, rubral nucleus, and globus pallidus, as well as a more generalized degeneration and gliosis involving the brainstem, cerebellum, cortex, and pons. DRPLA is caused by a polymorphic (CAG)*n* repeat in the carboxy-terminal coding region of the *atrophin-1* gene on chromosome 12. Normal individuals carry 6–35 repeats, while affected individuals carry 49–88 repeats. Anticipation is prominent in DRPLA, as very large repeat expansions can occur in a single generation, typically via paternal transmission.

The DRPLA disease protein, atrophin-1, is widely expressed and appears to be predominantly cytoplasmic. Atrophin-1 contains both a putative nuclear localization signal (NLS) and nuclear export signal (NES), and nuclear localization of normal atrophin-1 is observed. Nuclear localization of polyglutamine-expanded atrophin-1 has been linked to increased toxicity in cell culture models. Ubiquitinated NIs are present in neurons and glia from patient brains, and are also immunoreactive for small ubiquitinlike modifier (SUMO) protein. Atrophin-1 is a substrate for c-Jun N-terminal kinase (JNK), with JNK's affinity for atrophin-1 inversely proportional to the size of the polyglutamine tract expansion.

Although the relevance of JNK phosphorylation to atrophin-1 function is unknown, other insights into the function of atrophin-1 have been reported. Using *Drosophila melanogaster* as a model system, Zhang et al. took advantage of the existence of a fly ortholog of atrophin-1 (*Atro*) and created lines of flies carrying mutations in the *Atro* gene. These flies demonstrated severe developmental abnormalities due to complex patterning defects, and subsequent experiments revealed that *Atro* is a transcription corepressor whose activity diminishes with increasing polyglutamine tract length. Independent studies of human atrophin-1 in cell culture studies found evidence for transcription interference of polyglutamine-expanded atrophin-1 with CREB-mediated gene activation. Transcription dysregulation may thus play a prominent role in DRPLA. Another study suggests that disturbed carbohydrate metabolism may contribute to the DRPLA neurodegenerative phenotype.

3.4
Spinocerebellar Ataxia Type 1

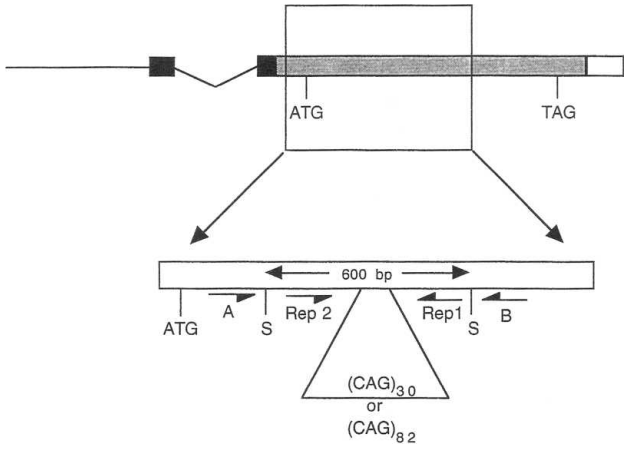
Spinocerebellar ataxia type 1 (SCA1) is an autosomal dominant disorder characterized primarily by a progressive cerebellar ataxia. It accounts for about 6% of all autosomal dominant cerebellar ataxias (ADCAs) worldwide. SCA1 patients suffer from coordination difficulties including dysarthria, dysphagia, and ophthalmoplegia. The cerebellum undergoes atrophy, gliosis, and severe loss of Purkinje cells, accompanied by degeneration of the dentate nucleus, inferior olive, and some brainstem nuclei. Disease onset typically occurs in the third or fourth decade of life, but presentation in childhood or adolescence to late life may be seen. SCA1 is caused by the expansion of a coding (CAG)*n* repeat in the amino-terminal coding region of the *ataxin-1* gene. The ataxin-1 CAG repeat is highly polymorphic, ranging in size from 6 to 44 triplets in unaffected individuals. The repeat length associated with disease ranges from 39 to more than 100 CAGs. Unaffected individuals with more than 20 repeats have CAT triplet interruptions within their (CAG)*n* repeat tracts. Such interruptions stabilize the repeat expansion, while absence of the CAT repeat interspersion is noted in SCA1 patient alleles. As in many other polyglutamine disorders, there is strong evidence supporting a gain-of-function mechanism in SCA1.

Ataxin-1 is widely expressed in the CNS and throughout the periphery, although expression levels are several-fold higher in nervous system tissues. The protein is predominantly nuclear in the CNS, however, some cytoplasmic staining is apparent in Purkinje cells of the cerebellum and in brainstem nuclei. Ataxin-1 knockout mice do not develop SCA1, although they do exhibit impairments in motor and spatial learning. These mice also have decreased paired-pulse facilitation in the CA1 region of the hippocampus, suggesting that ataxin-1 may normally function in synaptic plasticity and learning.

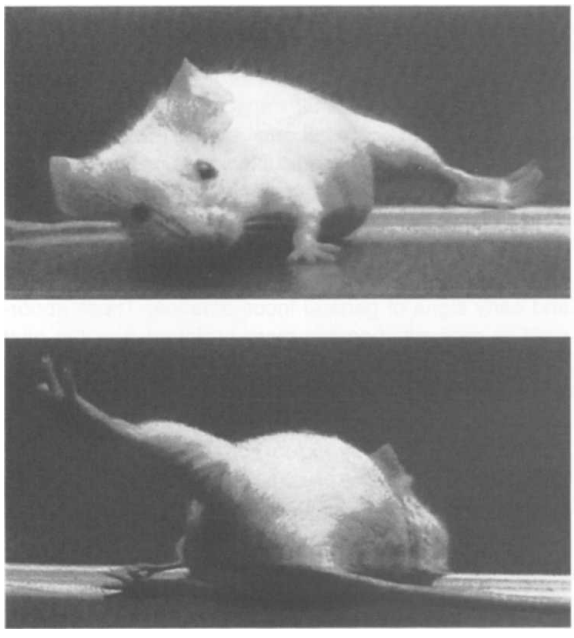
Large ataxin-1 containing NI's occur in the brainstem of affected individuals, and are immunoreactive for ubiquitin, the 20 S proteasome subunit, and HSPs HDJ2 and Hsc70. Work done on SCA1 in transgenic mice by the Orr and Zoghbi laboratories has been crucial in formulating models of not only SCA1 disease pathogenesis but also for influencing views of the molecular basis of all polyglutamine diseases. Indeed, the first mouse model for a polyglutamine disease was generated by transgenic overexpression of polyglutamine-expanded ataxin-1 in Purkinje cells (Fig. 3). This SCA1 transgenic mouse model has laid the foundation for

Fig. 3 The original spinocerebellar ataxia type 1 (SCA1) mouse model. (a) Diagram of the *Pcp2-SCA1* transgene construct. A Purkinje cell-specific expression cassette based upon inclusion of the promoter (straight line), first two noncoding exons (black boxes), and first intron (bent line) of the Purkinje cell protein 2 (*Pcp2*) gene and a SV40 polyadenylation sequence (open box) was the basis for this landmark work. Ataxin-1 cDNAs (gray box) containing either 30 CAGs (control) or 82 CAGs (expanded) were inserted into the *Pcp2* expression cassette. Sites of various PCR primer sets are also shown. (b) *Pcp2-SCA1* CAG-82 mice display ataxia. Still photographs of a 30-week-old *Pcp2-SCA1* CAG-82 mouse from a transgenic line that greatly overexpresses the mutant ataxin-1 transgene illustrates the inability of this mouse to maintain its balance when ambulating. Loss of balance when walking is consistent with the gait ataxia seen in human SCA1 patients. (From Burright et al. (1995) *Cell* **82**, 937, used with permission).

numerous follow-up studies of polyglutamine disease pathogenesis. For example, expression of mutant ataxin-1 lacking an intact self-association domain precluded aggregate formation, but permitted neurotoxicity, demonstrating that NIs are not required for SCA1 in mice. In a later study, crossing of SCA1 transgenic mice with mice lacking a ubiquitin ligase enzyme yielded SCA1 mice incapable of aggregate formation. These mice were more severely affected than their transgenic counterparts



(a)



(b)

due to absence of the ubiquitin ligase. This work supported the view that visible aggregate formation may represent a protective cellular response for neutralizing misfolded polyglutamine-containing peptides. In another study, mice expressing ataxin-1 with a mutated NLS were found not to develop SCA1, suggesting that nuclear localization is absolutely required for SCA1 molecular pathology. Although targeting ataxin-1 to Purkinje cells appears sufficient to recapitulate a dramatic SCA1-like disease in mice, a subsequent knockin mouse model of SCA1 indicated that expression in other regions of the CNS yields a more representative disease phenotype.

Over the past few years, numerous leads have emerged in the search for the pathogenic basis of SCA1. In one line of investigation, phosphorylation of serine 776 of the ataxin-1 protein was shown to affect pathogenesis, highlighting the importance of this posttranslational modification. SCA1 transgenic mice in which serine 776 had been mutated to an alanine, exhibited a dramatically attenuated phenotype and a complete lack of NI's. In an accompanying study, interaction of polyglutamine-expanded ataxin-1, but not wild-type ataxin-1, with several isoforms of the phosphoserine/threonine binding protein 14-3-3 was reported. This extremely abundant peptide is thought to serve a regulatory function by binding proteins and determining their subcellular localization, among other things. The interaction between ataxin-1 and 14-3-3 was shown to be dependent upon the Akt-mediated phosphorylation of serine 776. A novel mechanism for ataxin-1 toxicity was thus proposed: upon Akt phosphorylation of polyglutamine-expanded ataxin-1, ataxin-1 binds 14-3-3, is stabilized, and ultimately accumulates in the nucleus. The downstream effects of the nuclear accumulation of mutant ataxin-1 on neuronal function, however, remain undefined.

Transcriptional dysregulation is also a reasonable hypothesis for SCA1 pathogenesis. One study has demonstrated that ataxin-1 interacts with polyglutamine binding protein 1 (PQBP-1), and that this interaction results in interference with RNA polymerase-dependent transcription. Independent studies have supported a role for ataxin-1 as a transcription corepressor. In pull-down assays and in Drosophila, ataxin-1 interacts with the proteins SMRT (silencing mediator of retinoid and thyroid hormone receptors) and HDAC3 (histone deacetylase 3), both transcriptional repressors. Aggregates of polyglutamine-expanded ataxin-1 sequester SMRTER, the Drosophila ortholog of SMRT. Transcription repressors and histone deacetylases also appeared in an earlier screen for modulators of the Ataxin-1 phenotype in the fly. In addition, two separate studies of gene expression alterations in presymptomatic SCA1 transgenic mice have uncovered changes in the levels of transcripts encoding proteins involved in Ca++ flux and metabolism. It thus appears that transcription dysregulation may be a key step in SCA1 disease pathogenesis.

3.5 Spinocerebellar Ataxia Type 2

Spinocerebellar ataxia type 2 (SCA2) is an autosomal dominant, progressive cerebellar ataxia that accounts for about 13% of all ADCA cases. Although patients display problems with voluntary coordinated movements as in the rest of the SCAs, its main distinguishing clinical feature is extremely slow saccadic eye movements. Other symptoms may include hyporeflexia, myoclonus, and action tremor. Patients suffer a gradual degeneration of

the cerebellum, inferior olive, pons, and spinal cord. Both Purkinje and granule cells degenerate in the cerebellum, and CNS atrophy in some patients can be widespread. Interestingly, in certain cases, there is involvement of the substantia nigra, with such patients displaying a prominent degree of parkinsonism. The disorder is caused by a coding (CAG)*n* expansion in a novel gene of unknown function, named *ataxin-2*. The SCA2 CAG repeat displays little polymorphism in the normal population, with 95% of the population possessing 22 or 23 repeats in each allele. The remaining 5% of alleles in unaffected individuals do nonetheless range from 15–31 CAG repeats. Such unaffected individuals typically have two CAA interruptions in their CAG repeat tract. Affected SCA2 patients typically display CAG repeats numbering from 32–63 triplets, and such disease alleles are always uninterrupted CAG tracts. There is a nonlinear inverse correlation between expansion size and age of onset in SCA2, with some studies documenting a paternal transmission bias for larger expansions.

Both wild-type and expanded ataxin-2 mRNA is widely expressed, with highest levels in the substantia nigra and Purkinje cells of the cerebellum. The 140-kDa protein is cytoplasmic and its function remains uncertain. Since it contains Sm1 and Sm2 motifs common in proteins involved in RNA splicing and protein–protein interactions, involvement in RNA processing has been proposed. A yeast two-hybrid screen indicated that ataxin-2 has a binding partner, ataxin-2 binding protein-1 (A2BP1). A2BP1 is highly conserved throughout the animal kingdom and its expression pattern corresponds well with that of ataxin-2. A2BP1 contains a domain that is also conserved in RNA-binding proteins, the RNP motif. Thus, a complex including ataxin-2 and A2BP1 may be involved in RNA processing or metabolism.

The *ataxin-2* gene is evolutionarily conserved. The murine ortholog of ataxin-2 does not contain a polyglutamine repeat tract, however, but instead possesses a single glutamine residue at the analogous location. (Absence of a substantial glutamine repeat tract is typical for mouse orthologs of polyglutamine disease proteins.) In the case of ataxin-2, study of the Drosophila ortholog (*Datx2*), which does show two regions of marked amino acid similarity and does contain polyglutamine repeat regions, has yielded some potentially important insights into ataxin-2s normal function. Modulation of *Datx2* dosage resulted in mutant phenotypes whose cause could be traced to aberrant actin filament formation (Fig. 4). This work suggests that alteration of ataxin-2-mediated regulation of cytoskeletal structure could affect dendrite formation or other aspects of neuronal function in SCA2. As SCA2 is one of the few polyglutamine disorders to display prominent cytosolic aggregates, such a model of SCA2 pathogenesis seems plausible. In other experiments, eliminating the *C. elegans* ortholog of ataxin-2 (ATX-2) yielded a lethal phenotype, indicating that ATX-2 is required for early embryonic development of this nematode worm. It remains to be seen how these observations in worms and flies will apply to ataxin-2 function in mammals, especially since no simple or conditional knockout of the mouse *ataxin-2* gene has been performed.

3.6 Spinocerebellar Ataxia Type 3/Machado–Joseph Disease

Spinocerebellar ataxia type 3 (SCA3) is the most common inherited dominant

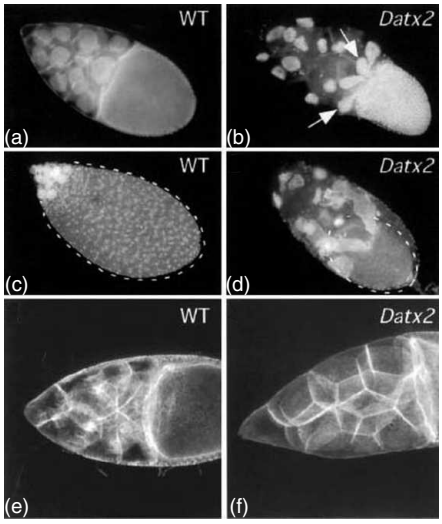


Fig. 4 Studies of the ataxin-2 ortholog in *Drosophila melanogaster* reveals a role for Drosophila ataxin-2 (*Datx2*) in actin filament formation during oogenesis. Egg chambers from normal (Wild-Type (WT)) and mutant flies with reduced expression (*Datx2*) of Drosophila ataxin-2 were stained with DAPI (blue) and phalloidin (red) to indicate nuclei and filamentous actin respectively (a–d). The egg chambers of WT flies prior to cytoplasmic transport (a) display well demarcated, separated but interconnected cells (blue) as expected, while the egg chambers of *Datx2* flies (b) contain irregularly arranged cells. After cytoplasmic transport, the egg chambers of WT flies (c) show one greatly enlarged oocyte (dashed line) with only a small section of compressed cells, while the egg chambers of *Datx2* flies (d) have failed to yield an enlarged oocyte, instead retaining dispersed and large adjacent cells. Confocal images of egg chambers prior to cytoplasmic transport stage reveal a prominent actin filament network in WT flies (e), but a remarkably transparent actin filament network in *Datx2* flies (f). The decreased density of the actin filament network underlies the cytoplasmic ''dumping'' defect in the *Datx2* flies. (From Satterfield, T.F., Jackson, S.M., Pallanck, L.J. (2002) A Drosophila homolog of the polyglutamine disease gene *SCA2* is a dosage-sensitive regulator of actin filament formation, *Genetics* **162**, 1687–1702, used with permission of *Genetics*.) (See color plate p. xxiii).

spinocerebellar ataxia worldwide. SCA3 is also known as Machado–Joseph disease (MJD) because of its initial description in a group of Portuguese residents of the Azores islands. It is a progressive, autosomal dominant cerebellar ataxia whose clinical features include ophthalmoplegia, dystonia, dysarthria, and signs of lower motor neuron disease, such as tongue and facial fasciculations. Degeneration occurs in the spinocerebellar tracts, dentate nuclei, red nuclei, substantia nigra, and spinal cord. This disease is unique among the SCAs because the cerebellar cortex and inferior olive are largely spared. SCA3 is caused by a (CAG)*n* repeat near the 3′ end of the coding region of a novel gene (*ataxin-3*). Normal alleles range from 12–40 CAG repeats while affected individuals carry 55–84 repeats. Unlike many other triplet repeat disorders, there is a substantial gap between the largest normal repeat allele and the smallest disease-causing repeat allele. Some researchers have proposed that this could be due to a SCA3 founder effect. The presence of SCA3 in every major racial population worldwide, however, would require the founder to be truly ancient. There is the typical inverse correlation between repeat number and age of onset in SCA3, and in this disease, paternal expansion bias is characteristic, as documented by repeat sizing of sperm.

Ataxin-3 is a ubiquitously expressed 42-kDa protein, making it the smallest of the polyglutamine proteins. Ataxin-3 is highly conserved in eukaryotes, with homology to ENTH and VHS domain proteins involved in regulatory adaptor functions and membrane trafficking. Ataxin-3 has several splice variants which reside in the nucleus and the cytoplasm, and it appears developmentally regulated. The existence of NIs was first documented in the brains of patients with SCA3, and this feature of polyglutamine-expanded

ataxin-3 remains evident in SCA3 cell culture and mouse models. Ataxin-3 NIs are ubiquitinated and contain numerous transcription factors.

A number of recent discoveries regarding the domain structure and normal function of ataxin-3 suggest pathways by which polyglutamine repeat expansion could result in disease pathogenesis. Comparison of ataxin-3 amino acid sequences across a wide range of eukaryotic species revealed the presence of an extremely highly conserved amino-terminal sequence that was named the *josephin domain*. Study of this region indicates that it may play a role in aggregate formation in concert with the expanded polyglutamine tract. A rather intriguing feature of ataxin-3 that was discovered independently is the presence of multiple ubiquitin interaction motifs (UIMs), and the demonstration that ataxin-3 is a polyubiquitin binding protein. This suggests a role for ataxin-3 in mediating protein refolding and degradation.

In addition to a possible normal role in protein surveillance, other studies have found ataxin-3 directly interacts with the histone acetyltransferases CBP and p300, and can block histone acetyltransferase activity by inhibiting access of such coactivators to their histone substrates. This appears to be mediated by the interaction of ataxin-3 with histones. *In vitro* and *in vivo* studies of ataxin-3 further revealed an interaction with histones and the chromatin remodeling machinery that led to a repression of transcription activation. Thus, polyglutamine-expanded ataxin-3 may also affect transcriptional processes once it begins to accumulate in the nuclear compartments of the cell types where it is expressed.

3.7 Spinocerebellar Ataxia Type 6

Spinocerebellar ataxia type 6 (SCA6) is an autosomal dominant, slowly progressing cerebellar ataxia that accounts for ~10–20% of ADCA worldwide. It is characterized predominantly by cerebellar dysfunction that may have an episodic component. Other common features may include dysarthria, nystagmus, loss of vibration sense and proprioception, and imbalance. Histopathological changes include loss of Purkinje cells, cerebellar granule neurons, and neurons in the dentate nucleus and inferior olive. SCA6 is caused by a coding (CAG)*n* expansion in exon 47 of the gene *CACNA1A*, which encodes the α_{1A} subunit of the P/Q-type voltage-gated calcium channel. This gene is located on chromosome 19 at band p13. The SCA6 CAG repeat is small compared to other polyglutamine disorders, with a pathogenic range of only 19–33 triplets. Unaffected individuals carry alleles of 4–18 repeats. There is an inverse correlation between repeat length and age of disease onset, and minimal intergenerational and somatic instability has been reported for the SCA6 repeat expansion in affected patients.

The 9.8 kb *CACNA1A* transcript implicated in SCA6 is expressed throughout the CNS, and most highly in cerebellar Purkinje cells and granule neurons. The α_{1A} subunit is the pore-forming component of the channel, which is important in neurotransmitter release at the synapse. Polyglutamine expansions in this subunit cause variable changes in calcium transmission rates, depending on the system and the β subunit coexpressed. Expansions do not cause a reduction in membrane channel density in HEK293 cells, suggesting that aggregation does not occur

at pathogenic repeat lengths. Ubiquitin-negative neuronal inclusions are visible in the cytoplasm of SCA6 patient Purkinje cells, however.

In addition to displaying a disease allele range that does not overlap with the other polyQ diseases, there are several other reasons to suspect that SCA6 is different from the rest of the polyglutamine repeat group. The first difference is the existence of two disorders, episodic ataxia type 2 (EA2) and familial hemiplegic migraine (FMH), that are both allelic to SCA6, as both are caused by point mutations in the *CACNA1A* gene. EA2 resembles SCA6 as affected EA2 individuals suffer from a slowly progressive form of episodic ataxia, accompanied by nystagmus, dysarthria, loss of balance and sometimes cerebellar atrophy. EA2 is usually caused by truncation mutations in *CACNA1A*, resulting in loss-of-function of the calcium channel. CACNA1A knockout mice similarly develop ataxia and late-onset cerebellar atrophy, characteristic of SCA6 and EA2 patient phenotypes. Another reason SCA6 is different from other polyQ disorders is that the CACNA1A protein probably does not undergo a structural change that converts it into an aggregate-prone, beta-sheet adopting, amyloid-like conformer. Indeed, even the largest SCA6 polyglutamine tract is below the threshold required for stable β-pleated sheet formation in other polyglutamine disorders. Consistent with this prediction, channel localization of mutant polyglutamine-expanded CACNA1A protein is not affected in cell culture models, and its channel function is not completely abolished. Cytoplasmic aggregates in patient material are ubiquitin-negative, suggesting that the protein may not be grossly misfolded. This evidence supports a model whereby a dominant-negative loss of function of the P/Q-type voltage-gated calcium channel due to association of the mutant α_{1A} subunit with other subunits causes SCA6. The coincidence that this disorder is caused by a polyQ tract expansion and causes a progressive cerebellar ataxia cannot be ignored, however, more data will be required to soundly refute a possible concomitant toxic gain-of-function effect.

3.8 Spinocerebellar Ataxia Type 7

Spinocerebellar ataxia type 7 (SCA7) is an autosomal dominant, progressive cerebellar ataxia. It is unique among autosomal dominant SCAs, as patients typically develop visual impairment in addition to their cerebellar ataxia. The visual impairment is due to a cone-rod dystrophy that results in retinal degeneration. Patients first develop problems distinguishing colors, but ultimately go blind in this type of retinal degeneration. SCA7 patients may present either with cerebellar ataxia or visual impairment. The likelihood of their presentation is dictated by the size of their CAG repeat disease allele, with larger repeats typically favoring presentation with visual impairment. Affected individuals display prominent dysarthria, and can develop increased reflexes, decreased vibration sense, and oculomotor disturbances. Neuronal degeneration and reactive gliosis occur in the cerebellar cortex, dentate nucleus, inferior olive, pontine nuclei, and occasionally in the basal ganglia. NIs are widespread. Infantile-onset SCA7 has been documented, and in this fatal form of the disease, nonneuronal tissues such as the heart and the kidney are severely affected. SCA7 is caused by a highly polymorphic (CAG)*n* repeat in the 5′ coding region of the *ataxin-7* gene. Unaffected individuals carry 4–35 repeats,

while affected individuals carry 37–306 repeats. The SCA7 trinucleotide repeat is one of the most unstable of all polyglutamine disease genes, sometimes expanding by as much as 250 repeats in a single generation. There is a pronounced paternal expansion bias, with large expansions occurring in male germ cells, frequently causing embryonic lethality that results in reduced transmission. Marked repeat instability can occur in the brain, and produce large somatic expansions on occasion.

Ataxin-7 is a ubiquitously expressed protein of 892 amino acids. It is expressed most highly in heart, skeletal muscle, and pancreas. Expression levels within the CNS are highest in the cerebellum and brainstem. One splice variant, ataxin-7b, is expressed predominantly in the CNS (32). Ataxin-7 contains a functional arrestin domain, a protein interaction domain that is highly selective for phosphorylated forms of its interacting protein(s). This suggests that it interacts with specific phospho-proteins, although none have been discovered to date. It also contains two SH3 domains, which are protein interaction domains that bind proline-rich sequences and mediate a number of cell signaling processes. Ataxin-7 also contains three putative NLSs and one NES.

Ataxin-7 is conserved throughout eukaryotes, and its yeast ortholog SGF73 is part of a multisubunit histone acetyltransferase complex called *SAGA* (*Spt/Ada/Gcn5 acetyltransferase*). The human orthologs of SAGA comprise the so-called STAGA (SPT3/TAF9/ADA2/GCN5 acetyltransferase) complex, and are essential transcription coactivators required for the transcription of certain genes. STAGA components immunoprecipitate with ataxin-7. Although pathogenic expansion of ataxin-7 does not alter its ability to be integrated into the STAGA complex, the presence of the polyglutamine-expanded ataxin-7 has a dominant-negative effect upon the GCN5 histone acetyltransferase activity of the STAGA complex, resulting in transcription dysregulation. The transcription dysregulation caused by polyglutamine-expanded ataxin-7 likely causes a disease phenotype by altering the ability of certain transcription factors to activate expression of their target genes.

The best characterized example of transcription dysregulation by polyglutamine-expanded ataxin-7 is its interference with the cone-rod homeobox protein (CRX), a glutamine domain containing transcription factor expressed only in the retina and the pineal gland. Ataxin-7 interacts directly and functionally with CRX, according to studies performed *in vitro* and in a mouse model of SCA7. Importantly, the interaction between ataxin-7 and CRX appears to involve the glutamine tract regions found in both proteins. Autosomal dominant mutations in CRX can cause a cone-rod dystrophy in humans, further supporting a model in which CRX's diminished transactivation competence is central to the SCA7 retinal degeneration phenotype. Several transcription factors, including CBP, can be found in SCA7. CRX may be but one of a number of transcription factors whose function is diminished by polyQ-expanded ataxin-7 interaction and dysregulation of STAGA complex-mediated gene expression.

One intriguing feature of SCA7 was discovered upon generation of transgenic mice expressing ataxin-7 with the mouse prion protein promoter. This promoter drives expression in every tissue, with the occasional notable exception of the Purkinje cells of the cerebellum. Despite lack of Purkinje cell expression of ataxin-7, mice

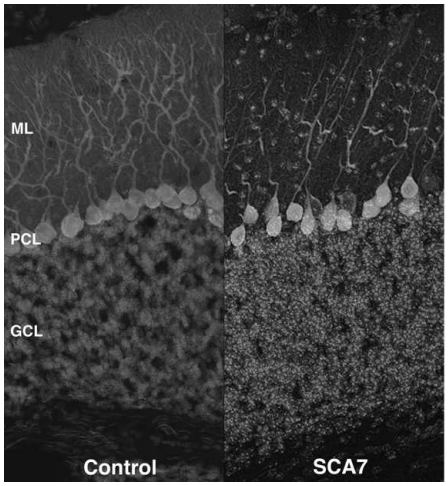

Fig. 5 Noncell autonomous Purkinje cell degeneration in a mouse model of spinocerebellar ataxia type 7 (SCA7). Confocal microscopy analysis of cerebellar sections from a SCA7 transgenic mouse (SCA7) created with an ataxin-7 CAG-92 containing murine prion protein expression vector and from an age- and sex-matched nontransgenic littermate (Control). Staining with an anti-ataxin-7 antibody (magenta), a calbindin antibody (green), and DAPI (blue) reveals a healthy, normal-appearing cerebellum characterized by properly oriented Purkinje cells with extensive dendritic arborization in the ''Control'' mice. However, SCA7 transgenic mice display pronounced Purkinje cell degeneration as evidenced by decreased dendritic arborization and displacement of Purkinje cell bodies. Interestingly, although numerous neurons in the granule cell layer (GCL) and the molecular layer (ML) display aggregates of ataxin-7, there is no accumulation of mutant ataxin-7 in the degenerating Purkinje cells due to lack of appreciable expression there. As the Purkinje cells degenerate without expressing the mutant protein, the degeneration is described as noncell autonomous. (Adapted from Garden, G.A., Libby, R.T., Fu, Y.H., Kinoshita, Y., Huang, J., Possin, D.E., Smith, A.C., Martinez, R.A., Fine, G.C., Grote, S.K., et al. (2002) Polyglutamine-expanded ataxin-7 promotes noncell-autonomous Purkinje cell degeneration and displays proteolytic cleavage in ataxic transgenic mice, *J. Neurosci.* **22**, 4897–4905, used with permission of the *Journal of Neuroscience*.) (See color plate p. xxiv).

developed a cerebellar ataxia accompanied by degeneration of the Purkinje cells (Fig. 5). This noncell-autonomous degeneration may point to a disease mechanism involving withdrawal of trophic support by communicating neurons (olivary, deep cerebellar, brainstem, or granule neurons) or dysfunction of glutamate transporters expressed by surrounding glia. Damage to inferior olivary neurons or Bergmann glia can indeed cause the degeneration of Purkinje cells, lending credence to this theory.

Another interesting feature of SCA7 that is common to other neurodegenerative disorders is the prominence of morphological and functional degeneration without pronounced apoptosis. Some neurons in SCA7 humans and mouse models exhibit indentations in the nuclear envelope, reduced arborization, ectopy, and increased autophagy. (Autophagy is the bulk degradation of cellular components by a membrane-bound autophagosome and is accelerated by a number of cellular insults.) Caspase-3, a proteolytic enzyme classically associated with apoptosis, is activated at abnormally high levels in SCA7 patient brains. This may suggest that caspase activation, rather than causing apoptosis, is contributing to a nonapoptotic degenerative process.

In normal human neurons, ataxin-7 is variably located in the nucleus or the cytoplasm. In SCA7 patients, ataxin-7 gradually undergoes a shift in localization into NIs. This process has been replicated in SCA7 transgenic mice, in which ataxin-7 immunoreactivity shifts from the cytoplasm to the nucleus, and ultimately forms foci there. In patient's brains, these NIs colocalize with promyelocytic leukemia (PML) protein, which is an integral part of nuclear bodies (NBs). NBs are associated with transcription regulation and the

ubiquitin-proteasome pathway; thus, accumulation of ataxin-7 in NBs may represent an attempt by the cell to degrade misfolded protein.

3.9 Spinocerebellar Ataxia Type 17

Spinocerebellar ataxia type 17 (SCA17) is the most recently discovered polyglutamine repeat disease. It is an autosomal dominant, progressive disorder characterized by dementia as well as cerebellar ataxia and involuntary movement abnormalities. Its symptoms are diverse and heterogeneous, but typically begin with behavioral disturbances and cognitive impairment. This is followed by ataxia, rigidity, dystonia, hyperreflexia, and rarely parkinsonism. Neuropathologically, patients may suffer degeneration of the cortex, cerebellum (including Purkinje cells), inferior olive, caudate nucleus, and medial thalamic nuclei. SCA17 is caused by the expansion of a coding (CAG)*n* repeat in the TATA-binding protein (TBP) gene on chromosome 6q27. Unaffected individuals carry 25–48 repeats, while affected individuals carry 43–66 repeats. The area of overlap between affected and unaffected alleles indicates incomplete penetrance at intermediate repeat lengths. The pathogenic threshold is higher than for most other polyglutamine disorders, yet there is an inverse correlation between repeat length and age of onset.

TBP is a ubiquitously expressed transcription initiation factor that is a core component of the RNA polymerase II transcription factor D (TFIID) complex. TBP possesses DNA binding activity in the TFIID complex, and is therefore required for the transcription of numerous genes. SCA17 patients have NIs immunoreactive for TBP, polyglutamine, and ubiquitin. Given TBP's central role in transcription regulation, the basis of SCA17 disease pathogenesis is proposed to involve transcription dysregulation, but this is yet to be proven.

3.10 Role of Aggregation in Polyglutamine Disease Pathogenesis

In most polyglutamine disorders and in many neurodegenerative diseases in general, protein aggregation is a prominent feature. It occurs in almost all polyglutamine diseases, despite the lack of domain or structural similarity between the different disease proteins. Aggregates have long been considered reliable indicators of disease, although their pattern and onset often do not correspond well with the cell-type specificity of disease pathology. As the role of aggregation in pathogenesis has been one of the most hotly debated issues in the field of neurodegeneration, it may have implications for Alzheimer's disease, Parkinson's disease, and amyotrophic lateral sclerosis. Why? There are several characteristics of polyglutamine-mediated aggregation that are presumably common to all of the disorders that show aggregation. First of all, aggregates are rich in β-pleated sheets and have many of the properties of amyloid. This is supported by Congo red birefringence and immunoreactivity with antiamyloid antibodies. Various studies have shown that the conformational change is associated with the production of visible aggregates rather than in the soluble nonaggregated phase, where polyglutamine tracts are thought to remain in a random coil conformation.

In vitro, the kinetics of aggregation are consistent with nucleated-growth polymerization, in which the rate-limiting step is

the formation of misfolded peptide assemblies, often referred to as *oligomers*. A mechanism involving nucleated-growth polymerization would predict that only one (or a few) visible aggregates would appear in each affected cell, and this appears to be the case for most polyglutamine disorders. In the cellular milieu however, where membranes and intermolecular interactions compartmentalize proteins, this prediction may not be valid. The discovery of polyglutamine microaggregates confirms this suspicion. The threshold for aggregation of polyglutamine tracts is similar to the disease threshold for most polyglutamine diseases. *In vitro*, longer polyglutamine tracts have a lower concentration threshold for aggregation and nucleate more quickly than shorter tracts. This is one possible explanation for the correlation between tract length and disease onset and progression.

Some data support a role for aggregation in polyglutamine disease pathogenesis. Some proponents of this theory invoke the fact that aggregates sequester many proteins besides the disease protein. Intermolecular interactions between transcription factors often involve glutamine tracts or glutamine-rich regions. Some studies have shown that normal proteins with glutamine tracts or glutamine-rich regions are enriched in polyglutamine aggregates in cell culture and animal models. Several transcription factors colocalize with such aggregates, including CBP, TBP, and numerous TBP-associated factors (TAFs). CBP is responsible for the prosurvival effects of BDNF, and its soluble concentration is lowered in HD patient's brains. Postnatal mice lacking CREB and its homolog CREM develop a progressive degeneration of the hippocampus and striatum.

Titration of enzymes and factors required for protein refolding and degradation away from the soluble phase and into aggregates has been proposed as a potential cause of cell toxicity in neurons with aggregates. Caspase activation is another way in which aggregation could be linked to pathology. Caspase recruitment into aggregates can lead to their activation, which could result in dysfunction or cell death in neurons. Further supporting the role of aggregates in polyglutamine protein toxicity, injection of preformed polyglutamine aggregates into the nuclei of cultured cells causes cell death, while the injection of nonpolyglutamine aggregates does not. At the same time, there is strong evidence that soluble polyglutamine protein, rather than aggregates, is the primary source of toxicity. Importantly, the pattern of aggregates observed in human patients often does not correlate with the pattern of neuronal dysfunction. For example, in the striatum of HD patients, large interneurons contain aggregates more frequently than medium spiny neurons, yet the former neurons are largely spared, while the latter are most vulnerable. HD transgenic mice expressing full-length mutant htt will develop inclusions in many brain regions many of which are neuropathologically unaffected, while few inclusions are detected in the striatum, the region of the brain displaying the most prominent pathology.

Aggregation and toxicity have been directly dissociated in other polyglutamine disease model systems. Studies of the SCA1 knockin mouse model revealed that neurons lacking aggregates were more susceptible to dysfunction and demise, while those neurons displaying prominent aggregates were protected. Similarly, SCA7 transgenic mice exhibit retinal pathology before the occurrence of visible aggregates. Finally, in a very provocative study, SCA1

transgenic mice lacking the ubiquitin ligase E6-AP were significantly less capable of forming large and numerous aggregates in neurons in comparison to SCA1 transgenic mice on a wild-type background, but displayed earlier onset of an ataxic phenotype and accelerated neurodegeneration. This suggests that the aggregates may be protective, although the toxicity of compromising the proteasome may have contributed to the accelerated phenotype. Thus ensued a contentious debate over the role of aggregate formation in polyglutamine disease – with some workers espousing the view that aggregates were responsible for disease pathology, others suggesting that the aggregation process was a protective coping mechanism of the cell and thereby beneficial, and still others insisting that aggregates were incidental and irrelevant. This debate was complicated by the existence of ''microaggregates,'' small clumps of aggregated protein visible only at the electron microscope level.

Over the last few years, studies deconstructing polyglutamine tract aggregation into a multistep process suggest a parsimonious explanation for the divergent views. Using a variety of biophysical approaches, including transmission electron microscopy (TEM), Fourier transform infrared spectroscopy (FTIR), and atomic force microscopy (AFM), one study dissected the process of huntingtin (htt) exon 1 peptide aggregation and found evidence for a number of sequential morphological and structural intermediates (Fig. 6). By showing that misfolded htt exon 1–44Q adopted intermediate structures, such work opened up the possibility that intermediates (not visible at the light microscope level) are the toxic species and that the ultimate visible aggregated forms of htt exon 1–44Q are neutralized versions of mutant protein. To examine the role of aggregate formation in polyglutamine toxicity, another group then tracked survival time versus diffuse, soluble htt protein expression levels in htt-transfected striatal neurons undergoing aggregate formation. Comparison of neurons that developed aggregates over time versus those that did not confirmed that the level of soluble nonaggregated mutant polyglutamine protein was the more reliable predictor of cellular toxicity. Such studies have shifted our attention to the role of the intermediates (oligomers, protofibrils, etc.) as the toxic species instead of the final, visible aggregates.

A reasonable model for polyglutamine toxicity predicts that the process starts with a protein that misfolds because of the presence of an expanded polyglutamine tract. The misfolded protein is initially detectable in the soluble phase due to the cell's ability to maintain the protein in a properly folded state and direct it to the degradation machinery. However, the refolding capacity of the cell is ultimately exceeded, and since the degradation machinery cannot turnover the misfolded mutant polyglutamine protein, accumulation occurs. Misfolded polyglutamine proteins can spontaneously change their structural properties and adopt abnormal conformations. These abnormally folded proteins can then nucleate, forming oligomers. Oligomers then form protofibrils that grow into fibrils. The transition to the fibril stage is characterized by the attainment of a β-sheet structure, so at this point the structures are amyloid-like. Fibrils then grow into fibers (also known as microaggregates), which then assemble into aggregates visible under a light microscope. According to such a model, blocking an intermediate step could be therapeutically effective. Consistent with this, one

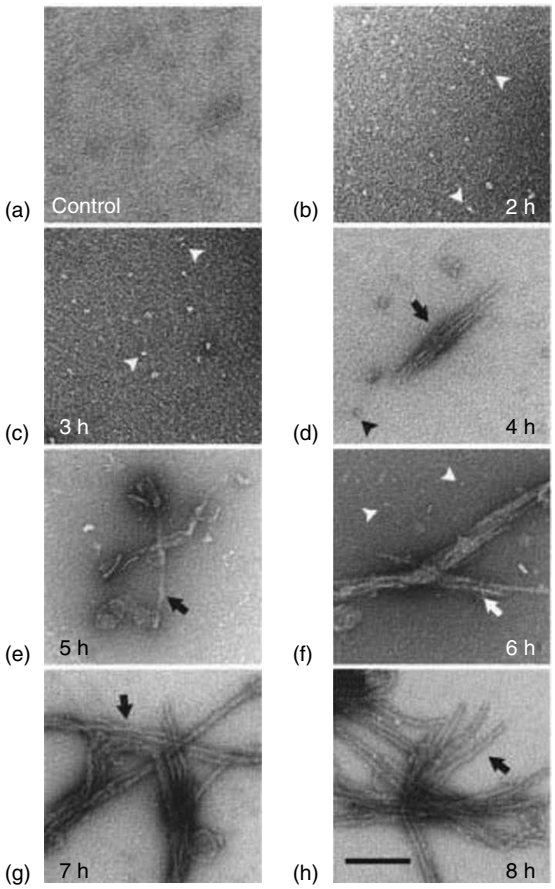

Fig. 6 Polyglutamine-expanded huntingtin protein undergoes a variety of structural alterations on its way to becoming a visible aggregate. In this experiment, transmission electron microscopy tracked the structure of huntingtin exon 1 peptide with 44 glutamines after release from a linked affinity tag. (a) Prior to affinity tag release, nothing is observed. (b-c) After affinity tag release, globular structures become apparent. (d) This is followed by formation of short fibers (4–5 nm in diameter). (e-f) Fiber formation becomes more prominent. However, during this time, large globular assemblies remain (arrowheads). (g-h) Eventually, only fibers are present, and the fibers begin to adopt a uniform appearance, suggesting consolidation into protofibrils. (From Poirier, M.A., Li, H., Macosko, J., Cai, S., Amzel, M., Ross, C.A. (2002) Huntingtin spheroids and protofibrils as precursors in polyglutamine fibrilization, *J. Biol. Chem.* **277**, 41032–41037, used with permission of the *Journal of Biological Chemistry*.).

group has nicely shown that Congo red can bind polyglutamine peptides once they are amyloid-like and prevent their conversion into fibers, while an independent group has shown that Congo red delivery to an HD mouse model is a highly effective treatment intervention.

One satisfying aspect of this model is that it allows us to simultaneously view aggregates as harmful, protective, and innocuous. How? First, aggregates clearly must be toxic as their creation is predicated upon the production of earlier intermediate toxic forms. At the same time, the final visible aggregates are less toxic than the earlier intermediates, so anything that enhances their sequestration into visible aggregates is beneficial. Finally, since oligomers are difficult to detect, it is often not possible to know whether cells are successfully sequestering the toxic precursors into aggregates or if high levels of toxic intermediates are building up. So, aggregates are thus also incidental, since their presence does not provide us with insight into the steady state levels of the toxic precursors. In conclusion, advances in our understanding of the role of aggregate formation in polyglutamine disease processes suggest that aggregates may be simultaneously viewed as harmful, beneficial, and incidental.

3.11
Protein Context

The importance of protein context in the pathogenesis of polyglutamine disorders is a subject of great interest to many researchers, because it is directly related to the mechanisms of toxicity in each disease. It is evident in the polyglutamine disorders that protein context plays a role in cell-type specificity. For example, a polyglutamine expansion in the Htt protein causes a severe degeneration of the striatum and cortex, while the same size glutamine tract in ataxin-1 causes a degeneration of structures in the cerebellum and brainstem, while sparing the striatum and cortex. This cannot be attributed to gross differences in expression patterns, since both proteins are pan-neural (Fig. 7).

One effect that protein context may have on pathology is to affect subcellular localization. For example, the presence of a functional NLS or NES dictates preferential subcellular localization in the nucleus or cytoplasm. Mice expressing expanded ataxin-1 with a mutated NLS do not develop the SCA1 phenotype, while those without mutated NLSs do. Interaction domains also affect polyglutamine protein toxicity. The ability of expanded polyglutamine proteins to interact with other molecules is a promising avenue in the search for mechanisms of cell-type specificity. Yeast two-hybrid screens and other techniques have yielded interaction partners for a number of polyglutamine proteins. For example, Htt's interactions with transcription factors may prove to be central to its pathological effects. At the same time, it is also evident that polyglutamine tracts are innately toxic. Pure polyglutamine tracts cause toxicity in cell culture. Mice that express a glutamine tract of 150 amino acids in the Hprt protein, which does not naturally contain any such tracts, exhibit progressive neurological deficits and NIs. Thus, it appears that pathology in each polyglutamine disease is due to a gain of function of the glutamine tract that is then modulated by the protein context in which it resides.

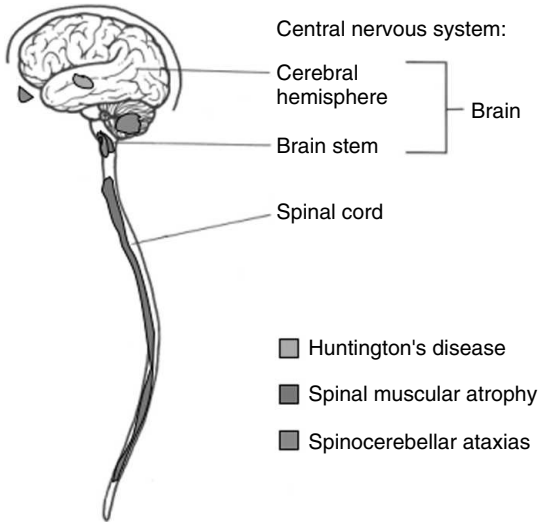

Fig. 7 The conundrum of cell-type specificity in the polyglutamine diseases. Although the different polyglutamine disease proteins are expressed throughout the central nervous system, only select populations of neurons degenerate in the different disorders. The principal regions of selective vulnerability are shown for certain of the polyglutamine diseases.

3.12 Transcriptional Dysregulation

Transcriptional dysregulation is one theory of polyglutamine toxicity that has gained support from many lines of evidence in several disorders, and it appears increasingly likely that it is one of the fundamental causes of pathogenesis. Microarray technology and other genomic techniques are facilitating rapid advances in this area of the polyglutamine field. The majority of polyglutamine disorders are caused by proteins that are either transcription factors/cofactors or interact closely with transcription factors. TBP and AR are transcription factors, atrophin-1 is a transcriptional corepressor, ataxin-7 is part of a transcriptional coactivator complex, and ataxin-1, htt, and ataxin-3 all interact with various transcription factors. It is therefore reasonable to suspect that an abnormally long polyglutamine tract could interfere with the transcriptional activity of these proteins and/or their interactors.

CBP is one of the most studied transcription factors in the polyglutamine field. It is a transcription activator that mediates part of the cellular response to cAMP, and it can interact with numerous polyglutamine proteins in the soluble or insoluble phase, including huntingtin, ataxin-3, ataxin-7, and AR. Expanded htt represses CBP-regulated genes, and overexpression of CBP causes a considerable rescue of the cell death phenotype in HD and SBMA cell culture models. Postnatal mice lacking CBP's upstream activator CREB and its homolog CREM display a profound degeneration of the striatum and hippocampus. Thus, interference with CBP appears to be a common theme in polyglutamine pathology.

Another common theme in the transcription dysregulation equation is the tendency for the polyglutamine disease proteins to alter transcription factor/coactivator-mediated histone acetyltransferase (HAT) activity. The ability of a gene to be transcribed depends upon its chromatin structure, and thus upon the degree of histone acetylation in its vicinity. This is because acetylated histones cause chromatin to be in an "open," transcription-friendly conformation. Acetylation status depends upon the balance between the activity of HATs and their countervailing counterparts, the HDACs. CBP, p300, and p300/CBP-associated factor (PCAF) are all HATs that are inhibited by polyglutamine-expanded htt exon 1 peptide and ataxin-3. In cell culture, expression of a mutant htt fragment reduces global histone acetylation.

Finally, according to a very recent study, ataxin-7 directly interacts with GCN5 as part of the STAGA complex, and upon polyglutamine expansion, mutant ataxin-7 causes a dominant-negative effect upon GCN5 HAT activity. This results in CRX transcription interference that may contribute to the SCA7 retinal degeneration phenotype. Inhibiting HDACs with drugs known as *HDAC inhibitors* (HDAC Is) attenuates the phenotype of HD and SBMA in mouse and fly models, presumably by shifting the cells' acetylation status. HDAC Is such as sodium butyrate and especially suberoylanilide hydroxamic acid (SAHA) have thus emerged as possible candidates for therapeutic trials in human polyglutamine disease patients.

3.13 Proteolytic Cleavage

The occurrence of proteolytic cleavage in polyglutamine diseases first became apparent when it was shown in HD that htt can be cleaved by extracts derived

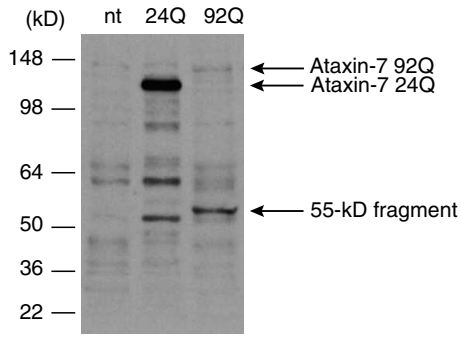

Fig. 8 Proteolytic cleavage in the polyglutamine diseases. Production of amino-terminal truncated proteins is observed in many of the polyglutamine diseases, as is shown here for SCA7. In this experiment, nuclear fractions of retinal lysates from age- and sex-matched nontransgenic (nt), ataxin-7 CAG-24 (24Q), and ataxin-7 CAG-92 (92Q) mice were prepared and immunoblotted with an antibody directed against the amino-terminal region of the protein ataxin-7. As shown here, in addition to soluble full-length ataxin-7 (which is typically reduced in cells where it is aggregating into insoluble inclusions), an ~50–60 kD fragment is detected. (Adapted from Garden, G.A., Libby, R.T., Fu, Y.H., Kinoshita, Y., Huang, J., Possin, D.E., Smith, A.C., Martinez, R.A., Fine, G.C., Grote, S.K., et al. (2002) Polyglutamine-expanded ataxin-7 promotes noncell-autonomous Purkinje cell degeneration and displays proteolytic cleavage in ataxic transgenic mice, *J. Neurosci.* **22**, 4897–4905. Used with permission of the *Journal of Neuroscience*.)

from apoptotic cells. Subsequent publications showed that only amino-terminal epitopes of htt protein are detectable in aggregates. SBMA, DRPLA, and SCA7 were then added to the list of diseases in which aggregates are only immunoreactive for a glutamine-containing fragment of the disease protein. Since then, evidence of proteolytic cleavage has been published for nearly all known polyglutamine disorders. Experimental studies revealed that inhibition of caspase cleavage reduces aggregate formation and toxicity in a cell culture model of HD, underscoring the relevance of proteolytic cleavage in polyglutamine disease pathogenesis. Cleavage promotes aggregation and/or toxicity in SCA3 and SCA7 (Fig. 8). Polyglutamine tract containing htt fragments are more toxic in cell culture than full-length htt, and the most widely used HD mouse model expresses only exon 1 of the *htt* gene.

There are several mechanisms by which cleavage may modulate polyglutamine neurotoxicity. Abnormal proteolysis of polyglutamine proteins may lead to a toxic species that can cause damage in the soluble or insoluble phase. Alternatively, proteolysis may be a normal event in protein turnover and the inability to clear cleaved protein may be the problem. Another possibility is that soluble polyglutamine proteins may cause the activation of proteases such as caspases, which then cleave the disease protein and send the cell on a path to degeneration and ultimately apoptosis. As we will see, each theory has support and not all are mutually exclusive.

Abnormal proteolysis of polyglutamine disease proteins is one possible mechanism of toxicity. Some studies have shown that polyglutamine repeat length modulates susceptibility to proteolytic cleavage, but results have been inconclusive. Few studies have been performed using human brain tissue, however. Considerable evidence exists to show that polyglutamine tracts themselves are resistant to degradation by mammalian proteasomes. The 20S and 26S eukaryotic proteasomes are incapable of cutting within polyglutamine tracts longer than 9 amino acids *in vitro*. The inability of the proteasome to digest glutamine tracts may contribute to the toxicity and aggregation of expanded polyglutamine peptide fragments.

Proteolysis may be a normal part of the turnover of wild-type and mutant htt. One group published evidence that caspase-3 cleaves both mutant and wild-type htt in the cytoplasm of HD brains, suggesting that this particular cleavage is a normal event in its turnover. Since this fragment was located exclusively in the cytoplasm, it also implies that further cleavage occurs before the nuclear translocation of htt. Another study suggested that pepstatin-sensitive aspartyl endopeptidases such as the presenilins and cathepsins D and E may be involved in the normal turnover of htt. This process, which may normally aid in maintaining the balance between htt synthesis and degradation, could generate a toxic, highly aggregation-prone (and hence intermediate oligomer/protofibril-prone) species when it cleaves mutant htt.

Another possible source of toxic cleavage products is the ubiquitin-proteasome system, which is responsible for labeling and digesting misfolded proteins, among other things. Polyglutamine tracts beyond a threshold of about 35 glutamines adopt an abnormal β-pleated sheet conformation, which may cause the host protein to be ubiquitinated and thus targeted for degradation. In support of this theory, a common feature of polyglutamine diseases is the presence of ubiquitin-positive inclusions. Arguing against this idea is an experiment showing that in a cell culture model of SCA1, increased proteasome degradation due to the introduction of a degradation signal reduces aggregates and toxicity. Another potential source of toxic fragments is the autophagy pathway, which is responsible for the bulk degradation of cellular components. According to one study, degradation of htt by autophagy and the autophagosome-associated cathepsin D creates toxic htt fragments.

There are many proteases that are suspected to play a role in the proteolytic cleavage of polyglutamine proteins, the most studied of which are the caspases. Caspases are cysteine- dependent aspartyl proteases that play a crucial role in apoptosis, but are increasingly being investigated for their nonapoptotic functions. In healthy cells, caspases are present predominantly as inactive proenzymes, which must be cleaved for full activity. Caspase-3 is the only protease that has been shown to cleave htt in HD patient's material, although caspases 1 and 6 have also been implicated in cell culture and *in vivo*. Inhibiting the cleavage of htt by any of these three proteases is protective, and an HD mouse model expressing dominant-negative caspase-1 showed significantly delayed disease onset. Caspase-3 has also been implicated in the proteolytic cleavage of atrophin-1, ataxin-3 and AR. Caspases are activated in response to a number of cellular insults, and in postmitotic cells such as neurons where inhibitors of apoptosis proteins (IAPs) are highly expressed, this may cause cellular damage that does not result in classical apoptosis.

Calpains are another family of proteases implicated in the cleavage of polyglutamine proteins. They are calcium-activated cysteine proteases that exist predominantly as proenzymes. As mouse models of HD and material from HD patients exhibit abnormal mitochondrial calcium regulation, some investigators have proposed that altered calcium flux is the mechanism of calpain activation. Indeed, several cell culture studies support the role of calpain proteases I, II, and ''m'' in htt cleavage. As mentioned previously, other aspartyl proteases such as the Alzheimer's disease-associated presenilins and autophagy-associated cathepsins have also been implicated in htt cleavage.

4
Type 2: the Loss-of-function Repeat Diseases

4.1
Fragile X Syndrome

Fragile X syndrome (FRAXA) is an X-linked disorder with a prevalence of 1 in 4000 in males and 1 in 8000 in females, making it the most common form of inherited mental retardation. Neurological presentation frequently includes mild to severe mental retardation, hyperactivity, poor eye contact, high-pitched speech, and flapping or biting hand movements. Physical signs in males include long, prominent ears, and jaws, macrocephaly, postpubescent macroorchidism, and occasionally, connective tissue abnormalities. The mutation responsible for FRAXA is typically an expansion of a polymorphic (CGG)*n* repeat found in the 5′-untranslated region of the fragile X mental retardation-1 (FMR1) gene. Expanded chromosomes have a folate-sensitive fragile site at Xq27.3 that can be viewed under a light microscope under special cell culture conditions. Normal alleles contain 6–53 triplets punctuated by one or more AGGs, which are considered to have a stabilizing influence on the repeat. Disease alleles contain expansions beyond 200 and up to 2000 repeats, with no AGG interruptions. Pathogenic expansions result exclusively from maternal transmission. FRAXA appears to be a loss-of-function disorder, since deletion of FMR1 and loss-of-function point mutations can also cause FRAXA. This view is further supported by the FMR1 knockout mouse, which reproduces certain aspects of the human disorder.

FRAXA patients have reduced levels of the *FMR1* gene product, FMRP, and there is a linear correlation between reduced protein levels and IQ test scores. Expansion of the disease allele results in hypermethylation of the (CGG)*n* tract, which spreads to a nearby CpG island in the FMR1 promoter region. Some of the proposed secondary structures formed by the FRAXA repeat contain C–C mispairs, which are good targets for human DNA methyltransferase. Another theory invokes the RNAi protein Dicer's ability to cleave CGG repeat RNA, postulating that the resulting siRNAs recruit DNA methyltransferases to the FMR1 locus. Affected alleles also display condensed chromatin, loss of histone acetylation and increased histone methylation. These data support a process whereby DNA methylation recruits transcription silencing machinery, which subsequently suppresses FMR1 transcription in the nearby promoter region. Interestingly, while premutation carriers had been viewed as perfectly normal for decades, recent work indicates that some premutation carriers (60–200 uninterrupted CGG repeats) display a phenotype distinct from FRAXA. Females have a predisposition to premature ovarian failure (POF), and males may develop late-onset ataxia and tremor with the presence of neuronal intranuclear inclusions (NIs) that consist of RNA. (This new FXTAS is discussed in a separate section.) Expression studies have shown that premutation carriers may express up to seven times more FMR1 mRNA than normal individuals. This upregulation is probably not due to compensation for loss of function, because individuals with point mutations resulting in loss of function of FMRP do not have higher levels of the transcript. Abnormal transcript levels due to premutations or full mutations are thought to be as a result of the expansion's effect

on transcription initiation rather than on mRNA stability.

The FMR1 promoter lacks a functional TATA box and initiator sequence. Four functional transcription factor binding sites have been identified in normal individuals: two sites binding USF1/USF2 and Nrf-1, and two GC boxes that bind members of the ''Sp'' family of transcription factors. Sp1 and Nrf-1 binding is disrupted in cells from FRAXA patients. The *FMR1* gene encodes the widely expressed FMRP, which is an RNA-binding protein most highly expressed in the brain and testes. It is 60% homologous to two other proteins, FXR1P and FXR2P, with which it interacts. The protein is thought to bind approximately 4% of all brain mRNA transcripts, through its RGG box domain. It selectively recognizes RNA-containing hairpin or tetraplex secondary structures (''G-quartet''), and shuttles into and out of the nucleus and associates with polyribosomes in messenger ribonucleoprotein complexes (mRNPs). The FMRP-containing mRNP complexes also contain Pur α and mStaufen, proteins involved in the transport of neuronal granules. These granules, which contain RNA and associated proteins, are transported to dendritic spines in a metabotropic glutamate receptor 5 (mGluR5)-dependent manner. FMRP can suppress the translation of certain transcripts *in vitro* and *in vivo*. FMRP may thus regulate the transport, localization, and translation of certain mRNAs in an activity-dependent manner (Fig. 9). In Drosophila, FMRP interacts with components of the RNAi machinery, which is involved in gene silencing and thus translational control. Although FMRP does not seem to affect the siRNA pathway, it may regulate microRNAs (miRNAs), which are noncoding RNAs thought to control the translation of mRNAs by binding to their 3′-untranslated region. FMRP associates with miRNAs, and proteins in miRNA-containing complexes in mammals, interactions that may be relevant to FMRPs regulation of translation.

FMRP is important for the development of dendritic spines and synaptic plasticity. It regulates the expression of MAP1B, an important regulator of microtubule stability. FMRP knockout mice have abnormally high levels of MAP1B, resulting in increased microtubule stability. This may affect the development of dendrites and/or dendritic spines. The absence of FMRP in hippocampal neurons results in immature dendritic spine morphology and delayed synaptic connections, perhaps contributing to the neurological phenotype observed in FRAXA. FMRP may also affect mGluR5-dependent long term depression (LTD). LTD is a process by which neuronal activity can cause a lasting desensitization of neurons to depolarization. LTD-associated protein synthesis at synapses may be enhanced by mGluR5 activation, while it appears to be suppressed by FMRP. This is supported by evidence of enhanced LTD in the FMR-1 knockout mouse. FMRP suppression and mGluR5 activation of LTD-dependent local protein synthesis may be opposing forces that are out of balance in FRAXA, perhaps accounting for part of the cognitive abnormalities.

4.2 Fragile XE Mental Retardation

Fragile XE mental retardation (FRAXE) is an X-linked disorder with a prevalence of about 1–4% that of FRAXA. It accounts for approximately two-thirds of families with nonspecific X-linked mental retardation (MRX), a classification in which mental retardation is the only consistent

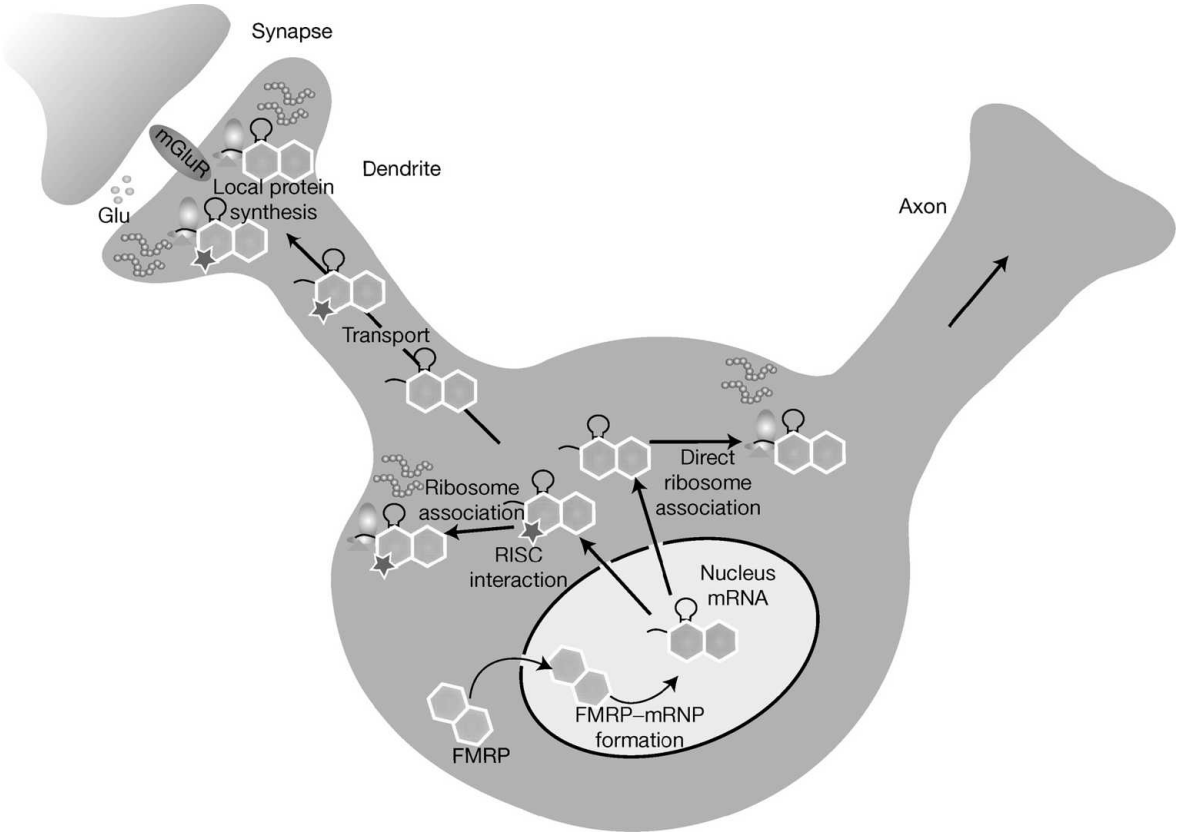

Fig. 9 Advances in the understanding of FMRP's normal function. FMRP binds to recently transcribed messenger RNAs in the nucleus to form a ribonucleoprotein complex (mRNP). The FMRP–mRNP complex moves out of the nucleus and then either directly associates with ribosomes *or* interacts with the RNA-induced silencing complex (RISC). The FMRP–mRNP complex is also transported to dendrites. Whether in the perinuclear cytosol or in dendrites, FMRP is believed to regulate protein translation. (From Jin, P., Alisch, R.S., Warren, S.T. (2004) RNA and microRNAs in fragile X mental retardation, *Nat. Cell Biol.* **6**, 1048–1053. Used with permission of *Nature Cell Biology*.).

clinical feature. Other characteristics are variable and may include hyperactivity, mild facial hypoplasia and nasal abnormalities. FRAXE is caused by the expansion of a (GCC)*n* repeat in the promoter region of *FMR2*, a gene 600 kb downstream of *FMR-1*. It also overlaps with the putative promoter of a gene called *FMR3*, transcribed in the opposite direction. Both maternal and paternal transmission can result in expansion. Normal individuals bear 6–35 GCC repeats, premutation carriers bear 61–200 repeats, and full mutation carriers bear >200 repeats. Pathogenic expansion results in a folate-sensitive fragile site at the disease locus.

In mice, FMR2 mRNA is expressed in adult and fetal brain, kidney, lung, and placenta, with highest brain levels in the hippocampus and amygdala. Transcripts of both FMR2 and FMR3 are reduced beyond detection in FRAXE patients. This may be due to a methylation-dependent silencing process similar to FRAXA. The presence of the repeat within the preinitiation region of the FMR2 promoter may also suggest a more direct disruption of transcription. FMR2 mRNA is highly expressed in the hippocampus, an area critical for learning and memory. Its paralogs AF4 and LAF4 are both transcription transactivator proteins, and the FMR2 protein seems to be a potent transcription activator itself. Furthermore, the FMR2 protein is nuclear, consistent with its proposed role in transcription regulation. The Drosophila ortholog of FMR2/AR4, Lilliputian, is essential for proper organ development, and its loss of function is lethal. FMR2 knockout mice display impairment in the conditioned fear test and enhanced LTP (long-term potentiation) in the hippocampus. The role of FMR3 in FRAXE, if any, is unknown. The mechanism of FRAXE pathogenesis may therefore involve silencing of the human *FMR2* gene resulting in altered transcription in many parts of the developing nervous system and mature brain. The neurological deficits characteristic of FRAXE may involve effects of altered transcription on the hippocampus, amygdala, and possibly other brain structures.

4.3 Friedreich's Ataxia

With a prevalence of about one per 50 000 individuals in the Caucasian population, Friedreich's ataxia (FRDA) is the most common inherited ataxia in this ethnic group. It is a multisystem degenerative disease that is unusual among the triplet repeat disorders due to its autosomal recessive inheritance. Neurological symptoms include gait, limb and truncal ataxia, loss of position and vibration senses, diminished tendon reflexes, and dysarthria. Neuropathology changes include degeneration of the posterior columns of the spinal cord, loss of large primary sensory neurons in the dorsal root ganglia (DRG), and mild, late-onset degeneration of the cerebellar cortex. Other common clinical features are cardiomyopathy, diabetes mellitus, scoliosis, and other skeletal abnormalities. Patients often present with symptoms in childhood, become wheelchair-bound by their late teens or early twenties, and have reduced lifespans due to cardiac failure. Adult presenting patients, however, can have nearly normal lifespans with more protracted progression and less severe nonneuronal involvement. Indeed, until the identification of the causal mutation, many of these adult-onset cases went undiagnosed.

FRDA results from the expansion of a polymorphic (GAA)*n* repeat in the first intron of the gene *X*25, now known as frataxin. FRDA patients have at least one

expanded allele. For the disease to occur, the second allele must contain either an expanded repeat, or rarely, a copy of frataxin containing a loss-of-function mutation. No patients have been described with loss-of-function allele mutations in both *FRDA* genes. This is probably due to prenatal lethality, as frataxin-null mice die in utero. Disease severity and onset age are determined by the size of the (GAA)*n* repeat of the smaller expansion allele. Unaffected individuals carry at least one allele between 7–38 repeats, while affected individuals carry two alleles of 66–1700 repeats. Interruptions of the (GAA)*n* repeat result in later onset and attenuated presentations. GAA expansion at the FRDA locus can result in enormous repeats in a single generation. Maternal transmission can result in expansion or contraction, while paternal transmission results primarily in contraction.

FRDA patients exhibit reduced frataxin RNA and protein levels, and evidence suggests a defect in transcription or RNA maturation. Current models propose that frataxin RNA elongation may be disturbed by triplex structure formation between expanded DNA strands during transcription. DNA triplexes are formed when one strand of a double-stranded DNA molecule folds back upon itself, and interacts with two previously annealed strands. This creates a local structure comprising three DNA strands held together by hydrogen bonds. Certain sequences favor this process, among them extended (GAA)*n* repeats. Triplex formation in the first intron would presumably affect transcript elongation but not initiation. In support of this model are *in vitro* transcription experiments demonstrating no effect of repeat length on transcript initiation.

Frataxin is a 210 amino acid protein that is well conserved from prokaryotes to mammals. It contains mitochondrial targeting signal sequences and localizes to the mitochondrial matrix. Frataxin expression occurs at the primary sites of pathology: dorsal root ganglia, spinal cord, sensory nerves, heart, and pancreas. These are tissues that rely upon high levels of oxidative metabolism and consequently are rich in mitochondria. In addition, such cell types are often postmitotic, meaning that most dividing cell types are spared in FRDA patients.

Studies with FRDA patient material have demonstrated an increased heart iron content and a deficiency in iron–sulfur cluster-containing proteins, including aconitase, a protein involved in iron homeostasis. In addition, fibroblasts derived from FRDA patients are abnormally sensitive to iron and hydrogen peroxide induced stress. Ablation of the yeast frataxin homolog results in respiratory dysfunction, abnormal accumulation of mitochondrial iron, impaired biogenesis of iron–sulfur proteins, and increased sensitivity to oxidative stress. Conditional knockout of frataxin in striated muscle results in a heart-specific phenotype resembling the cardiac abnormalities in human FRDA (Fig. 10). This supports a genetic mechanism involving loss of function of the disease protein. Frataxin may be part of a complex that delivers iron to Iron–sulfur clusters (ISCs), which are cofactors essential to the activity of many important cellular proteins. The accumulation of iron outside the mitochondria, although probably not central to FRDA pathogenesis, supports a deficiency in iron delivery to ISCs. Among ISC-dependent cofactors are proteins involved in mitochondrial electron transport and thus respiration. Disturbances in oxidative metabolism are often associated with increases in the production of

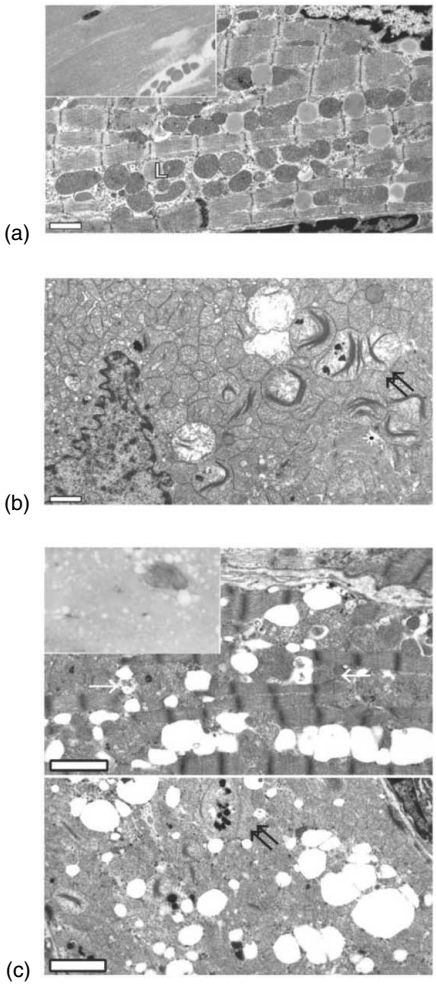

Fig. 10 Friedreich's ataxia mice display cardiac muscle pathology. (a) Transmission electron microscopy of mice lacking expression of frataxin in only their muscle reveals the abnormal accumulation of lipid droplets (L) in cardiac muscle at 4 weeks of age. (b) By 7 weeks of age, mitochondria appear abnormal and iron deposits are visible (arrows). (c) With further progression, large vacuoles emerge (inset-top) as mitochondria undergo continued prominent degeneration. Ultimately, the mitochondria become engorged with electron-dense material consistent with iron deposits. (From Seznec, H., Simon, D., Monassier, L., Criqui-Filipe, P., Gansmuller, A., Rustin, P., Koenig, M., Puccio, H. (2004) Idebenone delays the onset of cardiac functional alteration without correction of Fe-S enzymes deficit in a mouse model for Friedreich ataxia, *Hum. Mol. Genet.* **13**, 1017–1024, used with permission of *Human Molecular Genetics*).

toxic reactive oxygen species (ROS). FRDA therefore is thought to result from reduced frataxin levels, leading to abnormal iron–sulfur metabolism, mitochondrial dysfunction, oxidative stress, and tissue degeneration. FRDA is thus caused by the dynamic mutation of a nuclear-encoded mitochondrial protein. The disease shares features with classic mitochondrial disorders such as MELAS (mitochondrial myopathy, encephalopathy, lactic acidosis, and strokelike episodes syndrome) and MERRF (myoclonus epilepsy with ragged red fibers), which are caused by stable mutations to mitochondrial-encoded proteins. FRDA appears to be a classic mitochondrial disorder with an unusual genetic basis – dynamic mutation.

Given the data suggesting a role for oxidative metabolism and iron transport in FRDA pathogenesis, antioxidants and iron transport molecules are being evaluated as treatments for this disease. Several clinical trials have been conducted in FRDA

patients using idebenone, a synthetic analog of coenzyme Q10 and a potent antioxidant. Some studies have shown substantial improvements in the heart function of patients, although the lack of randomized placebo controls and the variability of the disorder render the results controversial. A recent conditional knockout mouse model of FRDA also supports the use of idebenone as a treatment for the disorder, making treatment of FRDA patients with this antioxidant a distinct possibility.

4.4 Progressive Myoclonus Epilepsy Type 1

Progressive myoclonus epilepsy type 1 (EPM1) is a rare, autosomal recessive neurological disorder most prevalent in Finland and parts of North Africa. Its most prominent symptoms are progressive photosensitive myoclonus and tonic-clonic epilepsy. Some patients also experience a progressive cerebellar ataxia and cognitive decline. Neurodegeneration occurs in the thalamus, spinal cord, and the Purkinje and granular neurons of the cerebellum. Typical age of onset is 6 to 16 years of age. EPM1 is sometimes caused by missense mutations in the *cystatin B* gene (CSTB); however, analysis of affected patients lacking such mutations revealed a dodecamer repeat expansion upstream of CSTB. The dodecamer repeat is located between 66 and 77 bp 5′ of two putative transcription start sites, and has the sequence CCCCGCCCCGCG. Unaffected individuals have a repeat number of 2–3, premutation carriers have 12–17 repeats, and affected individuals carry 30–150 repeat alleles.

CSTB is a highly conserved gene in the cystatin family of cysteine protease inhibitors. CSTB mRNA is ubiquitous, with high transcript levels in the hippocampus. The protein binds to and inhibits lysosomal proteases such as cathepsins B, H, L, and S. Pathogenic expansion of the repeat causes a reduction in CSTB transcription in some cell types. Cstb knockout mice develop symptoms similar to those seen in EPM1 patients, and missense mutations causing the disease disrupt the ability of CSTB to bind cysteine proteases. Together, these data suggest a loss-of-function mechanism for EPM1. Lowered inhibition of cysteine proteases may result in neuronal damage, causing the phenotype observed in EPM1.

There are several ways in which the repeat might reduce CSTB expression. The first is that reduced gene expression may be due to an increase in the distance between promoter elements and the transcription start site. AP-1 binding sites have been located upstream of the repeat. One study demonstrated a two- to fourfold reduction in promoter activity when the repeat is expanded. An equivalent reduction also occurred when similarly sized heterologous DNA was used in place of the expanded repeat. Independent studies have confirmed a large reduction in promoter activity due to repeat expansion. Another way the repeat could affect CSTB expression is through alterations in chromatin structure. The repeat region is G-C rich and might exclude nucleosomes or promote the formation of secondary structures. Abnormal DNA secondary structures have been observed in the EPM1 repeat region. These alterations could affect the expression of *CSTB* or other genes in the vicinity. A third possible mechanism for expression changes lies in the sequence of the repeat region. Each dodecamer repeat contains a GC box, which could act as an Sp1 binding site *in vivo*. In cases of abnormally large repeat numbers,

increased Sp1 binding could contribute to the suppression of CSTB transcription.

5
Type 3: the RNA Gain-of-function Repeat Diseases

5.1
Myotonic Dystrophy Type 1

Myotonic dystrophy or DM is an autosomal dominant, multisystem disorder with a prevalence of 1 in 100 000 worldwide, and 1 in 8000 in European and North American Caucasian populations. Patients typically present with proximal or distal muscle dysfunction including weakness, pain, and myotonia (failure of muscle relaxation). DM exhibits a combination of characteristic symptoms: cardiac conduction abnormalities, subcapsular iridescent cataracts, and unusual endocrine changes. Other features include testicular atrophy, type II diabetes, and late-onset cognitive impairment. In its most severe form, congenital DM, mental retardation, craniofacial deformities, and other developmental abnormalities are present. It exhibits both paternal and maternal transmission, although there is an almost exclusive maternal transmission in congenital DM. Myotonic dystrophy type 1 (DM1) is caused by a (CTG)*n* expansion in the 3′-untranslated region of the gene, dystrophica myotonica protein kinase (DMPK), on chromosome 19. Unaffected individuals carry 5–37 repeats, while affected individuals carry 50–4000 repeats. DM exhibits pronounced anticipation and dramatic somatic instability. Interestingly, the clinical phenomenon of anticipation (worsening severity as a disease gene is transmitted from one generation to the next) was first described nearly a century ago in a family segregating DM1. Although the anticipation phenomenon was dismissed as an artifact of ascertainment by geneticists of the mid twentieth century, anticipation is now known to be a genuine feature of dynamic mutation diseases. Anticipation results from the tendency of disease repeats to expand and the inverse correlation between repeat length and age of disease onset.

Several theories have been advanced to explain the molecular basis of DM1, including haploinsufficiency of DMPK, local chromatin effects on neighboring genes, and gain of function exerted by expanded RNAs. DMPK is proposed to have many functions, some of which could relate to the disease, such as modulation of skeletal muscle sodium channels, RNA metabolism, calcium homeostasis, and the cell stress response. Initial expression studies reported a decrease in DMPK RNA and protein levels, but a DMPK knockout mouse designed to test the haploinsufficiency theory exhibited only mild myopathy that was inconsistent with the DM phenotype. The (CTG)*n* tract is a strong nucleosome assembly site, and it was therefore hypothesized to have trans-effects on the expression of neighboring genes. According to this model, the myriad symptoms of DM1 are caused by disturbances in the expression of multiple nearby genes due to the expansion – making DM1 a ''contiguous gene syndrome.'' There are several genes in close proximity to the *DMPK* gene (i.e. <5 kb) whose roles in DM1 were considered; the most studied of these genes has been SIX5. The SIX5 homolog in Drosophila is required for normal eye development and its mouse homolog is involved in regulating distal limb muscle development. Expression data on SIX5 in

DM1 patients has been inconsistent, however. A Six5 knockout mouse developed cataracts, although they were not of the type observed in DM1. Another gene implicated by this model is *DMWD*, which is expressed in the testis and suspected to be involved in male infertility. Studies indicated that the expression of DMWD is not altered.

The third theory for the molecular basis of DM proposes that an RNA gain-of-function mechanism is responsible. RNA foci, which are accumulations of expanded transcripts, accumulate in the nuclei of patient cells (Fig. 11). The RNA gain-of-function theory was buttressed by the discovery that DM2, a disorder with symptoms almost identical to DM1, is caused by a (CCTG)*n* expansion in intron 1 of the zinc finger 9 protein (ZNF9). The two genes responsible for DM1 and DM2 are unrelated and reside on different chromosomes. Genes near the two loci bear no obvious resemblances. The only striking parallels between the two expansions are: (1) they both contain CTG triplets; and (2) they both occur in transcribed but noncoding regions of the genome. More support for the RNA gain-of-function model came from a mouse model generated by Mankodi et al. in 2000, which contained a (CTG)*n* expansion in the 3′ untranslated region of the skeletal actin (*HSA*) gene. This mouse exhibited myopathy typical of DM1, although the skeletal muscle-restricted expression pattern of HSA precludes broader conclusions. Thus, there are several lines of evidence suggesting that CUG expansion-containing RNAs are capable of causing DM.

RNA-binding proteins and transcription factors colocalize with the RNA foci found in DM, potentially altering nuclear processes. Elevated levels of CUG-containing RNA has been shown to alter gene splicing in specific transcripts which could be relevant to DM: cardiac troponin T (cTNT), involved in cardiomyopathy; Insulin Receptor (IR), involved in diabetes; and Clc-1, the main chloride channel in muscle. Abnormal splicing of cTNT, IR, and ClC-1 are proposed to account for the cardiac abnormalities, insulin insensitivity and myotonia observed in DM.

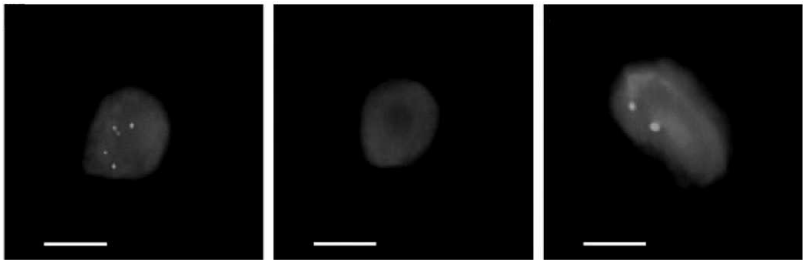

Fig. 11 *In situ* hybridization of muscle sections with fluorescently labeled antisense oligonucleotide probes reveals accumulation of mutant RNA in DM1 and DM2. (a) Probing of DM2 muscle with a CAGG probe indicates that multiple RNA foci are present. (b) Probing of normal muscle with a CAGG probe demonstrates absence of RNA foci. (c) Probing of DM1 muscle with a CAG probe yields prominent RNA foci. (From Liquori, C.L., Ricker, K., Moseley, M.L., Jacobsen, J.F., Kress, W., Naylor, S.L., Day, J.W., Ranum, L.P. (2001) Myotonic dystrophy type 2 caused by a CCTG expansion in intron 1 of ZNF9, *Science* **293**, 864–867, used with permission of *Science*).

Splicing abnormalities cause a reduction in the membrane concentration of ClC-1 and reduce chloride conductance to levels consistent with myotonia. These spicing alterations are thought to be due to the repeat-expanded RNA's effects on two families of RNA-binding proteins: ''CUG-BP1 and ETR-3-like factors'' (CELF) and ''muscleblind-like proteins'' (MBNL). CELF proteins regulate pre-mRNA splicing in cTNT, IR, and ClC-1. In patient tissue and cell culture, CUG-BP1 levels and activity are increased in response to elevated levels of CUG-containing RNA. This may be due to a lengthening of the protein's half-life. MBNL proteins were named after their Drosophila ortholog *muscleblind*, which is required for photoreceptor and muscle differentiation in flies. The three known proteins in this family (MBNL1 (MBNL), MBNL2 (MBLL), and MBNL3 (MBXL)) are splicing regulators that are thought to act antagonistically to CELF family proteins. They colocalize with RNA foci *in vivo*, and a mouse model lacking specific isoforms of MBNL1 recapitulates the myotonia, cataracts, and splicing dysregulation observed in DM.

The splicing alterations seen in DM patients are consistent with loss of function of MBNL proteins or an increase in CELF protein activity in muscle and brain. Because of the colocalization of MBNL proteins with RNA foci, it has been proposed that sequestration and subsequent depletion of these proteins from the cellular milieu is responsible for the symptoms of DM. Although this process probably plays a critical role in the disease, recent evidence suggests it is not solely responsible. The most plausible current theory explaining DM pathogenesis proposes an imbalance between the antagonistic MBNL and CELF proteins, resulting in specific splicing abnormalities that cause DM's diverse range of symptoms.

5.2 Myotonic Dystrophy Type 2

Myotonic dystrophy type 2 (DM2) is an autosomal dominant, multisystem disorder very similar to DM1. The majority of its symptoms resemble DM1: progressive weakness, myotonia, cardiac disturbances, iridescent cataracts, and insulin insensitivity. There are some notable differences, however. DM2, unlike DM1, predominantly affects proximal muscles at its onset, which is why many cases were originally classified as proximal myotonic myopathy (PROMM). Other interesting differences are that mental retardation is not observed in DM2, DM2 patients show increased sweating, and DM2 congenital forms have not been observed. DM2 is caused by a (CCTG)*n* tetranucleotide expansion in the first intron of the zinc finger protein 9 (*ZNF9*) gene on chromosome 3q21.3. The tetranucleotide repeat can expand to stunning lengths, with the longest cases comprising 44 kb of DNA, making them the longest tracts observed in the repeat expansion disorders. The DM2 locus exhibits marked somatic instability. Over the course of a patient's lifetime, the average repeat length increases substantially, as judged by blood drawings.

The similarities between DM1 and DM2 are not restricted to the clinical presentation. The expansions are both large, CTG-containing tracts that are transcribed, but not translated. Both disorders cause nuclear RNA foci that sequester specific RNA-binding proteins (Fig. 11), including CELF and MBNL family members. Similar splicing abnormalities are also observed in DM2. Since the genes associated with the repeat expansions in DM1 and DM2 are

unrelated, it is likely that the cause of both disorders is a toxic gain of function of long tracts of CUG-containing RNA. A mouse model generated by Mankodi et al. in 2000, which contained a (CTG)*n* expansion in the 3′ untranslated region of the skeletal actin (*HSA*) gene, exhibited myopathy typical of DM. Thus, even outside the context of the DM1 and DM2 loci, CTG-containing expansions can cause DM-like symptoms. This supports the RNA gain-of-function theory, as transcribed CTG-containing expansions are inherently capable of causing disease. Differences between DM1 and DM2 may be due to regional or temporal expression patterns or differences in the affinity of RNA-binding proteins for CTG or CCTG tracts.

5.3 Spinocerebellar Ataxia Type 8

Spinocerebellar ataxia type 8 (SCA8) is a dominantly inherited cerebellar ataxia. Affected individuals suffer from late-onset, slowly progressing gait ataxia as well as dysarthria, oculomotor incoordination, spasticity, and decreased vibration sense. The cerebellar cortices and vermis undergo a slowly progressing but dramatic atrophy, while the brainstem exhibits little evidence of degeneration. Patients may become wheelchair-bound as early as their fourth decade of life. Using a direct method for cloning expanded triplet repeats (i.e. RAPID cloning), a gene containing an expanded CTG tract was identified in a large family (MN-A) segregating the SCA8 phenotype. Interestingly, this CTG is contained within a gene on the long arm of chromosome 13 that is transcribed, but apparently not translated into a protein product. Thus, it was proposed that the production of an RNA transcript containing this expanded CTG repeat tract is the cause of SCA8. Numerous subsequent studies, however, have indicated that possession of the expanded CTG repeat tract appears necessary, but not sufficient, for the production of the SCA8 phenotype. Thus, reduced penetrance is viewed as a key feature of SCA8 at this time. On the basis of the available genetic data, normal individuals always carry fewer than 70 CTG repeats, while affected SCA8 patients can carry anywhere from 71 to >1000 CTG repeats. As extremely large CTG repeat alleles (>800 triplets) were shown to not cause disease in early reports, this was initially attributed to lack of stability of the mutant RNA product. However, further work has revealed considerable overlap between disease-causing CTG repeat expansions and nonpenetrant CTG repeat alleles, indicating that a secondary factor – either a trans-acting genetic factor or an environmental factor – must be present to yield the SCA8 disease phenotype. In the case of the original MN-A family, evidence for a *cis* modifier appears responsible for the extremely high penetrance in this large pedigree. Thus, while the causality of the CTG repeat expansion in SCA8 has been somewhat controversial, review of the current literature suggests that the CTG repeat expansion is directly involved in SCA8, but may not alone be sufficient to produce the disorder.

Another unique feature of the SCA8 CTG repeat is its extreme and unusual genetic instability. Paternal transmissions generally result in contractions, while maternal transmissions generally result in expansions. Expansions of up to 600 repeats have occurred in one generation through maternal transmission. Large deletions in expanded alleles often occur in sperm cells, offering an explanation for the paternal contraction bias. Pathogenic expansions

often have 5′ triplet interruptions, the role of which is unclear.

The molecular basis of how the expanded SCA8 RNA causes disease remains unclear. The transcript has been detected exclusively in the brain, and appears to be transcribed in the CTG orientation. Translation of a polyglutamine tract from the CAG-containing transcript in the opposite direction is precluded by the existence of stop codons flanking the repeat. The longest transcript identified to date contains 6 exons, and many alternatively spliced forms of the gene have been detected, although all these isoforms are expressed at very low levels. None contain significant open reading frames. In 1999, Koob et al. reported that a gene partially overlaps the 5′ end of the *SCA8* gene locus on the antisense strand. This gene, called *Kelch-like 1 (KLHL1)*, for its homology to the Drosophila *KELCH* gene, is highly conserved and predicted to encode an actin-binding protein of 748 amino acids. Its expression overlaps with that of the SCA8 transcript, suggesting that the *SCA8* gene may produce an antisense RNA whose function is to regulate KLHL1 expression. Whether or how this is occurring remains uncertain at this time.

With the discovery of the DM RNA toxic gain-of-function pathway, an emerging theory for SCA8 pathology holds that the production of a CUG-expanded transcript results in RNA gain-of-function toxicity within the restricted neuronal populations where the *SCA8* gene is expressed. In support of this hypothesis, transgenic mice derived with a human bacterial artificial chromosome containing the entire *SCA8* gene with a 118 CTG repeat expansion develop neurological disease. The severity of their phenotype depends on the expression level of the transgene. In the more moderate expressing lines, the SCA8 mice display a slowly progressive gait ataxia reminiscent of the human disease. While no protein product has been detected, 1C2 and ubiquitin antibody staining reveal intranuclear inclusions in cerebellar neurons, consistent with the RNA-containing inclusions observed in FXTAS brains. An alternative interpretation is that translation of CTG into a polyleucine tract is occurring. Further work will be needed to distinguish these two possibilities.

Studies of the SCA8 CTG repeat expansion in *D. melanogaster* have also been informative. Whether directing expression of the *SCA8* gene to fly retina with a normal CTG repeat tract or an expanded CTG repeat tract, a neurodegenerative eye phenotype results. Modifier screens using fly stocks carrying mutations in genes encoding RNA-binding protein yielded a number of genes that could either enhance or suppress this retinal degeneration phenotype. Interestingly, Drosophila *muscleblind*, whose mammalian counterpart has been implicated in the DM RNA toxicity pathway, modified the retinal degeneration caused by expanded SCA8 CTG repeat expression more so than the retinal degeneration caused by normal SCA8 CTG repeat expression. Such data supports the hypothesis that the SCA8 CTG repeat expansion is producing neurotoxicity by altering the function of RNA-binding proteins as in DM. Although it would be premature to definitively conclude that SCA8 is an RNA gain-of-function repeat disease, provisional classification in this category is appropriate.

5.4 The Fragile X Tremor – Ataxia Syndrome (FXTAS)

Fragile X tremor-ataxia syndrome (FXTAS) is a rare and unusual disorder

that is associated with premutation of the FRAXA locus in males. Patients develop a progressive ataxia and intention tremor. This is sometimes accompanied by dementia, parkinsonism, and autonomic dysfunction. Neuropathological changes include degeneration of the cerebellum and ubiquitin-positive intranuclear inclusions in neurons and glia. FXTAS is associated with the expansion of a (CGG)*n* tract in the 5′-untranslated region of the *FMR1* gene, found on chromosome Xq27.3. Expansion of this tract beyond 200 repeats causes FRAXA, a disorder resulting from a reduction in the expression of FMR1. Males with tracts between 55 and 200 CGG repeats are considered to be in the ''premutation range,'' and are now considered to be at risk for FXTAS beyond middle age.

In contrast to FRAXA, FXTAS patients show increased expression of the FMR1 transcript, with longer repeats corresponding to higher transcript levels. Premutation carriers with more than 100 repeats have an average of five times more FMR1 mRNA than individuals in the normal repeat range. Despite the increase in transcript level, the protein product of the *FMR1* gene, FMRP, is slightly reduced in FXTAS patients. Since elevated transcript

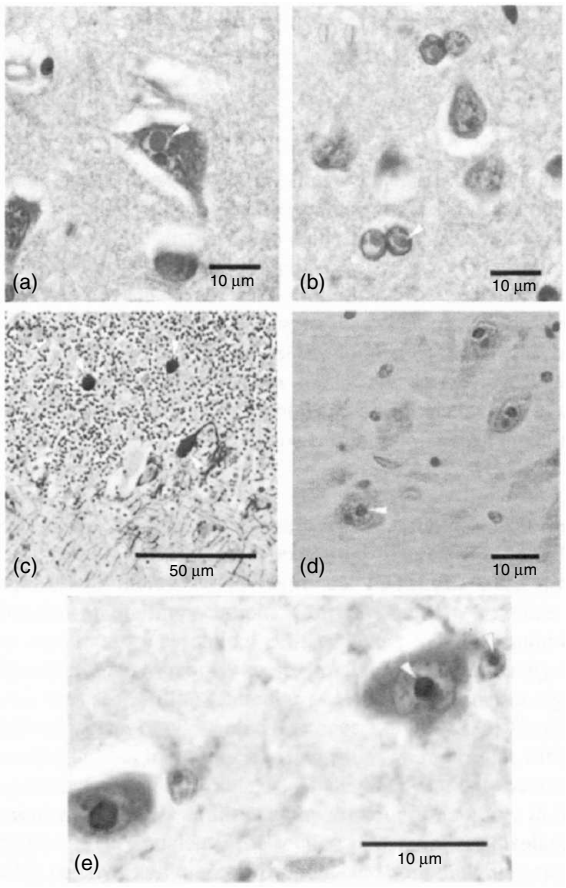

Fig. 12 Intranuclear inclusions are present in the brains of FXTAS patients. (a) Hematoxylin & eosin staining of cerebral neurons reveals a refractile, eosiniphilic nuclear inclusion of ~5 μM in diameter (white arrowhead). (b) Hematoxylin & eosin staining of cerebral astrocytes reveals refractile, eosiniphilic nuclear inclusions of ~2 μM in diameter (white arrowhead). (c) Antineurofilament antibody staining of cerebellum demonstrates presence of dystrophic neurites, consistent with ongoing Purkinje cell degeneration. (d) Antiubiquitin antibody staining of cerebral neurons labels intranuclear inclusions. (e) Antiubiquitin positive intranuclear inclusions form in both neurons (white arrowhead; larger cell) and astrocytes (white arrowhead; smaller cell). (From Greco et al. (2002) *Brain* **125**, 1760, used with permission).

levels are present without great alteration in protein levels, this disorder may be due to an RNA gain of function of the FMR1 transcript. Indeed, immunostaining of FXTAS patients' brain sections reveal intranuclear inclusions in neurons and glia, believed to be comprised of accumulated Fmr1 RNA transcripts and various proteins (Fig. 12). To determine the molecular basis of FXTAS, a knockin mouse model of FXTAS was generated using a human 98 CGG repeat, and was noted to produce elevated levels of the Fmr1 transcript and display intranuclear ribonucleoprotein inclusions, containing ubiquitin, Hsp40 and the 20S proteasome subunit. The inclusions may be a response to RNA toxicity or a result of the aggregation of CGG-binding proteins. While the mechanism of FXTAS may be due to a dominant gain of function of triplet-expanded RNA on RNA-binding proteins as in DM, there is currently no direct evidence supporting this theory.

6
Type 4: The Polyalanine Diseases

6.1
Overview

Polyalanine disorders are characterized by small expansions in trinucleotide repeats encoding alanine tracts. Most are rare, autosomal dominant developmental malformations. Although the normal function of the alanine tract is unknown, they tend to be found in transcription factors. The majority of alanine tract expansions associated with disease loci are also located in transcription factors, most of which play a role in development. In contrast to polyglutamine expansions, polyalanine expansions are small and stable, not exceeding 30 triplets. Most are composed of ''imperfect'' alanine tracts, including combinations of GCG, GCA, GCC, and GCT codons. This composition argues against an expansion mechanism involving single-strand, hairpin-like secondary structures as in other repeat disorders. A more plausible mechanism for polyalanine expansion is unequal crossing-over, in which alleles mispair during meiotic crossing-over, resulting in one expanded and one contracted tract.

6.2
Oculopharyngeal Muscular dystrophy

Oculopharyngeal muscular dystrophy (OPMD) is a predominantly autosomal dominant, late-onset disorder characterized by progressive drooping eyelids, dysphagia, and proximal limb weakness. Certain skeletal muscles in affected patients degenerate and contain nuclear inclusions and rimmed vacuoles. This effect is particularly striking in the levator palpebra and pharyngeal muscles, responsible for lifting the eyelids and swallowing. OPMD is caused by an alanine expansion in the gene polyadenine-binding protein 2 (PABP2). PABP2 normally contains a 10-alanine tract encoded by $(GCG)_6(GCA)_3GCG$. Affected individuals carry 12–17 alanines, probably resulting from unequal crossing-over of the two alleles. Repeat length appears to correlate with disease severity.

PABP2 is an abundant, ubiquitously expressed pre-mRNA-binding protein that plays a role in controlling the formation and length of mRNA polyA tails. NIs immunoreactive for PABP2 are present in the skeletal muscle cells of OPMD patients and sequester polyA-containing transcripts. The aggregates are filamentous and contain PABP2, ubiquitin and

proteasome subunits, leading investigators to conclude that expansion of the alanine tract probably causes PABP2 to misfold and aggregate. Aggregation in OPMD has been linked to toxicity in several experimental systems. Polyalanine-expanded PABP2 aggregates and causes cell death in cultured cells and transgenic mice. Indeed, widespread expression of the human *PABP2* gene in transgenic mice yielded polyalanine length-dependent muscle pathology, including rimmed vacuoles, central nuclei, and numerous dystrophic changes (Fig. 13). Deleting the C-terminal oligomerization domain, overexpressing chaperones, or exposing cells to aggregation inhibitors such as Congo red and doxycycline, reduces aggregate formation and toxicity in cell culture. A polyalanine-expanded peptide, similar to the amino-terminal region of PABP2 was shown to adopt a β-sheet conformation, whereas the same peptide with 7 alanines adopted an α-helical conformation. This is reminiscent of polyglutamine proteins, which also adopt a β-sheet conformation when the polyglutamine tract exceeds a threshold of about 35 glutamines. Expanded polyalanine proteins also activate caspase-3 and -8 in cultured cells, another feature reminiscent of polyglutamine toxicity.

In 2004, Wirtschafter et al. proposed a model for the selective vulnerability of

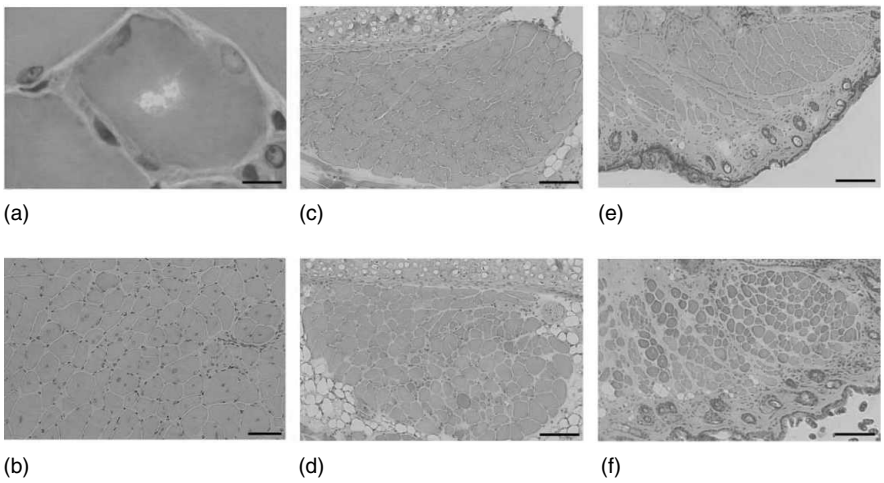

Fig. 13 Mice expressing polyalanine-expanded PABP2 protein display prominent muscle pathology consistent with the OPMD phenotype. Transgenic mice were generated using the pCAGGS expression vector that consists of the chicken beta-actin promoter and a CMV enhancer, and thus ubiquitously express either human PABP2 protein with six alanines (c, e) or nine alanines (a, b, d, f) at roughly comparable levels. Hematoxylin & eosin staining of sections from the soleus muscle (a, b), the pharynx muscle (c, d), and the eyelid muscle (e, f) reveal normal muscle histology in the six-alanine PABP2 expressing mice (c, e). However, mice expressing PABP2 with nine alanines display nonuniform muscle fiber size and prominent connective tissue in pharynx and eyelid musculature (d, f). At high power, cytoplasmic vacuoles, reminiscent of OPMD ''rimmed vacuoles'' are apparent in soleus muscle from the nine-alanine PABP2 expressing mice (a). Low power examination further indicates frequent central nuclei in the soleus muscle from such mice (b). (From Hino et al. (2004) *Hum. Mol. Genet.* **13**, 181, used with permission).

extraocular muscles in OPMD. Unlike other skeletal muscles, extraocular muscles are not postmitotic and they continually undergo remodeling. This requires the frequent upregulation of genes involved in cell cycling and protein synthesis. Failure of correct mRNA polyadenylation or transport in these cells may have a cumulative toxic effect resulting in the progressive degeneration of these muscles. The mechanism of OPMD could be due to an interference with polyadenylation, disturbances in intracellular trafficking of mRNA, or toxicity due to the aggregation of misfolded and/or aggregated PABP2 species. Further research will be required to distinguish between these possibilities.

6.3 Synpolydactyly (Syndactyly Type II)

Synpolydactyly (SPD) is a rare, autosomal dominant developmental disorder characterized by fused and extra digits (syndactyly and polydactyly, respectively). It is caused by the expansion of a polyalanine tract in the amino-terminal region of the transcription factor HOX-D13. *HOX* genes act in concert to coordinate axial patterning in animals. Tracts of 7–14 alanines in HOX-D13 have been linked to SPD, and disease severity is proportional to repeat length. Multiple studies support a ''dominant-negative'' role for expanded HOX-D13 protein in SPD. Mice null for Hox-d13 have a phenotype less severe than SPD, while mice with alanine tract expansions have a form that more closely resembles the disorder. Mice lacking Hox11, Hox12, and Hox13 have a phenotype similar to SPD, suggesting that the alanine expansion in SPD antagonizes the function of other *HOX* genes. This is supported by a genetic complementation study. In further support of this theory, humans with suspected loss-of-function mutations in the *HOX-D13* gene do not have a phenotype consistent with SPD.

6.4 Cleidocranial Dysplasia

Cleidocranial dysplasia (CCD) is a rare, autosomal dominant developmental disorder characterized by holes in the skull, dental malformations, absent or hypoplastic clavicles and maxillae, and other skeletal malformations. The primary cause of CCD is thought to be loss-of-function mutations in the gene *RUNX2*. This gene affects osteoblast differentiation and is a member of the Runt family of transcription factors. In one family, phenotypically distinct from classic CCD, an expansion from 17 to 27 alanines in RUNX2 has been detected. This family exhibited brachydactyly and a mild CCD phenotype. The difference in phenotype between the polyalanine expansion mutation family and typical presumed haploinsufficient, loss-of-function CCD patients supports a gain-of-function effect of the expanded alanine tract in this atypical family. Contraction of the tract in RUNX2 is common and does not cause a detectable phenotype.

6.5 Holoprosencephaly

Holoprosencephaly (HPE) is a common developmental malformation resulting in partial or full cyclopia, failure to develop midline structures in the ventral forebrain, and prenatal lethality. In rare cases, HPE is caused by the heterozygous expansion of a 15-amino acid alanine tract in the protein ZIC2. This protein is one member of a family of zinc finger proteins believed to regulate neurulation,

left–right axis formation and other developmental processes. Other individuals with heterozygous loss-of-function mutations have a phenotype indistinguishable from those with alanine tract expansions. Partial loss of function of Zic2 in mice similarly causes developmental abnormalities similar to HPE. Therefore, expansion of the alanine tract likely causes loss of function of ZIC2 in the case of HPE.

6.6 Hand-foot-genital Syndrome

Hand-foot-genital syndrome (HFGS) is a rare, dominantly inherited developmental abnormality characterized by malformation of the distal limbs and lower urogenital tract. Short thumbs, short great toes, and abnormal carpals and tarsals are some of its salient features. Some HFGS patients have alanine tract expansions in the protein HOX-A13, which is in the same family as the SPD-associated protein HOX-D13. HOX-A13 contains three alanine tracts, the most C-terminal of which is the most commonly mutated. Expansions enlarge the second or third tract by 6 to 9 alanines. In humans, deletion of HOX-A13 causes a phenotype that is mild in comparison to HFGS caused by alanine tract mutations. Hoxa13-null mice also have a milder phenotype than mice carrying a frameshift deletion suspected to confer gain of function. This evidence suggests a dominant-negative mechanism for HFGS caused by alanine tract expansions.

6.7 Blepharophimosis-ptosis-epicanthus Inversus Syndrome

Blepharophimosis-ptosis-epicanthus inversus syndrome (BPES) is a rare, autosomal dominant developmental disorder resulting in malformation of the upper eyelids and forehead, and occasionally premature ovarian failure in women. It is caused by a number of different mutations in the gene *Forkhead L2* (*Foxl2*), the most common of which is expansion of its carboxy-terminal 14-amino acid alanine tract. FOXL2 is a highly conserved transcription factor whose role in the ovary has been studied most thoroughly. It is expressed in the ovaries and eyelids during development and adulthood. Studies in which Foxl2 have been ablated in mice show that it is important for the differentiation of ovarian granulosa cells, and its absence causes accelerated follicle cell depletion leading to POF. Knockout mice also display craniofacial abnormalities consistent with BPES, suggesting that a dominant-negative mechanism may be responsible in humans.

6.8 Syndromic and Nonsyndromic X-linked Mental Retardation

Several loosely related disorders are associated with alanine tract expansions in the Aristaless related homeobox (ARX) protein on chromosome Xp22.13. One is nonsyndromic X-linked mental retardation (XLMR), a heterogeneous condition in which mental retardation is the main consistent feature. Several syndromic XLMR disorders linked to alanine expansion in ARX include West syndrome (WS) and Partington syndrome (PRTS). WS causes progressive mental retardation with abnormal EEG and infantile seizures, while PRTS causes mental retardation, dysarthria, and dystonic movements of the hands. Brain anatomy appears normal in these disorders.

ARX is a paired-class homeodomain protein that is expressed in the ventricular

and marginal zones of the developing mouse brain and continues to be expressed in adult cortex. It is suspected to play a role in neuroepithelial cell differentiation and maintenance of neuronal subtypes in the adult cortex. ARX-null mice have small brains and neuronal migration deficits. Expansions of two different alanine tracts in ARX cause XLMR: a 12-alanine tract at amino acids 144–155, and a second tract at amino acids 100–115. Both sites cause highly variable forms of XLMR, with expansions in the former alanine tract resulting in nonsyndromic XLMR, WS or PRTS. Alanine tract expansions in ARX probably result in partial loss of function of the protein. Heterozygous female carriers of expanded ARX do not exhibit XLMR, suggesting that one normal copy of the protein is sufficient for normal cognitive ability. Also, humans with null mutations of ARX suffer from X-linked lissencephaly with abnormal genitalia (XLAG), a much more severe condition causing major developmental abnormalities in the brain and genitalia. Thus, XLMR due to alanine expansions in ARX may be because of partial loss of function leading to subtle developmental defects and/or failure to maintain specific neuronal populations.

6.9
Congenital Central Hypoventilation Syndrome

Congenital central hypoventilation syndrome (CCHS) is a rare, autosomal dominant disorder causing a failure of autonomic control of breathing. It attenuates or abolishes responses to hypercarbia and hypoxemia. In the majority of cases, it is caused by the expansion of one of two alanine tracts in the protein PHOX-2B. Mutations expand the 20-residue tract to 25–29 alanines. PHOX-2B is a paired-class transcription factor containing a homeodomain. A loss-of-function mutation in murine Phox2b is homozygous lethal, and specifically prevents the development of parasympathetic ganglia. Heterozygous mice show chronic pupil dilation but no parasympathetic or respiratory disturbances. Also, a patient hemizygous for a 5-Mb deletion including Phox2b does not have CCHS. No cases of CCHS have been reported in which PHOX2B is truncated before the homeobox domain. This evidence suggests that the expansion of alanine tracts in PHOX2B may cause a subtle, dominant-negative effect on the development of respiratory control pathways.

7
Unclassified Repeat Diseases Lacking Mechanistic Explanations

7.1
Spinocerebellar Ataxia Type 10

Spinocerebellar ataxia type 10 (SCA10) is an autosomal dominant, progressive ataxia that exhibits nearly pure cerebellar signs. It appears restricted to individuals of Mexican ethnicity. SCA10 patients typically present with gait ataxia, followed by dysarthria, dysphagia, and ocular dysmetria, and most patients also experience recurrent motor seizures. Cerebellar atrophy is the most prominent neuropathological change. SCA10 is caused by the expansion of a highly polymorphic pentanucleotide repeat, (ATTCT)*n*, on chromosome 22. Unaffected individuals carry 10–22 repeats. While expanded alleles have not been successfully PCR amplified, transcript sizes on Northern blots and fragment sizes on Southern blots indicate that disease alleles can range from ~800 to 4500 repeats. Anticipation occurs in SCA10, independently

supporting the causal nature of the repeat expansion. The ATTCT repeat is located in intron 9 of the *SCA10* gene, a previously unrecognized 66-kb gene that encodes a novel putative 475 amino acid protein of unknown function with few recognizable motifs or domains. The 2-kb SCA10 transcript is ubiquitously expressed though the highest levels of expression occur in the brain, testis, and adrenal glands. Within the brain, it is most highly expressed in the cerebellum and associated structures. The carboxy-terminal portion of the protein appears to contain "armadillo repeats," which are responsible for the membrane association of β-catenins. Ataxin-10 does not seem to associate with membranes, however. The entire protein is highly conserved between humans and rodents, and potential orthologs exist in Arabidopsis and Drosophila.

There are several proposed mechanisms for SCA10 pathogenesis. The most obvious hypothesis is that the large intronic expansion affects ataxin-10 expression, perhaps by altering local chromatin structure. siRNA knockdown of ataxin-10 in cell culture experiments yields higher rates of cell death in cerebellar neurons than in cortical neurons. However, the expression levels of the SCA10 transcript are not reduced in patient's lymphoblast cells, arguing against simple haploinsufficiency. Consequently, RNA gain-of-function toxicity has been proposed as the potential mechanism; however, there are no further data at this time to support such a hypothesis. Additional work will need to be done to distinguish between these and other possibilities, and will need to account for the cell-type specific pattern of neurodegeneration that occurs in the face of apparently widespread expression of the *SCA10* gene mutation.

7.2 Spinocerebellar Ataxia Type 12

Among the more recent additions to the unstable repeat disease group is spinocerebellar ataxia type 12 (SCA12), a rare, autosomal dominant disorder that may be most prevalent in Indian populations. Its symptoms are distinct from the other SCAs, typically beginning with an action tremor of the upper extremities and progressing to include hyperreflexia, mild cerebellar dysfunction, bradykinesia, increased muscle tone, psychiatric symptoms, and dementia. The brains of SCA12 patients likely undergo a slow, generalized atrophy that is most prominent in the cortex, but also results in loss of Purkinje cells in the cerebellum. Disease onset typically occurs in the third or fourth decade, and a gradually progressive disease course is typical.

SCA12 is caused by a (CAG)*n* expansion in chromosome 5q31 – q33. The expansion is 5′ to the *PPP2R2B* gene, encoding a regulatory subunit of the protein phosphatase 2A enzyme (PP2A). This gene has many transcription start sites, some of which include the repeat (but many of which do not). GENSCAN predicts an exon including the expansion that would encode a polyserine tract, but this prediction is of low probability and considered unlikely. Other evidence suggests that the expansion is located in the promoter region, and this is currently the most widely accepted view. Unaffected individuals carry 7–32 CAG repeats while affected individuals carry 55–78 CAG triplets. The most common repeat size in unaffected individuals is 10 CAGs. The repeat is fairly stable, with only modest expansions and contractions resulting equally from maternal and paternal transmission. A significant correlation between repeat length and age of onset has not been documented.

The protein PP2A is an essential serine/threonine phosphatase expressed in all known eukaryotic cells. It is involved in diverse cellular functions, including cell growth, differentiation, DNA replication, neurotransmitter release, and apoptosis. PPP2R2B is a brain-specific regulatory subunit of PP2A. The class of regulatory subunits including PPP2R2B may affect PP2A's phosphatase activity for certain substrates, including histone-1, vimentin, and tau. It may also affect PP2A's subcellular localization.

There are several possible explanations for SCA12 pathogenesis. The first is that expanded PPP2R2B may generate a polyamino acid tract-containing protein, resulting in toxicity. Northern blots probing for sequence flanking the CAG repeat did not detect a PPP2R2B transcript, indicating that if a repeat-containing exon exists and is transcribed, it is not present at appreciable levels. Nevertheless, the possibility of polyglutamine, polyserine, or polyalanine toxicity, though unlikely, cannot be completely ruled out at this time. A second possible cause of SCA12 pathogenesis is RNA gain of function, as occurs in DM and FXTAS. The repeat expansions are smaller in SCA12 than in DM, however, and more importantly, CAG tract-containing transcripts appear to be rather scarce. A third possibility is altered splicing of the PPP2R2B transcript. Several different amino-termini are possible, the ratio of which may affect PP2A's subcellular localization. Yet another theory of SCA12 pathogenesis is that the expansion affects PPP2R2B transcript levels. Repeat expansion causes a substantial increase in PPP2R2B expression as measured in reporter assays using a neuroblastoma cell line. Altered levels of the protein could affect PP2A's specificity or subcellular localization. This has the potential to disturb a multitude of processes in the CNS. At this time, all of the above theories of SCA12 CAG repeat expansion neurotoxicity remain plausible.

7.3 Huntington's Disease Like 2 (HDL2)

Perhaps the most exciting and enigmatic recent discovery in the repeat expansion field is that of the mutational basis of a disorder known as Huntington's disease like 2 or HDL2. HDL2 is so named because it is in essence a genocopy of classical HD, as the original HDL2 pedigree was labeled with a diagnosis of HD until HD CAG repeat testing indicated that this family's HD-like disease did not result from a CAG repeat expansion in the *htt* gene. HDL2 patients present with weight loss and diminished coordination, and then develop tremors, dysarthria, hyperreflexia, and rigidity. Patients display psychiatric involvement, chorea, and dystonia, and ultimately become demented. Death occurs 15–25 years after onset, when patients become bedridden as in typical HD cases. MRI findings reveal marked atrophy of the caudate and of the cerebral cortex, making the neuropathology indistinguishable from classic HD. HDL2 patients do not show cerebellar signs or neuropathology.

As soon as it was found that HDL2 patients do not have the HD CAG repeat expansion, direct cloning methods for triplet repeat expansions of the CAG/CTG type were applied to patient samples and an expanded CAG/CTG repeat ($n = 55$) was isolated. Sequence flanking this repeat indicated that HDL2 is caused by CTG repeat expansions in the *junctophilin-3* (*JPH3*) gene, one of a family of structural proteins whose function is to link

Ca++ channels on the ER with voltage sensors on the plasma membrane. Analysis of JPH3 CTG repeat indicates that normal individuals typically carry 7–27 CTG repeats while affected HDL2 patients usually have expansions of 50–60 CTG repeats. Widespread screening of HD-like patients from around the globe suggests that the HDL2 JPH3 CTG repeat expansions are most common in individuals of African ethnicity.

The question of how the JPH3 CTG repeat expansion causes HDL2 remains unknown, but there are at least four possible explanations. These alternative (but not mutually exclusive) theories stem from the documented alternative processing of the *JPH3* gene, which permits the prediction of the CTG repeat tract as: (1) part of intron 1; (2) as part of the 3′ untranslated region; or (3) as encoding either a polyleucine or polyalanine tract. One theory is that haploinsufficiency of the Ca++ regulating brain- and testes-specific junctophilin-3 protein is responsible for HDL2. While JPH3 knockout mice display motor incoordination, no histological abnormalities are found in their brains. Further work with these mice is ongoing to evaluate this hypothesis. Evidence against simple haploinsufficiency has come from study of HDL2 patient's brain material, however. 1C2 and ubiquitin antibody immunostaining reveal intranuclear inclusions in neurons throughout the brains of these patients, with dramatic similarity in distribution to patients with classic HD (Fig. 14). At this time, the molecular basis of HDL2 is unknown; however, the incredible overlap between HD and HDL2 in terms of clinical phenotype and neuropathology strongly suggests that solving HDL2 should have profound implications for our mechanistic understanding of HD.

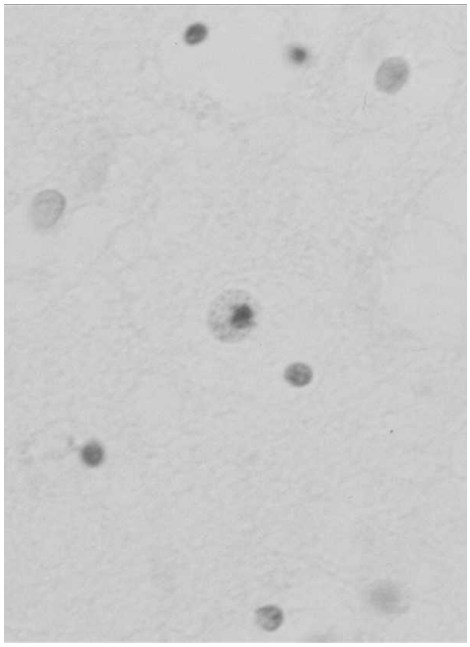

Fig. 14 HDL2 patients have 1C2-positive intranuclear inclusions. 1C2 staining of cerebral cortex (frontal lobe) from an HDL2 patient reveals a prominent intranuclear inclusion that resembles the intranuclear inclusions seen in classic HD patients. As the 1C2 antibody is directed against expanded, misfolded polyglutamine tracts, which are not predicted to be expressed from the causal *HDL2* gene, the explanation for the presence of such nuclear inclusions in HDL2 patients remains unknown. (From Margolis, R.L., O'Hearn, E., Rosenblatt, A., Willour, V., Holmes, S.E., Franz, M.L., Callahan, C., Hwang, H.S., Troncoso, J.C., Ross, C.A. Keywords

Confocal Microscopy (CM)
Microscopy technique where optical sectioning is achieved by using a detector pinhole that is confocal to the excitation focus to reject the out-of-focus signal.

Fluorescence
Light-emitting process of special molecules, called *fluorophores*, after excitation with photons of higher energy.

Laser-scanning Microscopy
Microscopy technique, in which the light source is focused to a diffraction-limited spot and the image is formed by scanning this spot across the sample while sequentially recording the signal generated at each position.

Multiphoton Absorption (MPA)
Process where two or more photons are absorbed simultaneously to excite a transition with an energy equal to the sum of the energy of the photons.

Multiphoton Microscopy (MPM)
Microscopy technique where the contrast mechanism is based on a multiphoton absorption process. Usually, but not always, the detected signal is fluorescence.

Two-photon Microscopy (2PM)
Most widely used variant of multiphoton microscopy.

Whole-field Detection
Detection scheme for laser-scanning microscopy where the light from the whole field of view is detected.

Wide-field Imaging
Imaging technique where the whole field of view is illuminated simultaneously and imaged onto a spatially resolving detector, for example, a charge-coupled device (CCD) camera.

Multiphoton microscopy (MPM) is an imaging technique that employs signals, such as fluorescence, generated by a multiphoton absorption (MPA) process as its contrast mechanism. Compared to other fluorescence microscopy techniques, MPM often has a higher sensitivity, superior penetration into scattering tissue, and causes less photodamage to the sample and less photobleaching of the fluorophore. These advantages make MPM the method of choice for optophysiological experiments and also make MPM the only technique available for high-resolution *in vivo* imaging deep within scattering tissue, such as the brain. The two-photon microscope (2PM) is the kind of MPM used in the overwhelming majority of applications since it has virtually all of the specific advantages of MPM. Recent advances in staining techniques including the booming development of genetically encoded fluorophores keep increasing the field of actual and possible MPM applications.

1 Introduction

Over the past 15 years, multiphoton microscopy (MPM) has developed into an indispensable imaging tool in the life sciences. MPM has higher sensitivity, superior penetration into scattering tissue, and often causes less photodamage in samples than alternative imaging techniques such as confocal microscopy (CM). This means that MPM – combined, in particular, with one of many new genetically encoded and functional dyes – has become the method of choice for *in vivo* imaging in strongly scattering tissues such as skin, muscle, and tumors, and even deep within intact organs such as kidney, pancreas, lymph nodes, and brain.

This article provides an overview of functional principles, instrumentation, and some of the applications of MPM. Further details can be found in the books and reviews and primary literature listed at the end of this article.

In laser-scanning microscopy, a three-dimensional image is generated by scanning the position of a tight laser focus around in the sample while recording, as a function of the focus position, a signal – such as fluorescence – that is generated by absorption of light from the beam.

Molecules that can easily absorb light generally have a structure where several atoms of the molecule are connected by conjugated single–double bonds. As a consequence, the most weakly bound electrons are delocalized and thus interact easily with the electromagnetic field. Near-ultraviolet or visible light is usually sufficient to promote the outermost electron to an excited level (Fig. 1). In general, the molecule is excited electronically and vibrationally, with the latter excitation decaying very fast ($\sim 10^{-12}$ s). From the state reached after vibrational relaxation, which is still electronically excited, the molecule then relaxes within nanoseconds (10^{-9} s) to a state that is only vibrationally excited. The energy difference can be carried away by fluorescence emission of a photon.

The difference between one photon (1P)-excited and multiphoton (MP)-excited fluorescence microscopy is that molecular absorption is of a single photon in the first case and a photon multiplet in the second (Fig. 1). In a 1P process, the photon energy equals the energy difference between the ground state and an excited state. Light

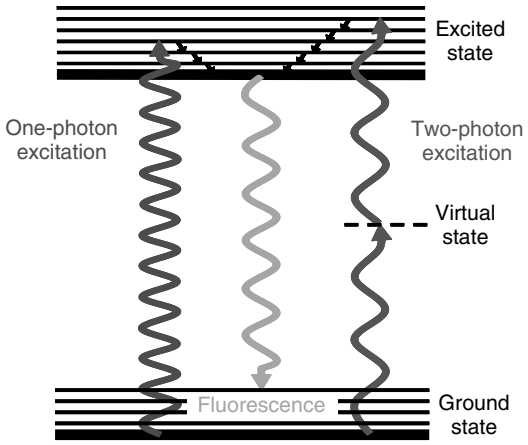

Fig. 1 Principle of one-photon and two-photon excited fluorescence. In 1PE fluorescence, a molecule is brought to the excited state by absorbing a single (blue) photon. Vibrational relaxation brings the molecule to the lowest excited state, from which it returns to the ground state by emitting a longer-wavelength (green) photon. In 2PE fluorescence, the molecule is brought to the excited state by simultaneously absorbing two NIR (red) photons. The molecule again vibrationally relaxes, and emits a fluorescence photon from the same level as in 1PE fluorescence (see color plate p. xxv).

with a quantum energy less than the gap between the ground state and the lowest lying electronically excited state cannot excite the molecule by a 1P process, but if the light intensity is sufficiently high, multiple photons of lower energy can cooperate and combine their energies to promote the molecule into the excited state. For example, two 800 nm photons can excite a transition that normally requires 400 nm light. One may picture this process as the first photon exciting the molecule to a virtual state from where the second photon then brings the molecule into its (real) excited state. For this process to occur, the two photons have to arrive at the fluorophore within the lifetime of the virtual state, which is less than 1 fs ($1\ \text{fs} = 10^{-15}$ s) as defined by the Heisenberg uncertainty principle ($\tau \leq \hbar/E$). The likelihood that two photons arrive at a fluorophore almost simultaneously is proportional to the intensity squared and is all but negligible for light sources other than a focused laser. Therefore, two-photon absorption (2PA) was observed only after the invention of the laser. It is the strongly superlinear dependence on the light intensity that gives 2PM (and MPM in general) its main advantages.

1.1 Optical Sectioning

In 1P microscopy, the signal generated is proportional to the light intensity (the power divided by the beam area: $I = P/A$). As a result, the signal generated in each slice of a sample depends on the slice thickness, but not the distance from the focus, since variations in the beam area are, as long as the power stays constant, exactly balanced by inverse variations in the excitation rate per molecule. When imaging thick samples, the light from the focus is thus always contaminated, in fact, dominated by fluorescence generated above and below the focus. This is the bane of wide-field fluorescence imaging of 3-dimensional (3D) samples. In CM, this problem is solved by placing a pinhole in front of the detector. The pinhole is confocal with the excitation focus and rejects light that did not originate from that focus (Fig. 2). This property of the confocal microscope, called *optical sectioning*, vastly improves the ability to obtain 3-D fluorescence images, particularly of thick biological samples.

The first nonlinear optical microscope used the second-harmonic signal and

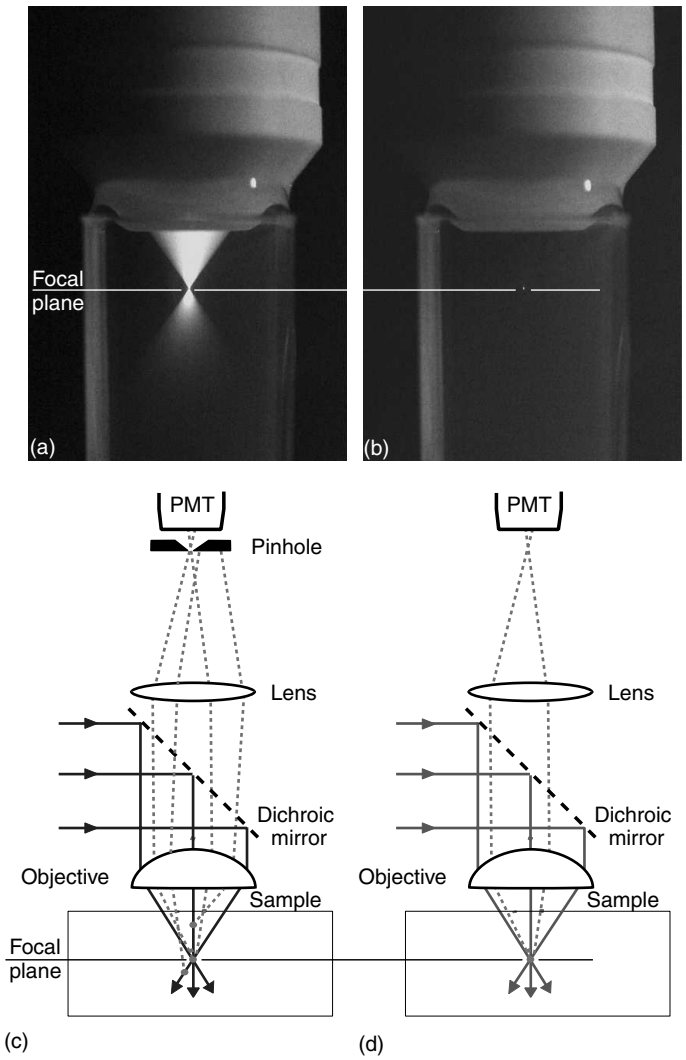

Fig. 2 Optical sectioning in one-photon confocal and in two-photon microscopy. (a) With 1PE, fluorescence is generated throughout the illumination cone. For 2PE (b), because of the nonlinear intensity dependence, fluorescence generation is limited to a small volume around the focus. In CM, optical sectioning is achieved by placing a confocal pinhole in front of the detector. This pinhole rejects (out-of-focus) fluorescence that is generated above and below the focus (c), fluorescence generated by scattered excitation light (e), and in-focus fluorescence that is scattered on its way to the detector (e). Because no out-of-focus fluorescence is generated in a two-photon microscope, no pinhole is necessary (d) and even fluorescence that is scattered on its way to the surface can be detected (f).

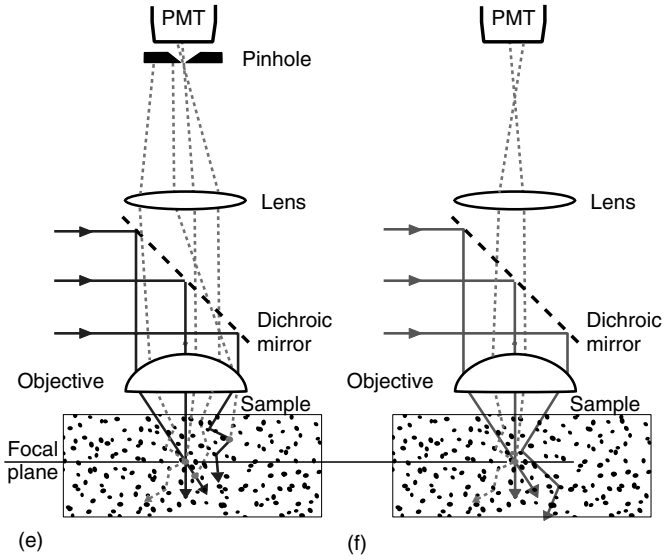

Fig. 2 (*Continued*)

wide-field imaging. Scanning the focus, which was introduced later, strongly enhances the focal but not the out-of-focus signal, and thus provides optical sectioning. The hopes placed on harmonic imaging for biological specimens were, however, not fulfilled, at least initially.

Two photon–excited fluorescence microscopy proved to be much more immediately applicable to biological problems, due, first, to the central importance of fluorescent labeling in biological microscopy (see Sect. 4) and second, to the differences in the physical characters of fluorescence and harmonic generation. The main difference being that harmonic generation is a coherent process, where field strengths rather than intensities add, and the generated signal depends on the square of the chromophore concentration, and is liable to interferences effects; in fluorescence, which is incoherent, light from different fluorophores does not interfere with each other and the signal increases linearly with the fluorophore concentration.

Common to scanned-focus nonlinear microscopies is that they provide excitation-based optical sectioning. This is because, different from the linear (1P) case, the total excitation in a slice intersecting the beam strongly drops with distance to the focus (Fig. 2). In fluorescence microscopy, excitation-based rather than confocal optical sectioning is particularly helpful since photodamage and photobleaching are enormously reduced (see below).

1.2 Increased Penetration Depth

MPM can generate high-resolution images from focal planes deep inside the tissue, much deeper than CM, because signal is generated only at the focus allowing scattered fluorescence to be collected without loss of resolution or optical sectioning. In CM, only light passing through the confocal pinhole is detected. However, due to scattering, the fraction of the signal

originating from the focus that does pass the pinhole in the CM decreases exponentially with imaging depth. Compensating for the loss in signal by increasing the excitation power in CM in most cases would lead to an unacceptable increase in photodamage (see below). A further reason for the deeper penetration of MPM is that, for the same fluorescent label it uses excitation light with a wavelength that is longer (up to two times for 2PM) and hence scattered much less. Occasionally helpful is the larger separation between the excitation and emission wavelengths in MP excited fluorescence, which allows a more spectrally complete detection of the fluorescence.

1.3 Reduced Photodamage and Photobleaching

Protracted and high-resolution CM imaging is often limited by excitation light-induced damage to the sample (photodamage) or the fluorophore (photobleaching), which in 1PM occur throughout the sample even though information is only gained from the focal slice. In MPM, damage is confined to those fluorophores (and their immediate vicinity) that do provide information. A reduced relative MP absorbance of intrinsic fluorophores may further contribute to the vastly improved tissue viability sometimes seen even in tissue that scatters only little.

2 The Multiphoton Microscope

The layout (Fig. 3) of a generic MPM is very similar to that of a laser-scanning CM, from which an MPM can often be constructed by modification. In this section, the components of an MPM will be discussed individually.

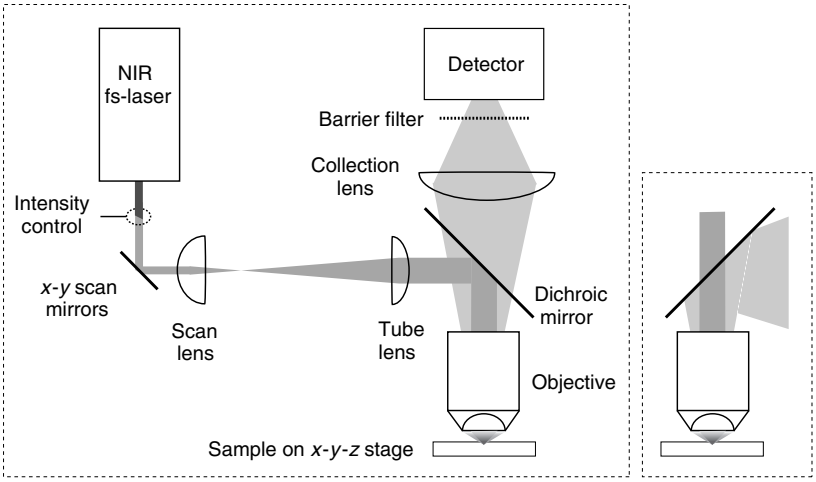

Fig. 3 Setup of a generic two-photon microscope. Light from an ultrafast laser or laser amplifier is focused to a diffraction-limited spot by an objective. The beam is raster-scanned across the sample and the fluorescence generated at each position is collected by the objective, separated from the excitation light by a dichroic mirror and additional filters either in a transmission or reflectance configuration (see inset), and detected by a whole-field detector.

2.1 Light Sources

The development of reliable ultrafast laser sources operating in the near infrared (NIR) coincided with the invention of MPM and has been an important factor in the broad adoption of MPM, since with continuous wave (cw) lasers, even 2PM is only marginally possible for brightly labeled samples. Today the vast majority of MPMs use mode-locked titanium sapphire lasers (Ti:sapphire, Ti:Al_2O_3), which can be tuned from about 680 to 1100 nm, allowing 2PE of almost all relevant labels, and 3PE into the deeper UV. The pulse length of this laser type is around ~100 fs with a repetition rate of around 100 MHz, i.e. every 10 ns a short burst of light arrives at the sample while for the remainder of this period no light is incident upon the sample. Alternative laser sources that produce similar pulse lengths are based on Cr:LiSrAlFl, Cr:Forsterite, or Nd:YLiF crystals, or on Yb-doped optical fibers, all of which have much smaller tuning ranges, but with the exception of the Cr:LiSrAlFl laser, operate at longer wavelengths than can be easily provided by the Ti:Sapphire laser. A very large tuning range but less total power is provided by optical parametric amplifiers.

An ultrafast laser increases the signal levels in the 2PM by 5 orders of magnitude as compared to a cw-laser of the same average power. This is because the average rate at which fluorescence photons are generated by 2PA is proportional to the average square of the instantaneous light intensity I:

$$\begin{aligned}\langle n_F(\mathbf{r})\rangle &\propto \delta C\langle I(\mathbf{r},t)^2\rangle \\ &= \delta C\langle I(\mathbf{r},t)\rangle^2\frac{\langle I(\mathbf{r},t)^2\rangle}{\langle I(\mathbf{r},t)\rangle^2},\end{aligned} \tag{1}$$

where $\langle\,\rangle$ indicates an average over time, δ is the two-photon absorption cross section (often expressed in units of Göppert-Mayer (GM); 1 GM = 10^{-50} cm^4s/photon), and C is the fluorophore concentration. For a spot with area A, power and intensity are related by:

$$I(\mathbf{r},t) = \frac{P(\mathbf{r})}{A}. \tag{2}$$

For a square pulse with pulse length τ, the ''two-photon advantage'' is

$$\frac{\langle I(\mathbf{r},t)^2\rangle}{\langle I(\mathbf{r},t)\rangle^2} = \frac{\frac{1}{T}\int_0^T I(\mathbf{r},t)^2\mathrm{d}t}{\left(\frac{1}{T}\int_0^T I(\mathbf{r},t)\mathrm{d}t\right)^2} = \frac{1}{f\tau}. \tag{3}$$

Equation 1 then becomes:

$$\langle n_F(\mathbf{r})\rangle \propto \delta C\frac{P(\mathbf{r})^2}{A^2}\frac{1}{f\tau}. \tag{4}$$

Thus, for example, to obtain the same signal with 1 ps pulses rather than with 100 fs pulses, the average power must be higher by a factor of $\sqrt{10}$.

Implicit in this derivation is the assumption that the 2P absorption cross section δ is constant across the spectrum of the laser pulse. For very short pulses this is not true because – due to the uncertainty principle – the shorter the pulse duration ($\Delta\tau$), the broader its spectral width ($\Delta\nu$). For a transform-limited (unchirped) Gaussian-shaped pulse $\Delta\tau\Delta\nu = 0.44$. A 100-fs laser pulse centered around 800 nm then ranges (full width at half maximum; FWHM) over 10 nm in wavelength and a 20-fs pulse over 50 nm, which is already as wide as the main features in a typical fluorophore absorption spectrum. However, in practice the main limitation for using shorter pulses is group delay dispersion (GDD), which occurs because

different wavelength components of the laser pulse travel at different speeds inside all materials, including of course, optical glass. After passing the microscope optics, the long-wavelength (''red'') components of the pulse arrive at the focus ahead of the short-wavelength (''blue'') components, leading to a so-called *chirped* pulse. Because the wider spectrum of a shorter pulse accentuates this effect, an initially shorter pulse can actually become longer once it reaches the focus than an initially longer pulse. Owing to the GDD in a typical microscope, a 20-fs pulse, for example, is stretched to about 700 fs, while a 100-fs pulse is stretched to only 200 fs. Without compensation (prechirping, see below), the shortest pulses that can be attained at the sample are about 150 fs. Therefore, lasers producing 100 to 200 fs pulses are typically used in 2PM. It is possible (but rarely necessary) to compensate for the microscope's GDD by the use of an optical arrangement (consisting of prisms, gratings, or special dielectric coatings) that has negative GDD. Negative GDD prechirps the pulse, giving the blue components a head start over the red components. This head start compensates all or part of the speed disadvantage that the blue components have when traveling through the microscope optics. Prechirping allows the arrival of transform-limited pulses as short as 15 fs at the focus. For such short pulses, compensation of higher-order dispersion and chromatic aberrations needs to be considered as well. For higher than 2PA, the effects of using shorter pulses are even more dramatic (the 3PA rate, for example, increases by 10 orders of magnitude compared with cw-excitation when using the typical Ti:sapphire laser).

2.2 Excitation Pathway

The pathway for the excitation light in a MPM is essentially that of a laser-scanning CM: shutter, beam conditioning and intensity control, scan mirrors, scan lens, tube lens, objective, and, finally, the sample (see Fig. 3). As in every laser-scanning microscope, the scan mirrors (or a point in between for proximity coupled scanners) is conjugate to (i.e. imaged into) the objective exit pupil. Coatings on lenses and mirrors need, of course, to be IR transmissive or reflective, respectively. The intensity control needs to be compatible with ultrashort pulses and should allow the automatic compensation of depth dependent losses (see Sect. 3.3) and should be fast enough to shut off the beam during retrace, i.e. while the focus is moved from the end of a scan line to the beginning of the next.

2.3 Final Focusing and Resolution

Many standard microscope objectives can be used for MPM, albeit with compromises in correction and transmissivity. While this was an issue in the early times of MPM, most objectives now are either corrected and transparent throughout the IR or come as special ''IR'' versions. To minimize tissue damage (see below), detection efficiency has to be maximized by keeping the transmission at the fluorescence wavelength(s) as high as possible. Optical correction at the fluorescence wavelength is not necessary. The numerical aperture (NA) of the objective determines the resolution (laterally $\Delta\rho \propto 1/NA$, axially $\Delta z \propto 1/(NA)^2$) and the peak intensity ($\propto (NA)^2$), and thus the peak excitation rate per fluorophore ($\propto (NA)^4$), but (and

this is a special property of 2PA, that neither 1P nor higher-order multiphoton absorption, MPA possess) when the concentration of fluorophores is uniform, the *total* amount of fluorescence generated throughout the focal volume $V = \Delta\rho^2\Delta z$ is independent of the NA:

$$\langle n_F\rangle_{tot} \propto \delta C P^2 \frac{NA^4}{f\tau}\Delta\rho^2\Delta z \propto \delta C P^2 \frac{1}{f\tau}. \tag{5}$$

A more extensive treatment that takes into account the exact spatial and temporal intensity distribution of the light in the sample yields:

$$\langle n_F\rangle_{tot} = \frac{4\eta g n\lambda}{\pi h^2 c^2}\delta C P^2 \frac{1}{f\tau}, \tag{6}$$

where η is the quantum-efficiency of the fluorophore (i.e. the percentage of excited molecules that emit their excess energy in the form of a photon), $g = f\tau\langle I(\mathbf{r},t)^2\rangle/\langle I(\mathbf{r},t)\rangle^2$ and depends on the exact temporal intensity distribution of the pulse. For the square pulse used in equation (3), $g = 1$. For more realistic shapes such as a Gaussian or a hyperbolic secant intensity distribution, $g = 0.66$ and 0.59, respectively; n, λ, h, and c are the index of refraction, wavelength of the excitation light, Planck's constant, and the vacuum speed of light, respectively.

While scattering *per se* need not reduce the resolution even if only a minor part of the beam energy reaches the focus unscattered (ballistically), eventually the stronger attenuation of the lateral rays due to their longer path length inside the tissue does lead to a reduction in the effective NA, and thus a larger focus size. Further, practical, considerations in selecting an objective are the detection efficiency (see below), working distance, which tends to decrease with increasing NA, and the immersion medium, which will usually be water or a physiological salt solution. Refractive-index mismatch between immersion medium and sample that was not taken into account during the lens design results in a loss of resolution and signal strength.

2.4 Detection

To preserve the main strength of MPM, i.e. the reduction of photodamage, the detection efficiency must not be compromised. This is because molecular excitation inevitably causes photodamage to the sample (see Sect. 3.4) and thus the number of molecular excitations necessary to generate a sufficient number of detected photons need to be minimized. In nonscattering samples, the main determining factor for detection efficiency is the solid angle of collection (assuming, of course, the avoidance of absorption and reflection losses as much as possible). Thus, a high NA objective is crucial if epi detection (through the objective lens, the usual configuration) is used. Better still is a combination of epi detection (where, for working distance reasons, a compromise with respect to the NA may be necessary) with transdetection through a high NA condenser. The separation of the fluorescence from the excitation light by a dichroic mirror is standard practice in fluorescence microscopy, as is the further separation into multiple spectral channels. Suppression of the excitation light often is easier in MPM because the wavelength separation is larger and the sensitivity of some detectors declines sharply toward longer wavelengths. In contrast to a laser-scanning CM, there is no need in the MPM to "de-scan" the fluorescence in order to thread it through the confocal pinhole. In fact, the detection optics in

a MPM can be rather crude but need to accept large opening angles and have a large field of view for deep imaging in scattering samples.

Deep imaging in scattering samples is where no other known fluorescence microscopy technique can compete with MPM because MPM can image deep in scattering samples virtually without loss of resolution and sensitivity as long as the detection pathway collects a large fraction of the diffuse fluorescence light emerging from the sample. Unlike in other techniques, the diffuse fluorescence contains high-resolution information about the focus because the excitation is highly localized to a volume of less than one femtoliter. The improvement possible by using whole-field detection has been directly demonstrated by switching quickly between whole-field and descanned detection. The main drawback of whole-field detection is its incompatibility with detectors that only accept a small phase space volume (the product of angular and area acceptances). This precludes the use of photon-counting avalanche photodiodes (APDs), which are the highest quantum-efficiency photon detectors available, and of spectrometer detectors. Fortunately, the characteristics of photo multiplier tubes (PMTs), which have large sensitive areas and acceptance angles and are the standard detectors for CM, have also improved, closing the quantum-efficiency gap.

3 Limitations

In this section, the limitation of spatial and temporal resolution, penetration depth and photodamage will be discussed.

3.1 Temporal Resolution

The temporal resolution of optical techniques can be very high. In fact, some of the fastest measurements are based on pulsed lasers. When fluorescence is used, the excited-state lifetime (in the nanosecond range) is the ultimate limit. In practice, temporal resolution is often limited by the time required to obtain a sufficient signal-to-noise ratio. When a whole image is to be acquired, this time has to be multiplied with the number of pixels in a frame. Another limitation of all laser-scanning microscopes is that the focus has to be raster-scanned across the field of view. In most CMs and MPMs, this is achieved by mechanically scanning the beam using galvanometer mounted mirrors, which are limited in frequency response to the low kilohertz regime, setting the rate at which scan lines can be acquired to about 1 kHz or so, depending somewhat on the extent of the scan. A high-resolution (1000 lines) image thus takes at least one second. By sacrificing one spatial dimension and scanning a single line only, a time resolution of 1 ms is common, and when measuring only from one spot, a time resolution in the microsecond range can easily be achieved. On the other hand, to acquire a high-resolution volume image (a stack of optical sections) can take many minutes. When trying to measure dynamic physiological signals from many locations simultaneously, as it is desirable, for example, in neuroscience, image acquisition time is a serious limitation. Attempts have, therefore, been made to speed up the scanning process by either using resonant scanners, or rotating polygonal mirrors, or by scanning the beam nonmechanically using an acousto-optical deflector (AOD). Owing to the spread wavelength spectrum

of the excitation pulses, the AOD, which is based on diffraction by a sound wave, is plagued by angular dispersion, which can only be sufficiently compensated for a limited field of view. The main attraction of AOD scanning is the capability of random-access scanning: the focus can be moved between distant location within microseconds without illuminating (and potentially damaging) the sample area in between.

Acquisition speed is limited ultimately, as mentioned above, by the fluorescence decay time, which has to be shorter than the pixel dwell time. But the limited rate at which a fluorophore can produce photons, even if the excitation light is arbitrarily intense, usually enforces a longer pixel dwell time just to collect enough photons. Beyond those limits, an increase is only possible by scanning multiple points, arranged either in a 2D pattern or in a line. This approach is rather successful in CM, but it requires confocal or at least spatially resolved detection, since at each point in time, fluorescence can come from any of the foci. Thus, using it in MPM means giving up one of the main advantages of MPM, namely the ability to detect fluorescence irrespective of how it reaches the detector (see above) and accepting either image degradation or signal loss. Other drawbacks are anisotropic lateral and reduced axial resolution (for line illumination) and the increased laser-power requirement (for any multipoint method).

3.2 Spatial Resolution

In the generic configuration (with whole-field detection), there is no spatial selectivity in the detection and hence the resolution of MPM (i.e. the size of the point-spread function) is completely determined by the intensity distribution (in fact, the point-spread function equals the intensity squared) at the focus. Thus, the resolution depends on the wavelength of the excitation light and on the NA of the objective. With 700-nm light and an NA of 1.3, a resolution (FWHM) of ~200 nm in the lateral and 600 nm in the axial direction can be achieved.

Even though in CM the resolution is determined by the combined (multiplied) excitation and detection point-spread functions, the mathematical expression for the resolution of CM and 2PM are identical. This holds, however, only under the somewhat unrealistic assumption that the pinhole has zero diameter and the 1PE and 2PE wavelengths and the emission wavelength are all the same. Realistically, the pinhole has to be opened up to gain sufficient signal, the emission wavelength is longer (both reducing the resolution of CM) and the excitation wavelength is close to twice as long for 2P as for1P (reducing the resolution in 2PM).

As a result, compared with CM, the resolution in 2PM (and MPM, in general) is typically somewhat worse, but can be improved by reintroducing a confocal pinhole, albeit at the expense (particularly in scattering specimens) of detection efficiency. 2PM can also be combined with the 4Pi microscope, which greatly improves the resolution in the axial direction, and where using 2PE rather than 1PE considerably reduces side lobes in the point-spread function and thus fills in the holes in the modulation transfer function.

In general, at a given wavelength, resolution improvements beyond the Abbe limit require optical nonlinearity, which is exploited in the Stimulated Emission Depletion (STED) microscope. This microscope is based on the saturation of

excited-state depletion, which has potentially unlimited resolution, because this saturation contains arbitrarily high orders of nonlinearity. 2PE, by contrast, contains only a second order (quadratic) nonlinearity, and consequently, in 2PM the resolution improvement beyond the Abbe limit is moderate.

3.3 Penetration Depth

In scattering samples where absorption of the light is negligible, the intensity of the ballistic light, i.e. light that has not been scattered, decreases with depth in the sample as:

$$I_{\text{ball}} = I_0 \exp\left(-\frac{d}{l_s}\right), \qquad (7)$$

where l_s is the scattering length, i.e. the average distance a photon travels before it is scattered. For near-infrared wavelengths, l_s in brain tissue is around 200 μm. To estimate the imaging depth, one can assume that only the ballistic light that reaches the focus contributes to the generation of two-photon fluorescence, which seems to hold for up to at least several scattering mean-free-path lengths. Then the number of fluorescence photons generated when the focus is at a depth d below the surface can be written as:

$$\langle n_F \rangle_{\text{tot}} = \frac{1}{2}\eta\delta C P^2 \frac{g}{f\tau}\frac{8n\lambda}{\pi h^2 c^2} e^{(-2d/l_s)}. \qquad (8)$$

As long as the detection system is designed to capture most of the fluorescence, which consists almost entirely of scattered light, the maximum imaging depth depends only on the laser power that is available. With the power available from standard mode-locked Ti:sapphire lasers, imaging depths of 2 to 3 scattering lengths (400–600 μm) are achieved routinely.

To increase the imaging depth further, the efficiency in generating 2P fluorescence needs to be increased, which is possible by reducing the laser pulse–repetition rate while increasing the pulse energy. The use of a so-called *regenerative amplifier*, which generates pulses that are about 250 times as intense as those directly from the laser "oscillator" but are also by the same factor less frequent, resulting in an unchanged average power, permits imaging to about 1000 μm. A somewhat technical but important issue is that each pixel needs to contain at least one pulse, limiting the pixel rate to several hundred kilohertz (the repetition rate of the amplifier). At such pulse rates, the average 2PA rate is increased by a factor of about 250.

Now the imaging depth is, however, no longer limited by the available laser power but instead by the fluorescence background generated near the surface of the sample. The reason for this is that in order to keep the fluorescence generation at the focus constant, the amount of ballistic light that reaches the focus must also be kept the same, and thus the laser power that needs to enter the sample must increase exponentially (equation 7). At large depths, this exponential increase overcomes the quadratic decrease in light intensity, which results from the increased beam cross section with distance from the focus. Eventually, the intensity at the surface becomes comparable to the intensity at the focus and surface fluorescence starts to dominate. For samples with staining throughout the sample, this limit may well be impossible to overcome, thus defining the ultimate depth limit of 2PM (a similar logic applies to higher-order MPM). This limit increases somewhat with the NA, but that may not help much since at higher NAs, focus blurring due to wavefront aberrations becomes a more serious issue, and

may, in turn, require the use of adaptive optics as a remedy.

3.4 Photodamage and Photobleaching

Cell viability is obviously important for imaging living tissue. Excitation of intrinsic or introduced chromophores often leads to photochemical effects, such as destruction of the chromophore (bleaching) or damage and subsequent cell-death, which are mostly mediated by reactive oxygen species. This problem is exacerbated in laser-scanning CM because of the rather poor utilization of the generated fluorescence light and the appearance of superlinear photochemical effects at high intensities, probably due to excited-state absorption. Utilization of the generated fluorescence is generally much better in MPM, with the improvement increasing as the specimen becomes more scattering and the imaging depth increases.

However, in clear (i.e. nonscattering) specimens, where the detection efficiency in the CM for focal photons can be rather high, bleaching and photodamage in the 2PM can actually be exacerbated, but is also clearly reduced in some cases compared with CM. Strategies for avoiding or reducing damage depend on the underlying photophysics and photochemistry. If damage is due to single-photon absorption, increasing the 2PE efficiency by reducing pulse length or repetition rate is helpful. Damage is, however, rarely dominated by 1PA for typical tissue, but can become so in pigmented cells or if much longer wavelengths are used and water absorption becomes an issue. If higher-order instantaneous nonlinearities, such as 3P absorption or optical breakdown are the culprits, increasing the pulse length can help. Chemical nonlinearities such as locally overwhelming cellular repair mechanisms should be avoidable by faster scanning. Often, as mostly anecdotal evidence suggests, damage decreases with increasing wavelength, which may be due to reduced 2PA by endogenous chromophores. While photobleaching can be quantitatively measured, this is more difficult with damage to cells, since photostress may be present but may not be evident below a certain instantaneous or cumulative threshold. This is consistent with the observation in several studies that at low intensities (up to $10^{14} - 10^{15}\ \mathrm{W\,m^{-2}}$ which corresponds to 1–5 mW at the focus) no obvious damage occurs. As the intensity increases, severe damage, optical breakdown, and strong luminescence eventually do occur.

4 Fluorophores

4.1 Comparison of 1PA and 2PA

While the fluorescence process itself is largely independent of the mode of excitation (and hence the fluorescence emission spectra are the same for 1PE and 2PE), the absorption spectra of 1PE and 2PE are expected and found to be quite different in some cases. The reasons for this are: (1) To excite a molecule from its ground state to the excited state, quantum-mechanical selection rules have to be fulfilled in addition to energy conservation. For example, the angular momentum (usually only the photon spin is relevant since the absorption of a photon with nonzero orbital angular momentum is unlikely) that is carried by a photon must be taken up by the molecule upon absorption. The selection rules for

2PA are different from those for 1PA, since in the first case, two photons, each carrying a spin of $1\hbar$, are absorbed. This means that the angular momentum of the molecule has to be unchanged (if two photons of opposite spin are absorbed) or changed by $2\hbar$. A change by $1\hbar$ (also corresponding to a change in parity) is not allowed. However, for complex asymmetric molecules, these selection rules are not necessarily as strict, due to interaction with molecular vibrations and rotations. (2) Since the transition to the excited state occurs in a sense via all molecular states, which serve as a combined "virtual" intermediate state, excitation is possible even if there is no direct orbital overlap between ground and target state.

For the use of fluorescent dyes in MPM, it is very important to know their MP-absorption spectra in order to choose the best dye and then excite it optimally. While it is not easy to measure MP-absorption spectra, at least the 2P-absorption spectra of many commonly used chromophores are now available (http://www.drbio.cornell.edu/) and it turns out that all dyes used with 1PE can also be used with 2PE, albeit with a larger spread in their cross sections because, in a way, transition matrix elements enter twice in the 2PA process.

In some cases, the 2PA spectra plotted on a $\lambda/2$ scale are rather similar to the 1PA spectra plotted on a λ scale. In most cases, however, the excitation maxima are shifted to the blue and the spectra are broader. Additional spectral features at wavelengths longer than the "red" 1P absorption edge are not seen, nor would they be expected. The reason for this is that fluorescence emission only occurs for molecules where the transition to the lowest lying excited state 1P is allowed. There have been a number of attempts to predict 2P cross sections and to develop, on the basis of theoretical calculations, chromophores with large 2P cross sections.

In the following, we will give a short overview of chromophores that are widely used with 2PM, with particular focus on dyes with biological relevance. Under this premise, the chromophores can be categorized into intrinsic, synthetic, and genetically encoded dyes, each group containing dyes with a variety of different indicator features.

4.2 Intrinsic Chromophores

Biological tissue is naturally fluorescent to a varying degree even without adding chemically synthesized molecules or introducing the gene of a fluorescent protein (see below). The molecular origin of this intrinsic "autofluorescence" depends on the excitation wavelength. For UV excitation, nucleotides and the aromatic amino acids are dominant, for excitation with visible wavelengths, other compounds such as nicotinamide adenine dinucleotide (phosphate) NAD(P)H and flavin adenine dinucleotide FAD are the main contributors.

Tryptophane fluorescence is rarely used for 2PM, but 2PE fluorescence correlation spectroscopy (FCS) is possible for proteins containing a large number of tryptophane residues. NAD(P)H is of special interest as its fluorescence intensity depends on its oxidation state. With excitation at 800 nm, NAD(P)H and flavoprotein fluorescence can be used together for a quantitative ratiometric measurement of cellular metabolism.

One of the advantages of MPA for exciting cellular autofluorescence is that it permits access to transitions that

require for 1PE, ultraviolet light of wavelengths that do not pass most microscope objectives.

On one hand, endogenous fluorophores can be useful because tissues can be imaged without dyes having to be applied to the tissue. On the other hand, endogenous fluorophores contribute most of the unwanted background when exogenous dyes, which provide enormous specificity and tailored indicator properties, are to be imaged. A special case is the green fluorescent protein (GFP, see below), which occurs naturally in the jellyfish and has a biological function there, but in other organisms GFP is an exogenous stain in the sense that it needs to be introduced by molecular genetic means.

4.3 Synthetic Dyes

Because of the specific advantage of MPM for the observation of living tissue, the most frequently used synthetic dyes are those that provide functional signals, called *fluorescent indicators*, in particular, ion-sensitive, and (more recently) voltage-sensitive probes.

4.3.1 Ion Indicators

In many cellular responses, changes in ion concentrations are involved. Most important is Ca^{2+}, with its key position in cellular signal transduction; also important are Na^{+}, K^{+}, Mg^{2+}, H^{+}, and Cl^{-}. Ion indicators go back to Arnaldus de Villanova, a doctor and alchemist (~1300 AD), who invented litmus, an indicator that changes its color (absorption spectrum) depending on the concentration of H^{+} ions. The first 2PM calcium measurements where done using Indo-1, a BAPTA-based Ca^{2+} indicator, which is, however, excited by rather short wavelength and has a rather moderate 2P cross section. Much larger cross sections are found in xanthene-derived indicators, which also use the BAPTA Ca^{2+}-binding group and are now available with a wide range of Ca^{2+} affinities, covering the entire physiological range. A selection of different peak emission wavelengths (from 530 to 670 nm) ensures discrimination ability against GFP or other cellular labels if needed.

In tissue imaging, labeling without damage to cells is crucial and several methods have been used in connection with MPM. (1) Loading individual cells by diffusion or iontophoresis from dye-filled micropipettes in brain slices or *in vivo*; (2) applying cell-permeable acetoxymethoxyl (AM) esters variants, which become trapped in cells by intracellular esterases. AM loading is straightforward in isolated cells, but is also possible in brain slices and even *in vivo*; and (3) particle (''gene'')-gun delivery.

For an overview of fluorescent indicators see http://www.probes.com/. All of these indicators can be efficiently 2P excited somewhere between 700 and 1000 nm, i.e. they are accessible when using a Ti:sapphire laser.

4.3.2 Voltage-sensitive Dyes

Voltage-sensitive dyes (VSDs) measure electrical activity directly rather than indirectly via Ca^{2+} influx. Most VSD-based measurements have, until recently, not used laser-scanning microscopy, since the fractional fluorescence changes that occur with physiological voltage swings are small and thus need for detection and quantification of a large number of fluorescent photons. Recently, it was shown that by using band-edge excitation, fractional changes are substantially increased, and are for equivalent excitation wavelengths, larger with 2PE than with 1PE.

4.4 Genetically Encoded Fluorophores and Indicators

Labeling with synthetic dyes is in most cases not cell-type specific. For example, when injecting AM ester-Ca^{2+} indicator into brain tissue, many cell types take up the dye, and it is impossible to stain, for example, only neurons. Genetically encoded protein "dyes," often called XFPs by generalizing from GFP, the green fluorescent protein, with "X" standing for the color such as for yellow in YFP and for cyan in CFP, overcome this problem because their expression can be put under the control of specific promoters that are only active in certain cell types. XFPs can also be fused to other proteins to then map their dynamic distribution in the cell. Fusion protein with XFPs have also been designed to act as indicators for Ca^{2+}, Cl^{-}, pH, and other cellular signals and physiological parameters such as cAMP, phosphorylation, redox potential, protein kinase B and C, as well as membrane voltage. The molecular genetic methods used to label intact animals are either the creation of transgenic animals, infection with properly engineered viral vectors, or *in vivo* electroporation.

For imaging in intact animals XFPs and MPM are rather synergistic, since together they solve the deep labeling and the deep imaging problem, with 2PM even allowing imaging through the thinned but intact skull.

5 Applications

On the basis of the unique imaging properties described earlier, MPM has become the preferred and virtually the only method that allows morphological and functional imaging in thick living tissue and in live animals. While many of the essential uses of MPM are in the field of neuroscience, the range of biological structures and processes investigated using MPM have continuously grown. Applications of MPM now include photodynamic therapy, noninvasive optical biopsy of human skin, the study of cellular metabolism, embryogenesis, immunology, tumor pathophysiology, and neurodegenerative disease. In the following, we will discuss some of these applications in more detail.

5.1 Neurobiology

After it became clear that 2PM is particularly well suited to high-resolution imaging in scattering tissue, it was applied to neural tissue, which is strongly scattering and requires the use of intact pieces of tissue for functional studies owing to the high degree of cellular interconnectivity. Early studies focused on Ca^{2+} dynamics in dendritic spines. Then it became clear that it is possible to image Ca^{2+} dynamics with high spatial and temporal resolution in the wholly intact brain as well, where 2PM can now be used to guide recording pipettes to selected cells. It has also been possible to study the structural stability and plasticity of neuronal morphology in explanted tissue and, over periods of months, in intact animals.

2PM has helped to reveal neural structure and function at various levels ranging from individual synapses to entire neural networks (see also Fig. 4). The retina, a spatially separate but functionally integral part of the brain, has been a particularly rewarding specimen for 2PM. Because of the

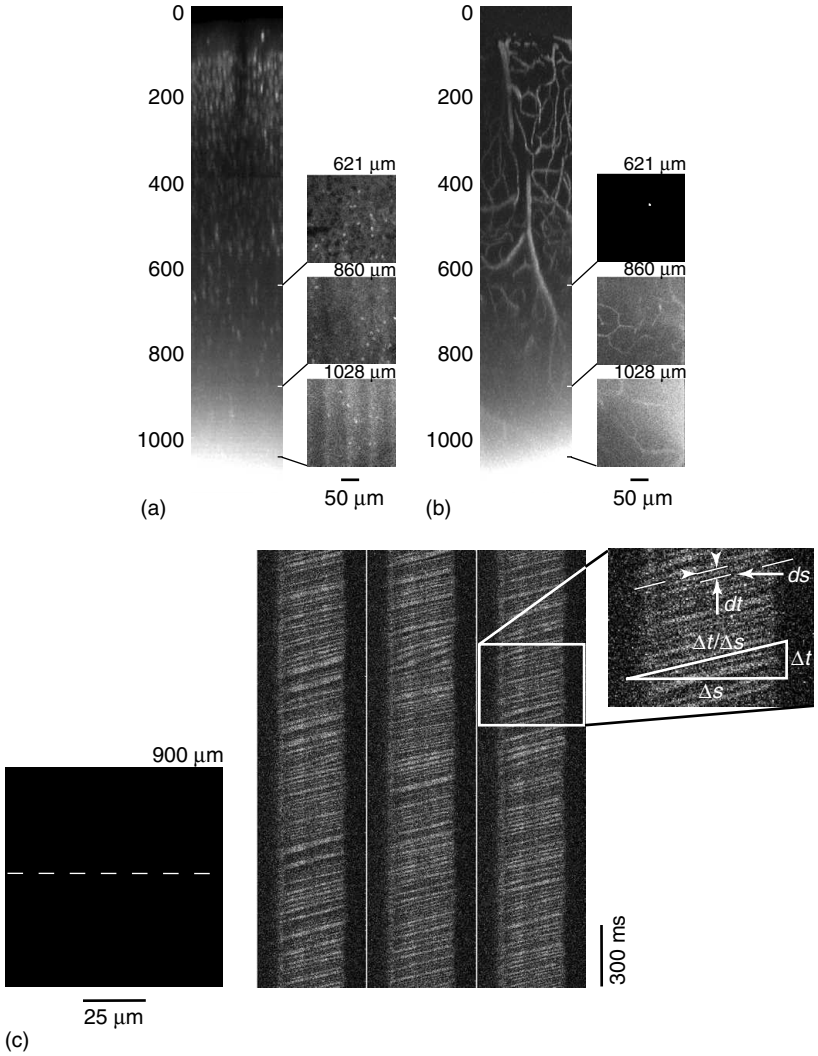

Fig. 4 (a) *x-z* projection and single planar scans of GFP labeled neurons and (b) stained vasculature obtained throughout almost the entire gray matter of the mouse neocortex. (c) Blood flow measurement in the mouse neocortex at 900 μm below the brain surface. Blood cells appear as shadows in surrounding blood plasma. Their motion traces out shaded bands in an image consisting of line scans repeatedly taken along the capillaries (dashed line in the planar scan). Blood flow parameters as velocity, linear density, average spacing, and flux of red blood cells can be inferred from the slope (d*t*/d*s*) of, and the distance (d*s*) and time (d*t*) between shaded bands.

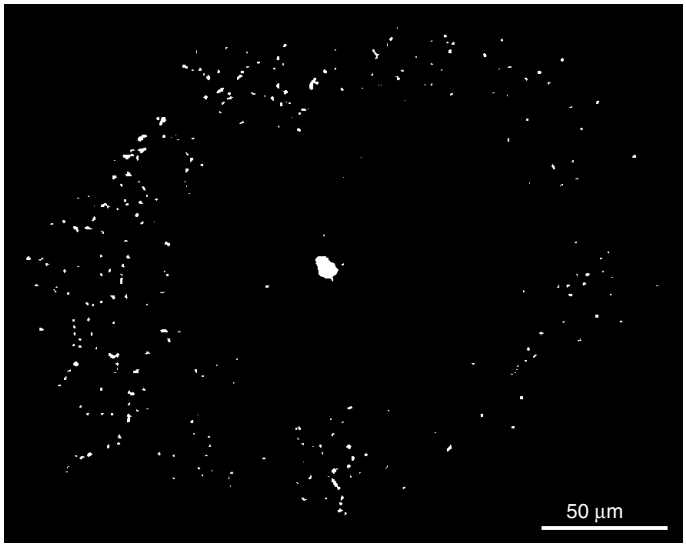
retina's high sensitivity for UV and visible light, 1PE of common fluorescent probes inevitably perturbs the observed specimen; in fact, intensities used commonly for fluorescence microscopy completely bleach the photopigments within seconds. In

contrast, photoreceptors are blind to light in the near-infrared wavelength region, allowing the use of IR-excited 2PM to measure light stimulus-evoked calcium signal in the functionally intact retina, which has been used to study the mechanism of motion detection in retinal cells (see Fig. 5).

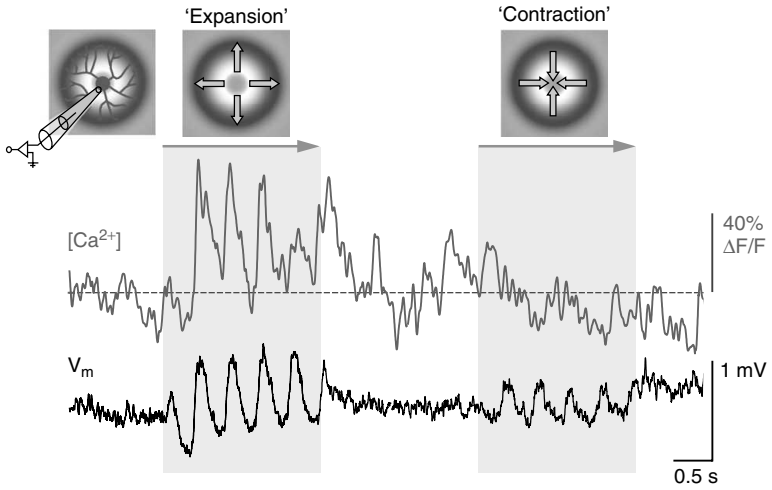
5.2 Calcium Imaging

"Calcium imaging" constitutes the bulk of ion imaging, both with 1PM and with MPM, because of the important role of Ca^{2+} in coupling electrical processes to biochemical processes, for example, in muscular contraction and neurotransmitter secretion, and because $[Ca^{2+}]$ transients can often be used as a proxy for electrical excitation. The particular advantages of MPM are, again, excitation-based optical sectioning and highly efficient fluorescence collection in scattering tissue. A disadvantage of MPM is that ratiometric indicators that require dual-wavelength excitation are difficult to use because a second laser is required for the second excitation wavelength (at this point in time, changing the wavelength even in a fully automated Ti:Sapphire lasers still takes seconds). Therefore, ratiometric calcium imaging with 2PM has to resort



(a)

Fig. 5 Two-photon optophysiology in the retina. Dye-filled "starburst" amacrine cell (a) in flat-mounted rabbit retina. Like many amacrine cells, this neuron bears no axon; it receives inputs and makes output synapses with its dendrites. Starburst cells are involved in the detection of image motion. Using (b) two-photon microscopy, light stimulus-evoked Ca^{2+} signals (green trace) were recorded in the dendritic tips of a starburst amacrine cell. Simultaneously, membrane voltage (black trace) was measured at the soma using a patch electrode (see schematic drawing). The light stimulus, a concentric sinusoidal wave, induced stronger responses when it was expanding (left) than when it was contracting (right) (see color plate p. xxv).



(b)

Fig. 5 (*Continued*)

to Indo-1, which has drawbacks, such as a short absorption wavelength and fast bleaching, but has been used to measure calcium oscillations in tumor mast cells and calcium transients in cardiac myocytes. More common nowadays is the use of dye mixtures that provide virtually all the advantages of proper ratiometric indicators. Furthermore, single-wavelength indicators are often sufficient, particularly if one is interested mainly in the temporal $[Ca^{2+}]$ dynamics (see Figs. 5 and 6). Satisfactory calibration can often be achieved by using the intensity prior to stimulation as a reference, such as was done in the early studies of $[Ca^{2+}]$ dynamics in dendrites, and dendritic spines in brain slices, and in whole animals.

5.3 Imaging of Metabolic Activity

The fluorescence from the reduced pyridine nucleotides NADH and NADPH, which are metabolic intermediates, can be used to localize and characterize the activity of respiratory enzymes and thus is an intrinsic probe of cellular metabolism. 1P-CM of two-dimensional NADH/NADPH-fluorescence maps is possible, as has been shown in rabbit cornea, but is hampered by photobleaching and photodamage due to the UV illumination (~360 nm) needed for the excitation of NADH/NADPH. Those problems are substantially reduced with 2PE so that now nearly continuous NADH/NADPH imaging is possible throughout the entire thickness (400 μm) of the rabbit cornea. Because metabolic events can be fast but may need to be monitored for extended time periods, low-damage imaging is of paramount importance. With MPM, it has become possible to follow the response to glucose application in β-cells inside intact pancreatic islets and in muscle cells.

5.4 Photoactivation (Uncaging)

The excellent localization of MPE can be used to confine photochemical generation

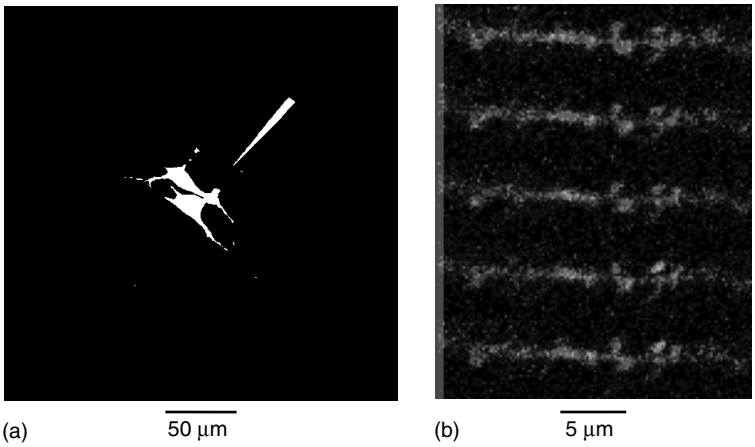


Fig. 6 Measurement of calcium dynamics in dendritic spines of a hippocampal neuron (a) using simultaneous excitation, at 910 nm, of two different fluorophores – a red fluorescent Ca^{2+}-insensitive dye (Alexa-594) helping in visualization of small structures and a green fluorescent Ca^{2+} indicator (Fluo-5F), which is very dim at rest, but shows large fluorescence changes in activated spines. (b) Following extracellular electric stimulation, presynaptic fibers release transmitter in the synaptic cleft whose binding to corresponding receptors on the postsynaptic membrane causes a Ca^{2+} rise in a single dendritic spine leading to an increase in green fluorescence observed by successive planar scans of a dendritic branchlet (see color plate p. xxvi).

of chemical compounds, such as fluorescent tracers or biological signaling molecules, to volumes smaller than a femtoliter. Typically, this is achieved by the illumination of a photolabile precursor that then absorbs two or more photons and decays via a photochemical pathway into the desired product. Scanning 2P photochemical microscopy, first demonstrated by mapping the distribution of neurotransmitter receptors on cultured muscle-like cells, has, however, been hampered by the very low 2PE cross sections of the available ''caged'' compounds (an example of the rule that weak 1P absorbers tend to be very weak 2P absorbers) even though there has been recent progress in the synthesis of better caged compounds, having allowed the study of calcium ''sparks'' in cardiac muscle cells and the mapping of glutamate sensitivities on dendritic spines. A combination of 2P uncaging and bleaching of fluorescence has been used to measure diffusional resistance of spine necks.

5.5 Human Diseases and Therapy

In conjunction with animal models, MPM has provided some insights into human diseases such as Alzheimer's dementia. There, 2PM *in vivo* imaging allows the observation over time of how senile plaques (amyloid-beta peptide aggregates) develop. This is extremely helpful when evaluating antiplaque therapies, since the fate of individual plaques can be followed over weeks and months by repeated imaging through a thinned skull. These experiments have shown that, surprisingly, plaques do not change size after formation.

2PM has also been used to measure blood flow at the level of single capillaries and to observe leucocytes-endothelial interactions in tumors *in vivo* at tissue depths that are not accessible otherwise. Such studies have revealed, for example, the depth dependent dynamics of tumor angiogenesis. In the area of immunology, 2PM allows the observation of lymphocytes in their native environment such as monitoring the motility of T cells that invade the brain during neuroinflammation.

Potential clinical applications on MPM are optical skin biopsy and photodynamic therapy. Traditional biopsy is an invasive procedure, which requires the removal and fixation of tissue before imaging. During this process, biochemical information is often poorly preserved. Optical biopsy does not require the removal of any tissue sample, but it remains to be seen whether the quality of 2PM images will become good enough to allow a pathological analysis with accuracy comparable to that of traditional biopsies.

Photodynamic therapy is based on the preferential accumulation of certain photosensitizing agents in tumorous or otherwise abnormal tissues and the subsequent selective tissue destruction by illumination. 2PE photodynamic therapy has the potential of providing more spatially specific destruction of, for example, cancer tissue than 1PE, which can be confined not as easily or not at all.

6 Future Directions

Among the ''exponentially'' growing number of papers on MPM, about half are still on methods development. With these ongoing improvements and extensions of MPM, the range of applications that benefit from MPM continues to expand. Much of the current improvement efforts are directed at excitation and detection efficiencies, which, as was discussed at length earlier, is the main factor determining imaging depth and specific (i.e. per information gained) photodamage. Novel chemical fluorophores with large two photon–absorption cross sections still await significant biological applications. Closer to being really useful appear to be semiconductor quantum dots (QDs), which have the largest 2PA cross sections measured, are very photostable, and are available with widely varying but narrow emission spectra. Recent advances have all but solved early problems with solubility, quenching, and toxicity. Different coats allow covalent linking to biorecognition molecules, such as antibodies or biotin/avidin, so that QDs can be used as specific fluorescent probes. In conjunction with their broad excitation spectra, QDs are very well suited for multilabel imaging.

An entirely different route to improving excitation efficiency is the use of coherent control, which involves tailoring the phase and amplitude of a laser pulse to optimize the optical response of a molecule, to achieve selective excitation, or to reduce photobleaching.

Inhomogeneities in the index of refraction across the tissue lead to degradation of the focus and thus a reduction in 2PE efficiency. In particular at large depths, therefore, adaptive aberration correction can significantly improve excitation.

In order to image structures that are beyond the penetration depth of the MPM, overlying tissue has to be removed. In order to keep the lateral extent of such removal, limited ''endoscopic'' approaches are being developed that use a small diameter gradient-index (GRIN) lens as

the objective. This limits the NA and the field of view, but may be the only way to reach deeper brain structures such as the hippocampus *in vivo*.

Regular MP microscopes are bulky and thus most *in vivo* imaging is done in anesthetized and immobilized animals. To achieve the goal of high-resolution imaging in freely moving animals, scanners and optics have to be miniaturized. This requires a different scanning mechanism because the weight of a galvo scanner rules out its use in a headpiece that can weigh at most a few tens of grams without encumbering an animal such as a rat too much. An alternative is the ''2P-fiberscope'' in which scanning is achieved by deflecting the free end of the fiber that is used to deliver the excitation light to the headpiece. The deflection can, for example, be achieved by using resonant oscillations. One challenge peculiar to nonlinear fiber microscopy is that special measures, including the use of large core or microstructured fibers, have to be taken to limit the degradation of the pulse shape by nonlinear optical effects in the beam-delivery fiber.

DUBs) that hydrolyze the peptide or isopeptide bond following the last residue of ubiquitin.

ER-associated Degradation (ERAD)
It removes proteins from the ER membrane or ER lumen. ERAD involves retrotranslocation of the target protein from the ER into the cytoplasm, ubiquitination, and proteolysis by the proteasome.

Proteasome (a.k.a. 26S proteasome)
It is a large, multisubunit ATP-dependent protease found in all eukaryotic cells responsible for most regulatory proteolysis. The proteasome is composed of a cylindrical *20S core particle* encompassing the proteolytically active subunits, and a *19S regulatory particle* that recognizes polyubiquitinated proteins and prepares them for proteolysis in the 20S core particle.

Proteolysis or Protein Degradation
It is the hydrolysis of peptide bonds in proteins yielding short peptides or amino acids.

Ubiquitin
(Ub) is a highly conserved, compact, and stable 76-residue protein found in all eukaryotes that can be covalently attached at its free carboxyl-terminus to amino groups on other proteins. This posttranslational modification of proteins by ubiquitin is called *ubiquitination* and is carried out by ubiquitinating enzymes.

Ubiquitinating Enzymes
They are a modular assembly of enzymes that are responsible for tagging a designated protein with *ubiquitin*. Ubiquitinating enzymes include an ATP-utilizing E1 that activates the free carboxyl-terminus of ubiquitin, a number of E2s that transfer the activated ubiquitin to the target protein, and numerous E3s that select unique substrates and mediate the action of the proper E2s.

Ubiquitination
It is the posttranslational modification of proteins with ubiquitin or a chain of multiple ubiquitin units. Usually, the outcome of ubiquitination is recognition and proteolysis by the *26S proteasome*. In some cases, ubiquitination does not lead to degradation but serves to alter intrinsic properties of the target protein, or direct its subcellular localization.

Ubiquitin-like Proteins
(Ubl) are small proteins that share homology with ubiquitin either structurally or in sequence. Similar to ubiquitin, most can be attached to the amino group of a lysine side chain on a target protein.

Cells contain many different kinds of proteins, each fulfilling structural, functional, or regulatory roles. Monitoring the state of all these proteins, as well as continuously adjusting their levels to suit demands is paramount to survival. The presence of damaged or mutated proteins, as well as altered levels of normal proteins could cause pathological conditions and even cell death. To exercise such quality control, cells are continuously spending energy both to synthesize new proteins, and to simultaneously degrade them, even though many may still be functional. An important characteristic of regulatory degradation is that it is specific; only the correct proteins are removed in a time-coordinated manner. Such extraordinary specificity is achieved by a modular system that identifies the proteins to be degraded, marks them by covalently attaching ubiquitin to an amino residue, and finally proteolyses the substrate by the 26S proteasome. Recognition of target proteins is carried out by a specific ubiquitin-protein ligase, called an E3. This protein recognizes the substrate and usually directs a ubiquitin-conjugating enzyme, an E2, to attach ubiquitin, a small 76 amino acid protein, onto the substrate. Ubiquitin molecules are often added to one another as well as to the substrate, resulting in chains of ubiquitin extending from the protein targeted for degradation. These polyubiquitin conjugates are then shuttled to the 26S proteasome, a large proteolytic complex, where they are degraded. Interestingly, ubiquitination is a reversible process, with deubiquitinating enzymes able to remove ubiquitin from the target before it can be recognized by the proteasome. Hence, transfer of the polyubiquitinated conjugate to the proteasome must happen swiftly or be shielded from these enzymes. The balance of these processes allows the ubiquitin-proteasome system to control the cellular levels and half lives of thousands of proteins making it a key player in basic biological pathways such as cell division, differentiation, signal transduction, trafficking, and quality control. Not surprisingly, aberrations in the system have been implicated in the pathogenesis of many diseases, certain malignancies, neurodegenerative disorders, inflammation, and immune response. Understanding the underlying mechanisms involved is important for the development of novel, mechanism-based drugs.

1
Mechanisms of Ubiquitination and Protein Degradation

1.1
Ubiquitination

The cellular levels of many proteins are kept in check by regulated degradation via the ubiquitin-proteasome pathway. Substrates are first tagged by covalent attachment of multiple ubiquitin molecules. These tagged proteins are then proteolysed by the 26S proteasome complex simultaneous with release of the ubiquitin tag. This last process is mediated by deubiquitinating enzymes (DUBs), a number of which are attached to the proteasome itself and work together to define the efficiency of the overall process.

Ubiquitin is a 76-residue protein and one of the most (if not the most) evolutionarily conserved proteins; its sequence and structure being almost identical in all

eukaryotes. Conjugation of ubiquitin to the protein substrate requires the participation of a slew of ubiquitinating enzymes that are usually broken down into three distinct classes. Initially, the ubiquitin-activating enzyme (UBA; also known as E1), activates ubiquitin in an ATP-dependent reaction to generate a high-energy thiol ester intermediate between the carboxyl-terminus of ubiquitin and the active site cysteine of E1 (E1-S∼ubiquitin). One of several E2 enzymes (ubiquitin-conjugating enzymes; UBCs) transfers the activated ubiquitin from E1, via an additional high-energy thiol ester intermediate, E2-S∼ubiquitin, to the substrate that is specifically bound to a member of the ubiquitin-protein ligase family, E3 (Fig.1). E3s catalyze the last step in the conjugation process: covalent attachment of ubiquitin to the substrate. The protein to be degraded is recognized by a specific E3. This protein directs the addition of ubiquitin from the E2 onto the substrate. There are several classes of E3 enzymes. Members of the RING finger-containing E3s, the largest family of ubiquitin ligases, mediate the transfer of the activated ubiquitin directly from the E2 to the E3-bound substrate. In the case of another class of E3, the so-called HECT (*Homologous to the E6-AP C-Terminus*) domain E3s, the ubiquitin is transferred from the E2 enzyme to an active site cysteine residue on the E3 to generate yet a third high-energy thiol ester intermediate, ubiquitin-S∼E3. Ubiquitin is then transferred from the E3 to the substrate protein that is bound to the ligase.

At the end of the ubiquitination cascade, the ubiquitin molecule is attached by

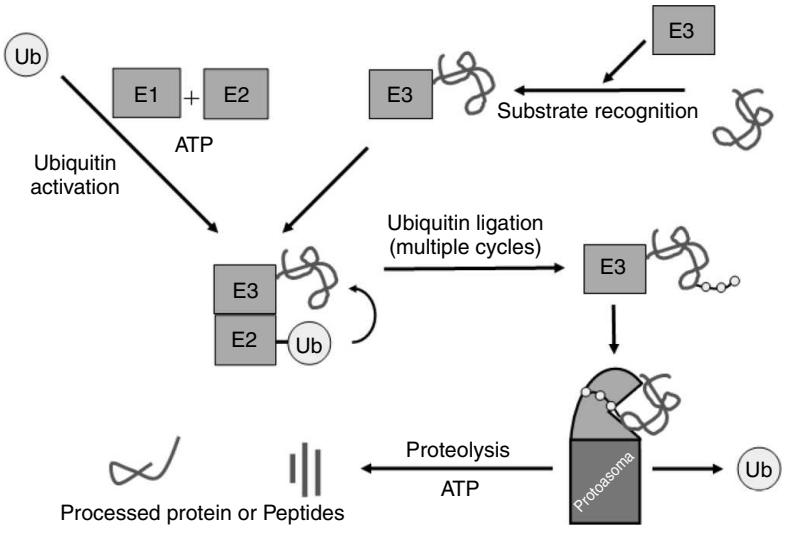

Fig. 1 General scheme of the ubiquitin system. Ubiquitin is activated by the ubiquitin-activating enzyme, E1, followed by its transfer to a ubiquitin-conjugating enzyme, E2. E2 transfers the activated ubiquitin to the protein substrate that is bound to a ubiquitin ligase, E3, which is specific for the substrate. Successive conjugation of ubiquitin moieties to one another generates a polyubiquitin chain that serves as the recognition signal for the 26S proteasome. The substrate is degraded by the 26S proteasome into short peptides, while ubiquitin is released by deubiquitinating enzymes (DUBs) for reuse.

its carboxyl-terminus to an amino group in the substrate protein. Generally, this is the amino group of an internal lysine side chain (an ε-NH_2 group), resulting in a covalent amide bond also known as an *isopeptide bond*. In some cases, ubiquitin is conjugated to the primary amino-terminus forming a linear amide bond; essentially a peptide bond. The ubiquitination reaction continues successively, adding an activated ubiquitin molecule to an internal lysine residue on the previously conjugated ubiquitin in each round, creating a polyubiquitin chain. In some instances, chain extension may require an additional auxiliary ligase called an *E4*. In this scenario, the first ubiquitin moiety is conjugated to the substrate by one E3, while chain elongation is catalyzed by a different ligase, the E4. It is thought that chains containing more than four ubiquitin moieties can bind to the proteasome with particularly high affinity, thus serving to target the protein to which they are conjugated for proteasomeal degradation.

1.2 Selection of Proteins for Degradation

A major task for the ubiquitin system is how to achieve high specificity and selectivity toward its numerous substrates. How to guarantee that the correct substrate will be removed whereas another, often similar protein will remain unscathed? In other words, why are certain proteins stable in the cell, while others are extremely short-lived? Complicating matters, some proteins are inherently short-lived and constitutively degraded while others are stable under most other conditions and degraded only upon a signal such as extracellular stimuli or a particular point in the cell cycle. Within the ubiquitin system, substrate selection is carried out predominantly by the E3 ligases. As such, E3s are the most diverse component of the pathway; to date, over 1000 different E3s or subunits of E3 ligase complexes have been identified in the human genome based on specific, commonly shared structural motifs. Each E3 is specific for a substrate or class of substrates.

Substrates must be recognized by a specific E3 and bind to it as a prerequisite to their ubiquitination. In most cases, however, the substrates are not recognized in a constitutive manner but must undergo posttranslational modification such as specific phosphorylation, dephosphorylation, or oxidation that renders them susceptible for recognition by an E3. In some cases, recognition of the target proteins by the E3 depends on association with an auxiliary protein (such as molecular chaperones) that serves to link the substrate with the appropriate ligase. In fact, many E3 ligases are themselves multisubunit complexes with each subunit participating in a unique network of protein–protein interactions. Certain subunits detach from, or dock to, the core E3 platform tweaking the ligase properties. Such modular behavior allows a limited set of proteins to target a much larger pool of substrates, each at the correct time and cellular context. Well-studied examples are the cullin-based E3 ligases, which regulate many steps of the cell cycle. The cullin subunit and the ring-finger component Rbx1 (plus a few additional subunits) serve as a stable platform while the substrate-recognition domain is a modular component that can be replaced as needed thus directing the cullin-based E3 to ubiquitinate a wholly new subset of substrates. In still other targeting mechanisms, substrates have to dissociate from a complexed form in order to be susceptible for E3 recognition and ubiquitination. This is a common feature of transcription

factors that usually have to dissociate from their DNA segment before they can bind to an E3 ligase to be ubiquitinated. Stability of yet other proteins depends on oligomerization. Thus, modifying enzymes (such as kinases), ancillary proteins, or DNA sequences to which substrates bind, also play an important role in the recognition process, in addition obviously to the E3s. In some instances, it is the E3 that must ''be switched on'' by undergoing posttranslational modification in order to yield an active form that recognizes the target substrate more efficiently.

1.3 Degradation

Degradation of polyubiquitinated substrates is carried out by the 26S proteasome. This multicatalytic protease degrades polyubiquitinated proteins to short peptides and releases ubiquitin for reuse by the ubiquitination machinery. There are a few reports indicating that the 26S proteasome – *in vivo* as well as *in vitro* – can also proteolyse certain (usually unstable or misfolded) proteins that are not covalently modified with the ubiquitin tag. However, the proteasome is the only enzyme that can proteolyse polyubiquitinated proteins. It is composed of two subcomplexes: a 20S core particle (CP) that contains the catalytic sites and proteolytic activity, and a 19S regulatory particle (RP) that is essential for recognition and treatment of ubiquitinated substrates.

The 20S CP is a barrel-shaped structure composed of four stacked rings, two identical outer α-rings and two identical inner β-rings. The eukaryotic α- and β-rings are each composed of seven distinct subunits, giving the 20S complex the general structure of $\alpha_{1-7}\beta_{1-7}\beta_{1-7}\alpha_{1-7}$. Some (though not all) of the β-subunits are proteolytically active, with the remainder serving structural roles in forming the barrel structure. The proteolytically active β-subunits are threonine proteases, members of a unique N-terminal nucleophile hydrolase family. The active site nucleophile is the N-terminal threonine (the protein undergoes activation by posttranslational cleavage *after* it properly assembles into the 20S structure), while the proton acceptor is the N-terminus of the protein itself. This unique active site structure has drawn efforts to design proteasome-specific inhibitors that would not affect other cellular proteases. A number of proteasome inhibitors that target the 20S CP β-subunits are indeed available, with one, Valcade^{tm}, recently receiving FDA approval for treatment of multiple myeloma in humans.

Substrates must enter the lumen of the 20S CP where proteolysis occurs by transverseing through the α-ring at either of the two ends of the 20S barrel. It appears that they can enter from both ends simultaneously enhancing the proteolytic capacity of the proteasome. The α-ring at either of the two ends of the 20S barrel can be capped by a 19S RP. One important function of the 19S RP is to recognize ubiquitinated proteins and other potential substrates of the proteasome. Indeed, a number of polyubiquitin-binding subunits have been identified in the 19S RP, and are thought to recognize, transfer, bind, and anchor the tagged protein to the 19S RP. However, the interplay between these ubiquitin-binding subunits and how each contributes to proteasome function has yet to be deciphered. A second function of the 19S RP is to open an orifice in the α-ring of the 20S CP that will allow entry of the substrate into the internal proteolytic chamber. Even in its opened-state, the passage through the α-ring is too narrow to allow folded proteins through. It is assumed that the

19S regulatory particle unfolds substrates and inserts the unstructured polypeptide chain into the 20S CP. Both the channel opening function and the unfolding of the substrate require metabolic energy, and indeed, the 19S RP contains six different ATPase subunits. Biochemical characterization and mutational analysis have shown these ATPases to be involved in the unfolding and channel gating properties.

Following degradation of the substrate, short peptides derived from the substrate are released from the proteasome. The bulk of these peptides are further degraded in the cytoplasm into free amino acids by cytosolic amino- and carboxypeptidases. A small fraction of product peptides is transported by the TAP (transporter associated with antigen processing) across the ER membrane, further trimmed by specific proteases within the ER, bind to the MHC class I complex, and are carried to the cell surface where they are presented to cytotoxic T cells. In this manner, the proteasome is the major producer of antigenic peptides. Since the proteasome degrades both natural proteins as well as foreign (viral or mutated) proteins, both ''self'' and ''nonself'' antigens are produced. When these peptides are derived from a ''nonself'' protein, the T cell lyses the presenting cell. In rare instances, the proteasome may even splice nonconsecutive segments together, creating a new peptide with a novel sequence not found ''as is'' in the protein it was derived from. If substantiated as a general phenomenon, peptide splicing will have far reaching implications to the study of antigen presentation.

It should be emphasized that proteasomal degradation does not always continue to completion. In some cases, the proteasome can carve the ubiquitinated substrate in a limited manner, releasing a stable and functional truncated product. The best-studied example is the case of the NF-κB transcriptional regulator: an active subunit (p50 or p52) is generated by the proteasome from a longer inactive precursor (p105 or p100).

In addition to proteolysing the substrate (partially or in full) in the 20S CP, a totally unrelated proteolytic activity is present in the 19S RP and is intimately linked to proteasome function. Proteasomes hydrolyze the peptide or isopeptide bond immediately following the final residue of ubiquitin, thus severing the link between ubiquitin and the substrate or one ubiquitin unit and another in a polyubiquitin chain. This ubiquitin-specific protease activity has been mapped to a subunit of the 19S RP, Rpn11/POH1, as well as to a number of tightly associating components such as UCH37 and ubp6/USP14. The combined action of these DUBs releases ubiquitin, sparing it from being degraded along with the target protein and allowing it to be reused by the ubiquitin system.

1.4 Regulation of the Ubiquitin System

The ubiquitin-proteasome pathway can be regulated at the level of ubiquitination or at the level of proteasome activity. Since conjugation and proteasomal degradation are required for numerous cellular functions, regulation must be delicately executed. In a few cases, general regulation of the entire pathway is observed in response to physiological signals that call for increased or decreased proteolysis. For example, in fungi and plants, a dramatic increase in levels of ubiquitin, ubiquitinating enzymes, and proteasome subunits is observed under many stress conditions such as heat shock or oxidative damage. In animals, upregulation of the entire pathway

is observed during massive degradation of skeletal muscle proteins that occurs under normal fasting, and also under pathological conditions such as malignancy-induced cachexia, severe sepsis, metabolic acidosis, or following denervation. In general, these conditions are correlated with accumulation of damaged or misfolded proteins, which should be efficiently removed for cell survival; hence, the need for increased rates of proteolysis. Conversely, it has recently been shown that some conditions require less proteolysis for survival of the cell. During long-term starvation or prolonged and severe heat exposure, proteasome activity is inhibited and general proteolysis rates are slowed down in yeast cells.

In most cases, however, regulation is specific targeting defined substrates that are recognized by specific ligases. By far, the greatest degree of molecular complexity in the ubiquitin system is among the E3 ligases. There are hundreds of ubiquitin ligases encoded in the genomes of multicellular eukaryotes, in addition to hundreds of substrate-recognition subunits that function together with the E3 ligases to target specific substrates. The modular nature of these ligase complexes ensures that slight changes in ratios of the components will direct the pathway to degradation of specific pathways. Thus, many substrate-recognition components of E3 ligases are either differentially expressed or stabilized only upon certain physiological signals.

E3 activity or specificity can also be regulated by posttranslational modifications of defined motifs within the ligase or the substrate. The targeting motif can be a single amino acid residue (e.g. the N-terminal residue), a specific sequence (the destruction box in cyclins), or a domain (such as a hydrophobic patch) that is not normally exposed. In other cases, the motif is generated by a posttranslational modification such as phosphorylation (two neighboring serine residues in the case of IκBα, or a single serine residue in the case of p27), or oxidation (hydroxyproline in the case of the hypoxia-inducible factor-1α—HIF1α). Interestingly, phosphorylation is required also to activate certain ligases, such as c-Cbl. Many proteasome subunits, both in the 20S CP and in the 19S RP can be modified by phosphorylation or glycosylation. These modifications alter proteasome stability or activity, though it is still unclear whether the effect is general toward all substrates, or more interestingly, influence the efficiency of degradation of a subset of substrates.

Eukaryotic genomes also usually encode several dozen different deubiquitinating enzymes. Such a large number suggests that some of them may act only on particular substrates, and raises the possibility that the rate of degradation of some proteins is determined by how fast ubiquitin is removed from them rather than by how fast it is added. Furthermore, substrate delivery to the 26S proteasome probably requires accessory or adaptor molecules, which may be differentially expressed to promote degradation or some ubiquitinated substrates over others.

2 Biological Processes Regulated by the Ubiquitin System

The list of cellular proteins that are targeted by ubiquitin is growing rapidly. By removing these cellular proteins, ubiquitin-mediated proteolysis plays an important role in regulating many basic cellular processes. Among these processes are cell cycle, cell division, differentiation, organ development, cellular response to stress

and extracellular effectors, morphogenesis of neuronal networks, modulation of cell surface receptors ion channels and secretory pathways, DNA repair, transcriptional regulation, transcriptional silencing, long-term memory, circadian rhythms, regulation of the immune and inflammatory responses, and biogenesis of organelles.

The paradigm of regulated degradation, where involvement of the ubiquitin-proteasome pathway is well understood, is the cell cycle. Numerous cell cycle regulators such as cyclins, cyclin-dependent kinase inhibitors, proteins involved in sister chromatid separation, tumor suppressors, transcriptional activators and their inhibitors are all short-lived proteins that are rapidly proteolysed upon the correct cues. For example, mitosis must follow duplication of the chromosomes, so certain factors required for DNA synthesis are degraded at the end of S phase and are stabilized only once mitosis has been completed. Progression of mitosis requires that certain inhibitors of mitosis are quickly degraded only once the chromosomes are aligned and are ready to be separated to opposite poles, allowing the cell cycle to advance. The SCF family of ubiquitin-protein ligases is largely responsible for protein ubiquitination in the G1/S phase and the related APC/cyclosome complex performs similar functions in G2/M.

Signal transduction at numerous levels is kept in check by specific ubiquitination and degradation of key components from cell surface receptors, through kinases or phosphatases and down to the ultimate transcription factors. Receptor downregulation (such as growth-hormone receptor) by ubiquitin-dependent degradation is an important aspect of signal transduction. Downstream adaptor proteins such as c-Cbl have been shown to be ubiquitinated, as well. Recently, a number of kinases from the MapK, or other signaling pathways have been shown to be substrates of ubiquitinating enzymes. The synthesis of proteins and transcriptional regulation is also regulated in part by the ubiquitin-proteasome system. Numerous transcription factors are rapidly degraded, usually when dissociated from their DNA sequence. An incomplete list of short-lived transcription factors that are substrates of specific E3 ligases includes members of the AP-1, Id, HIF, P53, NF-κB families. Finally, metabolic pathways are under strict regulation as well. For example, the rate-limiting enzymes in both the sterol and unsaturated fatty acid biosynthetic pathways are located in the membrane of the ER, and their levels are regulated by ubiquitin-dependent degradation. Ubiquitin-dependent degradation of these enzymes is crucial for reducing their activity when levels of sterols or unsaturated fatty acids, respectively, become too high.

Proteasome-dependent proteolysis is a vital component of combating viral infections and aiding the immune response. Upon viral infection, Interferon-γ causes mammalian cells to synthesize new catalytic subunits of the 20S proteasomes with a preference for cleaving peptide bonds between hydrophobic amino acids. These βi subunits are incorporated into newly assembled proteasomes – the so-called *immuno-proteasomes* – with an increased ability to generate protein fragments appropriate for MHC class I presentation. Interferon-γ also induces expression of the 11S regulator, which facilitates the production of antigenic peptides for optimal binding to MHC class I molecules and accelerating the cytotoxic lymphocyte response.

The ubiquitin-proteasome system plays a critical role in heat shock and oxidative damage response by removing mutated,

denatured, or misfolded proteins. It appears that in some cases, chaperones (such as Hsp70) cooperate with the ubiquitinating machinery to recognize and ubiquitinate unfolded proteins. By selectively removing these proteins, the system plays a key role in protection against aggregate buildup and in the quality control of the proteome.

All secretory proteins and most transmembrane proteins are inserted into or pass through the membrane of the ER. These proteins must fold, assemble into complexes with other proteins, and undergo various posttranslational modifications. If these proteins fail to fold or assemble properly, or lack appropriate glycosylation, they are prevented from proceeding to the Golgi and instead they are sent back to the cytosol for proteasomal degradation in a process known as *ER-associated degradation* (ERAD). Elaborate machinery exists on the cytoplasmic side of the ER membrane to recognize target proteins, to polyubiquitinate, to extract from the membrane in an ATP-dependent manner and to shuttle to the proteasome for proteolysis. Extraction from the membrane into the cytosol is probably carried out mainly by a hexameric ATPase ring called *Cdc48* or *p*97. This complex is located on the cytoplasmic surface of the membrane, can bind to polyubiquitinated substrates and undergo ATP-dependent conformational changes that ratchet the substrate through the ER channel.

Finally, it is important to note that ubiquitination also plays nondegradative roles in regulating certain biological processes. For example, histone H2A is monoubiquitinated in many places, though not proteolysed. Histone ubiquitination is thought to influence chromatin structure and accessibility. Ubiquitination can also serve to target proteins to certain localizations in the cell. In one case, monoamine oxidase A is ubiquitinated and inserted into the outer membrane of the mitochondria though there is no evidence so far that it is targeted for proteasome proteolysis on the way. Modification by polyubiquitin chains that polymerase via lysine 63 on each ubiquitin molecule (rather than the more common polymerization via Lys48) plays a role in a variety of processes, including endocytosis, postreplicative DNA, stress response, mitochondrial DNA inheritance, ribosomal function. Even though such chains probably do bind the proteasome, experimental evidence so far suggests that this type of modification does not involve proteolysis of the target substrate, but rather the modification plays a role in the activation/inactivation of the target protein.

3 Modification by Other Ubiquitin-like Proteins

In parallel to the ubiquitin-conjugating system, there are additional protein conjugation systems. The modifiers are always small globular proteins structurally related to ubiquitin and are known as *ubiquitin-like modifiers* (Ubls). These include SUMO, Nedd8/Rub1, ISG15, Apg8, and Apg12. In all the cases so far, the conjugation process has been carried out in an analogous manner to ubiquitination, utilizing conjugating enzymes that are similar to (yet distinct from) ubiquitinating enzymes. Modification is always on a lysine side chain of the modified proteins to which the carboxyl-terminus of the Ubl is covalently attached. Thus,

SUMO (small ubiquitin modifier), for example, is conjugated by a heterodimeric E1 – Aos1/Uba2, and the E2-conjugating enzyme Ubc9. Though Ubc9 can recognize the SUMOylation motif and transfer SUMO directly to certain substrates, for some proteins, specific E3 enzymes have been described that mediate these processes. A notable distinction between ubiquitination and modification by Ubls, however, is that the latter modification is monomeric, with only one Ubl molecule attached to the target. Recently, evidence has been provided that the ubiquitin-like modifiers SUMO-2 and SUMO-3 may form short chains. Similarly to ubiquitination, modification by Ubls is reversible on account of ubiquitin-like proteases (Ulps) that can shave the modifier off its target. A rapidly increasing number of Ulps have been identified, usually with clear homology to deubiquitinating enzymes.

Both enzymes and substrates of the ubiquitin system as well as other proteins have been found to be modified by ubiquitin-like proteins. The process serves many functions, such as activation of enzymes and transcriptional regulators, subcellular localization, or protecting proteins from ubiquitination. One role of modification by Ubls is to modulate the ubiquitin system. Modification of E3 ubiquitin ligases by ubiquitin-like molecules affects their activity. For example, conjugation of NEDD8/Rub1 to the cullin component of the SCF ligase complex increases its affinity to bind the E2 component of the conjugation machinery, thus increasing overall efficiency of conjugation. In the case of substrates, since modification occurs on lysines – the same residue to which ubiquitin is conjugated – modification can block ubiquitination and consequently enhance cellular stability. For example, in the case of IκBα, the inhibitor of the transcriptional regulator NF-κB, modification by SUMO-1 was shown to protect the substrate from ubiquitination. The activity of yet other transcription factors such as C-Jun, p53, c-Myb to name a few is also altered upon SUMOylation. In a completely different case, SUMOylation of RanGAP1 targets the protein to its final subcellular destination in the nuclear pore complex, NPC. Many SUMOylated proteins are found in promyelocytic leukemia (PML) nuclear bodies suggesting that SUMO may serve as a targeting signal to these or other locals. Complicating matters is that p53 can also be modified by NEDD8, though the exact relationship between ubiquitination, SUMOylation, and NEDDylation of this protein is not yet understood. Modification by the Ubl proteins Apg12 and Apg8 participates in autophagy, while modification by ISG15 functions in interferon-γ signaling.

A completely different group of ubiquitin-like proteins are those that are not involved in protein modification. Thus, certain proteins contain an intrinsic domain that folds into a ubiquitin-like domain. Many are proteins that are part of the ubiquitin system: among them are some E3 ligases, deubiquitinating enzymes, and polyubiquitin-binding proteins. For example, Parkin is an E3 ligase that contains a ubiquitin-like domain that probably facilitates its interaction with other components of the system. hHR23/Rad23, hPLIC/Dsk2, and Ddi1 are ubiquitin-binding proteins that all have an N-terminal Ubl. These proteins have all been implicated in the recognition and turnover of substrates targeted for degradation. They probably shuttle polyubiquitinated substrate to the

proteasome to which they bind via their Ubl domain.

4 Ubiquitination in Health and Disease

Inactivation of the key junctions in the ubiquitin–proteasome pathway, such as the enzyme E1 or the proteasome is lethal. Yet, mutations or acquired changes in enzymes or recognition motifs in substrates that do not affect vital pathways or that only partially affect proteolysis may result in a broad array of diseases. Pathological cases include those that result from loss of function – stabilization of a substrate that is normally targeted for degradation by evading the ubiquitin system or due to a mutation in a ubiquitin system enzyme – and those that result from gain of function such as abnormal or accelerated degradation of the protein target. Following are a number of well-studied cases that tie the ubiquitin system to pathogenesis of malignancies, neurodegenerative disorders, genetic diseases, and disorders of the immune and inflammatory responses.

4.1 Cancer

Alterations in ubiquitination and deubiquitination reactions have been directly implicated in the etiology of many malignancies. In general, cancers can result from *stabilization* of oncoproteins, or *destabilization* of tumor suppressor gene products. Some of the natural substrates of the system are oncoproteins that if not properly removed from the cell, can promote malignant transformation. For instance, ubiquitin targets N-Myc, c-Myc, c-Fos, c-Jun, Src, and the adenovirus E1A proteins. Similarly, inadvertent destabilization of tumor suppressors such as p53 and p27 has also been implicated in the pathogenesis of malignancies.

In the case of uterine cervical carcinoma, the level of the tumor suppressor protein p53 is extremely low. Most of these malignancies are caused by high-risk strains of the human papillomavirus (HPV). Detailed studies have shown that the suppressor is targeted for ubiquitin-mediated degradation by the virally encoded oncoprotein E6. Degradation is mediated by the normal and naturally occurring HECT domain E3 enzyme E6-associated protein – E6-AP, where E6 serves as an ancillary protein that allows recognition of p53. E6-AP will not recognize p53 in the absence of E6. E6 associates with both the ubiquitin ligase and the target substrate and brings them to the necessary proximity that is assumed to allow catalysis of conjugation to occur. Removal of the suppressor by the oncoprotein is probably an important mechanism used by the virus to transform cells. While the nature of the native substrates of E6-AP is still elusive, a mutation in the enzyme has been implicated directly as the cause of Angelman Syndrome characterized by mental retardation, seizures, out of context frequent smiling and laughter, and abnormal gait. It is possible that the protein, which accumulates as a result of the mutation, is selectively toxic to the developing neuronal cells.

Similar to the case of p53, low levels of the cyclin-dependent kinase inhibitor $p27^{Kip1}$ have been demonstrated in colorectal, prostate, and breast cancers. p27 acts as a negative growth regulator/tumor suppressor that binds and negatively regulates CDK2/cyclin E and CDK2/cyclin A complexes and thus does not allow cell cycle progression from G1 and entrance into the S phase. As noted, its level is markedly

reduced in several cancers, and in many of these cases there was a strong correlation between the low level of p27 and the aggressiveness of the disease – tumor grading, clinical staging, and poor prognosis of the patients. Dissection of the mechanism that underlies the decrease in p27 revealed that the protein is of the WT species and it is probably abnormal activation of the ubiquitin system, and, in particular, dysregulated overexpression of its cognate E3, the F-box protein Skp2, that leads to rapid removal of the suppressor.

β-catenin plays an important role in signal transduction and differentiation of the colorectal epithelium, and aberrations in ubiquitin-mediated regulation of its levels may play an important role in the multistep development of colorectal tumors. In the absence of signaling, casein kinase I (CKI) and glycogen synthase kinase 3β (GSK3β) are active and promote phosphorylation, recruitment of the β-TrCP ubiquitin ligase, ubiquitination, and subsequent degradation of β-catenin. Signaling promotes dephosphorylation, stabilization, and subsequent activation of β-catenin via complex formation with otherwise inactive subunits of transcription factor complexes. β-Catenin interacts with the 300 kDa tumor suppressor APC (adenomatous polyposis coli) and Axin to generate a complex that appears to regulate, in a yet unknown manner, its intracellular level. Aberrations in degradation of β-catenin that lead to its stabilization, accumulation, and subsequent oncogenic activation, can result from two distinct mechanisms: (1) mutations in the phosphorylation motif of the protein by CKI and GSK3β, and (2) mutations in the targeting APC/Axin machinery.

Mutations in components of the ubiquitination machinery can also cause malignancies. Mutations in one germline copy of *VHL* predisposes individuals to a wide range of malignancies, including more then 80% of sporadic cases of renal cell carcinoma, pheochromocytoma, cerebellar hemangioblastomas, and retinal angiomas. A hallmark of $VHL^{-/-}$ tumors is a high degree of vascularization that arises from constitutive expression of the α-subunit of the master switch transcription factor hypoxia-inducible factor-1 (HIF-1), which results in overexpression of hypoxia-inducible gene products including the crucial vascular endothelial growth factor (VEGF). It has been recently shown that pVHL is a subunit in a ubiquitin ligase that is involved in targeting of HIF-1α for ubiquitin- and proteasome-mediated degradation. HIF-1α heterodimerizes with the constitutively expressed HIF-1β to generate the active transcription factors. Under normoxic, and obviously hyperoxic, conditions, HIF-1α is hydroxylated specifically on Pro residue 564 to generate a hydroxyproline derivative. This hydroxylated proline residue is recognized by the pVHL E3 complex that targets the molecule for ubiquitination and subsequent degradation. Under hypoxic conditions, HIF-1α is stable, as the efficiency of the hydroxylation reaction under these conditions is extremely low. Loss of VHL function stabilizes HIF-1α, which can explain the stimulation of vascular growth in tumors in which VHL is mutated or lacking. Since overexpression of VEGF alone or many of the other known target proteins of HIF does not lead to malignant transformation, and since WT VHL can restore normal growth control in these malignant cells, researchers assume that pVHL and/or HIF must have additional, yet unknown substrates.

Defects in deubiquitinating enzymes can also lead to aberrations in growth control and to tumorigenesis. Overexpression of the ubiquitin proteases (UBP) Unp has

been found in lung carcinoma in humans and in mouse tumors. Unp may have a role in regulating the degradation of specific, yet unidentified, substrates in these tissues, though it does not seem to be crucial for general proteolysis. An interesting deubiquitinating enzyme is CYLD that is involved in deubiquitinating K63-Ub from NEMO (NF-kB essential modifier), TRAF2 [tumor necrosis factor receptor (TNFR)-associated factor 2] and TRAF6. Ubiquitination of NEMO [a regulator of the IKK (IκB kinase) signaling complex] and the TRAF proteins (which are ubiquitin ligases), and generation of polyubiquitin chains linked via Lys63 of the ubiquitin moiety, does not target these proteins for degradation, but results in their activation. Thus, inhibition of deubiquitination of NEMO, by mutation in CYLD, for example, may lead to uncontrolled activation of the IKK complex with increased activity of NF-κB. Indeed, CYLD was found mutated in familial cylindromatosis, a rare pathology characterized by predisposition to multiple tumors of the skin appendages and the salivary gland.

4.2 Neurological Disorders

Accumulation of ubiquitin conjugates and/or inclusion bodies associated with ubiquitin, proteasome, and certain disease-characteristic proteins, have been reported in a broad array of chronic neurodegenerative diseases, such as the neurofibrillary tangles of Alzheimer's disease (AD), brainstem Lewy bodies (LBs) – the neuropathological hallmark in Parkinson's disease (PD), and nuclear inclusions in CAG repeat expansion (polyglutamine extension) disorders such as occurring in Huntington's disease. However, in all these cases, a direct pathogenetic linkage to aberrations in the ubiquitin system has not been established. One factor that complicates the establishment of such linkage is the realization that many of these diseases, such as Alzheimer's and Parkinson's, are not defined clinical entities, but rather syndromes with different etiologies. Accumulation of ubiquitin conjugates in Lewy inclusion bodies in many of these cases may be secondary, and reflects unsuccessful attempts by the ubiquitin and proteasomal machineries to remove damaged/abnormal proteins. While the initial hypothesis was that inclusion bodies are generated because of the inherent tendency of the abnormal proteins to associate with one another and aggregate, it is now thought that the process maybe more complex and involves active cellular machineries, including inhibition of the ubiquitin system by the aggregated proteins. This aggregation of brain proteins into defined lesions is emerging as a common but poorly understood mechanistic theme in sporadic and hereditary neurodegenerative disorders.

The case of Parkinson's disease highlights the complexity of the involvement of the ubiquitin system in the pathogenesis of neurodegeneration. Mutations in several proteins such as α-synuclein that plays a role in synaptic vesicles dynamics and that leads to its stabilization and accumulation, or in the deubiquitinating enzyme UCH-L1, have been described that link the ubiquitin system to the pathogenesis of the disease. One important player in the pathogenesis of Parkinson's disease is Parkin, which is a RING-finger E3. Mutations in the gene appear to be responsible for the pathogenesis of autosomal recessive juvenile Parkinsonism (AR-JP), one of the most common familial

forms of Parkinson's disease. Parkin ubiquitinates and promotes the degradation of several substrates, such as CDCrel-1 (cell division control related protein), a synaptic vesicle-enriched septin GTPase or the Pael receptor, a putative G protein-coupled ER transmembrane polypeptide. It is possible that aberration in the degradation of one of these substrates that leads to its accumulation is neurotoxic and underlies the pathogenesis of AR-JP. However, it should be noted that such a protein has not been identified with any certainty. Complicating the situation is the recent finding that inactivation of the Parkin gene in mice does not lead to any symptoms that are even reminiscent of Parkinson's disease.

Alzheimer's disease is characterized by accumulation/association of ubiquitin with the phosphorylated form of Tau in neurofibrillary tangles and senile plaques, two lesions that are characteristic of the neuronal abnormalities associated with the disease. However, the role of Tau and other putative target proteins in the pathogenesis of the disease is still not clear. A more direct, relationship between the ubiquitin system and pathogenesis of Alzheimer's disease was established with the discovery of a frameshift mutation in the ubiquitin transcript, which leads to extension of the molecule with 20 amino acid residues [Ub(+1)], and, which has been selectively observed in the brains of Alzheimer's disease patients, including those with late onset, nonfamilial disease. Ub(+1) is an efficient acceptor for polyubiquitination, though it cannot be activated by E1 (as it lacks the essential G76 residue) and be transferred to a substrate or to another ubiquitin moiety. The resulting polyubiquitin chains are refractory to disassembly by deubiquitinating enzyme, in particular, isopeptidase T that requires for its activity an exposed G76 residue at the proximal ubiquitin moiety. The accumulated polyubiquitin chains block proteasomal degradation, which results in neuronal apoptosis. Thus, expression of Ub(+1) in the brain, that increases apparently with aging, can potentially result in dominant inhibition of the ubiquitin-proteasome system, leading to accumulation of toxic proteins with neuropathologic consequences. Since (Ub(+1)) was described also in other disorders such as Down's syndrome or supranuclear palsy, it is clear that it is not entirely specific to Alzheimer's disease and a major problem of how the mutation leads to distinct pathologies in different patients remains unsolved.

4.3 Cystic Fibrosis

The cystic fibrosis gene encodes the CF transmembrane regulator (CFTR) that is a chloride channel. Only a small fraction of the protein matures to the cell surface, whereas most of it is degraded from the endoplasmic reticulum (ER) prior to its maturation by the ubiquitin system. One frequent mutation in the channel is ΔF508. The mutation leads to an autosomal recessive inherited multisystem disorder characterized by chronic obstruction of airways and severe maldigestion due to exocrine pancreatic dysfunction. Despite normal ion channel function, $CFTR^{\Delta F508}$ does not reach the cell surface at all, and is retained in the ER from which it is degraded. It is possible that the rapid and efficient degradation results in complete lack of cell surface expression of the F508 protein, and therefore contributes to the pathogenesis of the disease.

4.4 Immune Response and Inflammatory Disorders

A wide array of immune and inflammatory disorders can be caused by untoward activation of the immune system central transcription factor NF-κB. Activation of the factor stimulates transcription of many cytokines, adhesion molecules, inflammatory response, and stress proteins, and immune system receptors. The factor is activated by the ubiquitin system via a two-step proteolytic mechanism: (1) limited processing of the precursor protein p105 to yield the active subunit p50, and (2) signal-induced phosphorylation and subsequent degradation of the inhibitor IκBα that enables translocation of the factor into the nucleus where it initiates specific transcriptional activity. An interesting case in that respect involves mutations in NEMO. Mutations in the protein lead to a series of diseases that affect the skin, among them incontinentia pigmenti (IP), hypohidrotic/anhidrotic ectodermal dysplasia, but also, as expected, immune deficiency. The immunological and infectious features observed in patients result from impaired NF-κB signaling, including cellular response to LPS, and a variety of cytokines.

As described above, the HPV evolved a mechanism for proteolytic removal of p53 that enables continuous replication and propagation of the virus under conditions of DNA damage (insertion of the viral genome into the cellular DNA) that normally would have ended with p53-induced apoptosis. Two other viruses evolved mechanisms that also utilize the ubiquitin system, here to escape immune surveillance. In one case, the Epstein-Barr Virus (EBV) EBV nuclear antigen 1 (EBNA1) persists in healthy virus carriers for life, and is the only viral protein regularly detected in all EBV-associated malignancies, such as Burkitt's lymphoma. Unlike EBNAs 2–4 that are strong immunogens, EBNA1 is not processed and cannot elicit a cytoxic T-cell response. The persistence of EBNA1 contributes, most probably, to some of the pathologies caused by the virus. An interesting structural feature common to all EBNA1 protein is a relatively long and unusual glycine–alanine repeat at the N-terminal domain of the molecule. These Gly–Ala repeats constitute a cis-acting element that inhibits processing of the protein by the 26S proteasome and subsequent presentation of potential antigenic epitopes. Thus, the evolution of the Gly–Ala repeat enabled the virus to evade proteolysis and subsequent presentation to the immune system. An additional interesting observation involves the pathobiology of the human cytomegalovirus (CMV). The virus genome encodes two ER proteins, US2 and US11, that downregulate the expression of MHC class I heavy chain molecules. The MHC molecules are synthesized, transported to the ER where they are glycosylated, but shortly thereafter, in cells expressing US2 or US11, are transported back to the cytosol, deglycosylated, and degraded by the proteasome following ubiquitination. It appears that the viral products bind to the MHC molecules and escort\dislocate them to the translocation machinery where they are transported back into the cytosol.

Thus, it appears that evolution of many viruses has involved intimate recognition with a variety of proteolytic processes. This enabled the evolution of viral mechanisms that enhance the function, via subversion of the normal proteolytic machinery, of the viral replication and propagation machinery.

5 Summary and Outlook

Ubiquitination is involved in the majority of regulated protein degradation in the cell. For proteolytic purposes, usually a polyubiquitin chain is assembled on the protein allowing for tight binding to the 26S proteasome and efficient degradation. However, it should be emphasized that the process is not a unidirectional irreversible process and that ubiquitinated proteins are in a dynamic state balancing further rounds of ubiquitination, deubiquitination, or degradation by the proteasome. Ubiquitin-like proteins have also been found to be regulators of ubiquitination enzymes, or of intracellular targeting and localization. Many questions are still unanswered. Is ubiquitin a strict requirement for proteasome-dependent intracellular degradation, or can some substrates be degraded in an ubiquitin-independent manner? Furthermore, does the ubiquitin-proteasome pathway play additional nonproteolytic roles, such as protein remodeling, transcriptional activation or altering protein–protein interactions or with nucleic acids?

Because of the central role the ubiquitin system plays in such a broad array of basic cellular processes, development of drugs that modulate the activity of the system may be difficult. Inhibition of enzymes common to the entire pathway, such as E1 or the proteasome, may inhibit many processes nonspecifically, although at the right dosage they could affect some targets more than others. One example in which such inhibitors have shown to be beneficial is multiple myeloma, a malignancy that affects the bone marrow. Alternatively, development of small molecules that interfere with the recognition step between specific E3s and their substrates, or site-specific inhibitors of deubiquitinating enzymes may be productive approaches as well.

DNA (genetic or nucleic acid) vaccination
Stimulating an immune response to antigen(s) produced *in vivo* by cells transfected with injected expression plasmid DNA.

In genetic or nucleic acid (DNA or RNA) vaccination, antigenic information is delivered by *in vivo* expression of antigen from inoculated vector DNA (or RNA). Combining different antigen-encoding sequences, modifying their sequence and/or codelivering them with sequences encoding immune-stimulating factors (readily achieved through recombinant DNA technologies) strikingly enhances and modulates the immunogenicity of genetic vaccines and extends the repertoire of epitopes to which different compartments of the adaptive immune system can be specifically primed. Large-scale production of DNA vaccines, their formulation and alternative modes of delivery are currently optimized. Experimental DNA vaccines have demonstrated efficacy in priming antibody and/or cellular immune responses that protect against a variety of pathogens or transplantable tumors in animal models.

Genetic vaccination has therefore become an unrivaled tool in preclinical research. Although highly attractive in principle, the practical development of DNA vaccination for clinical applications is at an early and experimental stage, and will have to resolve different issues before entering widespread use.

1 Principles

1.1 The Emerging Technique of DNA Vaccination

Active immune prophylaxis (vaccination) has been undeniably one of the greatest achievements in medicine. Vaccine development started centuries ago with the identification and large-scale production of attenuated pathogens. As these induced only limited clinically apparent disease after infection but expressed many of the immunogenic determinants of the pathogenic strain, they could elicit specific, protective immunity with a low burden of clinical disease after deliberate infection. This vaccination strategy evolved into the use of defined products of pathogens feasible after their molecular identification, inactivation (if they displayed a pathogenic potential like toxins, for e.g.), and formulation (to enhance their often weak intrinsic immunogenicity).

Genetic (nucleic acid) vaccination is a recently developed immunization technique in which antigen is expressed in immunogenic form (i.e. able to specifically prime an immune response) from inoculated nucleic acid fragments containing antigen-encoding sequences. The nucleic acid fragments are engineered to efficiently support expression of the respective antigen(s) *in situ*. Nucleic acid fragments used as genetic vaccines can be either plasmid DNA (DNA vaccines), or messenger (m) RNA (RNA vaccines). If cloned into suitable expression vectors, and delivered in an appropriate formulation at a suitable dose by a suitable route, these vaccines efficiently prime humoral and cellular immune responses to a large spectrum of protein antigens. The different steps in developing and testing a DNA vaccine are outlined in Table 1.

1.2 The Novel Aspect of DNA Vaccination

Genetic vaccination introduced new prospects into the field of vaccinology, which remain to be fully explored. Antigens produced *in situ* from DNA or RNA vaccines undergo all posttranslational modifications, such as folding, glycosylation, and oligomerizations (with host cell-derived or pathogen-derived molecules). This is a key issue in eliciting protective, neutralizing antibody (B cell) responses to many pathogens, as these usually bind only conformational epitopes. This is difficult to achieve by recombinant protein vaccines (expressed in a heterologous source and subjected to extensive purification procedures), but comparatively easy to achieve by genetic vaccines. Furthermore, genetic immunization has been shown to be exceptionally potent in stimulating cellular (T cell) responses. Antigenic peptides are generated from proteins produced from the DNA or RNA vaccine within a cell of the host. These can be introduced into

Tab. 1 The objectives of consecutive steps in DNA vaccination and the issues that have to be addressed.

Step	*Objective*	*Issues to be addressed*
1.	Construction of DNA vaccine	• Type of vector • Selection of antigen, antigenic domains, epitopes • Choice of costimulator (cytokine) to be codelivered
2.	Evaluate antigen expression from DNA vaccine	• Test amount, integrity, longevity of antigen expressed from the DNA vaccine in transient transfection assays
3.	Large-scale DNA vaccine production	• Production and isolation of supercoiled plasmid DNA on a large scale • Quality control (quantitative assessment of contaminants) • Define storage and shipment conditions
4.	Formulation of DNA vaccine	• Nonpackaged (''naked'') plasmid DNA • Plasmid DNA packaged into liposomes, lipoplexes, polymers, cationic peptides, aluminum phosphate • Particle-coated plasmid DNA • Transformation of bacteria
5.	Delivery of DNA vaccine	• Intramuscular, subcutaneous, intradermal injection • Directly ''shooting'' DNA-coated gold microprojectiles into cells of the skin or the mucosa with the ''gene gun'' • Electroporation • Oral infection with DNA vaccine-carrying bacteria
6.	*In vivo* expression of antigen from a DNA vaccine	• *In situ* production of secreted antigen for priming antibody responses (humoral immunity) • Production and processing of antigen to (cross) prime T-cell responses (cellular immunity)
7.	Evaluate the vaccine-induced, specific immunity	• Follow over weeks postvaccination the specific serum antibody titers elicited • Measure numbers and functional properties of specifically primed CD4 and CD8 T-cell responses • Test response to boost injections • Test longevity of specific immunological memory • Test protective efficacy of the specific immunity
8.	Evaluate long-term safety issues	• Persistence of integrated plasmid DNA in the vaccinated individual • Autoimmune reactions

different processing pathways to generate presentation-competent major histocompatibility complex (MHC) (class I or class II) molecules, an essential prerequisite to prime cellular (T cell) responses. Modifications introduced into the antigen expressed by a DNA vaccine can facilitate its processing, thereby enhancing its antigenicity for T cells. Hence, both compartments of the specific immune system can be specifically stimulated by genetic vaccines.

Large numbers of vaccine candidates have been identified in different pathogens

through sequencing of their genomes. DNA vaccination is an attractive tool to evaluate this expanding repertoire of potentially interesting antigens to experimentally identify vaccine candidates, and to evaluate and modulate their immunogenicity. This can be achieved through either expression library immunization, or genomic vaccination. DNA vaccines opened new ways to produce (native, variant, or chimeric) antigens in heterologous expression systems including complex, chimeric antigens that prime multivalent responses to different proteins of the same or different pathogens. Genetic vaccination has been shown to efficiently prime immune responses to viral, bacterial, parasitic, and tumor antigens in informative, preclinical animal models (including e.g. mice, rats, woodchuck, pig, rabbit, sheep, cattle, dogs, monkeys, chimps, fish, and chicken). Some of these vaccines demonstrated protective value, that is, either induced specific resistance to pathogens, or primed immunity that specifically rejected transplantable tumors. DNA vaccination contributed to the rational design of adjuvants by defining factors that modulate the immunogenicity and/or the polarization of an immune response (i.e. the repertoire of immune effector functions specifically activated).

Though similar to vaccines based on recombinant viruses, genetic vaccination has distinct advantages. The antigen load delivered by a genetic vaccine is restricted and readily controlled. DNA or RNA vaccines do not replicate, thus avoiding the complications of uncontrolled infections in immunodeficiency conditions. Many viral proteins selectively and efficiently interfere with distinct steps of antigen-processing pathways that generate and/or present antigenic peptides. They thereby inhibit immune responses. This does not operate in genetic vaccines, which can focus the response to selected determinants and exclude suppressive interfering determinants or molecules. This stresses the value of genetic vaccination as an attractive candidate for prophylactic or therapeutic immunization against intracellular and extracellular (viral, bacterial, or parasitic) pathogens and cancer.

2 Techniques

2.1 Basic Structure of a Eukaryotic Expression Vector

A ''DNA vaccine'' is a nonreplicative, closed circular, double-stranded plasmid DNA often 2 to 10 kb in size. Plasmids >10 kb in size are often ineffective as DNA vaccines. The vector contains 2 units. In the *transcription unit*, the target antigen-encoding sequence is cloned downstream from appropriate promoter/enhancer sequences that control transcription in human cells. Additional sequences regulating transcription (e.g. intron sequences, termination, and polyadenylation signals) are usually inserted into this unit. The *bacterial backbone* is required to produce the recombinant DNA in bacteria. It contains a bacterial origin of replication and a prokaryotic selection marker. These sequences are not essential constituents of DNA vaccines as minimal expression constructs with a transcription unit (as a covalently closed, linear DNA fragment) but no bacterial backbone have been successfully used as DNA vaccines. Plasmids used for DNA vaccination should be designed to minimize chances for integration into the host cell genome although it is difficult to exclude integration events.

Most genetic vaccines are DNA vectors because work with DNA is easier than work with RNA. However, successful vaccination with antigen-encoding mRNA has been reported. The half-life of antigen expression, the persistence of the vaccine (and the related safety issues), and the intrinsic adjuvant effect differ between RNA- and DNA-based vaccines.

2.2 Increasing the Antigenic Information Delivered by DNA Vaccines

A key objective in vaccinology is the development of multivalent vaccines. This facilitates acceptance and logistics of the vaccine, and decreases its cost. It is furthermore desirable to include different antigens of the same pathogen to increase the chance to prime protective immunity in an outbred population. DNA vaccine technology offers different options to achieve this goal. The technology comprises expression strategies that range from the expression of ''minigenes'' encoding only a single epitope (at the one extreme), to the coexpression of different, large antigens at stoichiometrically defined ratios (at the other extreme).

Minigenes inserted into DNA vaccines focus the immune response to only a single epitope. This allows selective priming of a monospecific response, excluding interferences from coprimed and potentially suppressive (regulatory or immunodominant) responses. Although an interesting tool to study the requirements for the induction and regulation of monospecific immune responses, the approach has limited practical value. Combining different minigenes into a single sequence leads to polytope vaccines. Different short sequences encoding only a single epitope inserted into a DNA vaccine like ''pearls on a string'' are coexpressed by these vaccines that have been shown to successfully prime multispecific responses in inbred animal species. By fusing sequences encoding large antigens (or antigenic domains), DNA vaccines that produce chimeric antigens can be generated. Such constructs specifically stimulate multispecific T-cell responses. Coexpression of different antigens by either polycistronic expression constructs or bidirectional promoters, or a combination of both, generates complex expression vectors in which up to four complete antigens can be coexpressed at stoichiometrically defined ratios in immunogenic form. The large size of such vectors limits their usefulness as DNA vaccines. Expression of different antigens from alternative reading frames of the same nucleotide sequence is another way to increase the antigenic information delivered by a DNA vaccine of limited size. Coinjection of mixtures of DNA plasmid vectors encoding different antigens can prime multispecific antibody and T-cell responses. Extreme cases of mixing different expression plasmids are the immunization with mixtures of plasmids containing either large numbers of transcripts generated in expression libraries, or genomic fragments representing the complete genome of a pathogen. These studies showed that as few as one plasmid in 10^5 can give rise to an immune response. Rapidly evolving strategies for expressing antigens in DNA vaccines thus cover a broad range, from a strictly monospecific T-cell response, to a single epitope (present in a minigene), to multispecific T- and B-cell responses, to epitopes on independent antigens coexpressed by complex expression constructs.

2.3 Strategies to Enhance the Immunogenicity of DNA Vaccines

Immune responses to DNA vaccines alone have been weak, especially in humans. To be immunogenic (i.e. to prime a specific immune response), an antigen has to be produced by a DNA vaccine *in situ* in sufficient quantity with ''costimulatory signals'' mostly provided by antigen-presenting cells (APC). DNA vaccines can be designed to optimize antigen expression (through the choice of promoter sequences and optimization of codon usage) in the relevant tissues (secondary lymphoid tissues, i.e. lymph nodes) by appropriate APCs (macrophages, B cells, or dendritic cells). ''Costimulatory signals'' are ligands that activate receptors expressed by cells of the innate immune system or APC. Some of the molecularly defined ''costimulatory factors'' are of microbial origin while others are produced early in infection as ''danger signals'' by the host. Codelivery of such factors is often essential to prime a specific response, but can sometimes be bypassed by copriming responses in different compartments of the specific immune system (e.g. eliciting $CD4^+$ T-cell and $CD8^+$ T-cell responses to different epitopes of the same antigen). Here, the specific interaction of APCs with two different T-cell subsets allows initiation of both T-cell responses through mutual ''help.''

2.3.1 Synthetic Genes

Recently, synthetic genes have been designed with optimized codon usage that can strikingly enhance translation efficiency of antigens from some vector constructs. This technology is particularly interesting for expressing bacterial antigens in eukaryotic cells.

2.3.2 Promoter/Enhancer Sequences

To support optimal translation of the protein antigen from a DNA vaccine, the antigen-encoding sequence in the transcription unit has to be inserted downstream from strong promoter/enhancer sequences. Different promoter sequences can be used to construct effective DNA vaccines. Viral sequences (e.g. from cytomegalo, papova, or retroviruses), especially those from the immediate early region of the human cytomegalovirus (HCMV), have been favored as they drive high-level production of proteins in many cell types. Control sequences from other viruses (e.g. retrovirus or papova virus) or bacteria (e.g. borrelia) have been demonstrated to support high-level antigen expression from DNA vaccines that efficiently prime humoral and cellular immune responses. Alternatives to this viral control element have been developed because interferons (released early in an immune response) suppress many viral promoters. Mammalian cell–derived promoter sequences (controlling e.g. desmin, elongation factor-1α or metallothionein expression) have therefore been used to drive antigen production in DNA vaccine. Attempts to selectively express antigen from DNA vaccines in APCs (e.g. dendritic cells) through tissue-specific promoter/enhancer sequences have been less successful, presumably because tissue specificity of expression requires large, discontinuous sequence elements that are not yet correctly defined and are difficult to accommodate into a small DNA vaccine plasmid.

2.3.3 Enhancing Transfection Efficiency of DNA Vaccines

The DNA vaccine has to be delivered to the cytosol of the cell. The most critical process in transfection is the transport

of DNA from the cytosol to the nucleus. Tagging DNA vector constructs with viral sequences, or coupling DNA to nuclear localization signal peptides can facilitate the delivery of vector DNA to nuclei where transcription can take place.

2.3.4 Subcellular Targeting of Antigen Expression

To facilitate B-cell priming (antibody responses), antigen is usually expressed as a membrane-anchored or secreted protein because antibodies recognize cell surface or extracellular antigens in their native conformation. Antigens (or its fragments) should be expressed as intracellular proteins to facilitate T-cell priming because the T-cell receptor for antigen recognizes peptides generated by partial proteolytic degradation of antigens within cells. Antigen produced in the cytosol is degraded by proteasomes into peptides that are translocated into the endoplasmic reticulum by specialized transported molecules, where they are loaded to MHC class I molecules before trafficking to the cell surface. This is the prerequisite for priming $CD8^+$ T-cell responses. Priming $CD4^+$ T-cell responses is facilitated if antigens (or their antigenic fragments or epitopes) are targeted to a vesicular pathway. This allows their degradation in a specialized endolysosomal compartment. The generated peptides are ''loaded'' to MHC class II molecules that are transported to the cell surface. This is a prerequisite for priming $CD4^+$ T-cell responses. Subcellular targeting of antigen traffic by appropriate engineering of the DNA vaccine can thus be used to prime selected compartments of the specific immune system.

2.3.5 Targeting Antigens to APCs

Uptake of secreted antigen produced from a DNA vaccine can be targeted to professional APCs to enhance its immunogenicity. This can be achieved by fusing the antigen-encoding sequence to a ligand of a receptor expressed (preferentially or exclusively) by APCs. Ligands binding CD58, CD40, or CD80/CD86 have been used for this purpose. Such strategies also facilitate uptake of antigen by APC through receptor-mediated endocytosis, an efficient way to deliver antigen directly to some antigen-processing compartments. Similarly, antigen released at the site of DNA vaccine inoculation can be targeted to lymph nodes (the site of priming of immune responses) by fusion with CD62L (L-selectin) that binds to a receptor selectively expressed by high endothelia of venules of these tissues.

2.3.6 Codelivery of Antigen with Immune-stimulating/modulating Cytokines and Chemokines

Short-range humoral mediators regulate most steps of the immune response, that is, specific activation (priming), clonal expansion, effector cell differentiation, and memory cell generation. The factors exert their function *in situ* in a paracrine or autocrine manner at the right site (often in synapse-like contact areas between cells) at the right time (often as a short pulse at a critical stage of the process) in the right dose (often at very low concentrations). It is difficult to develop a DNA vaccine that codelivers a cytokine or chemokine signal together with the antigen and can fulfill all these requirements. Nevertheless, many cytokines have been reported to enhance priming of humoral and/or cellular immune responses when codelivered with DNA vaccines. In addition to enhancing the immunogenicity of an antigen, codelivered cytokines modulate the spectrum of immune effector functions that are specifically stimulated.

Cytokines reported to enhance and modulate DNA vaccine-induced immune responses include GM-CSF, IL-2, IL-15, IL-6, interferon-α, IL-10, or IL-12/IL-23. Expression plasmids encoding chemokines act as strong adjuvant for eliciting Th1-derived immunity when inoculated together with DNA vaccines. In these experimental settings, cytokines were codelivered by DNA vaccines as fusion constructs with the antigen, as plasmid mixtures, or as polycistronic constructs. Delivery of cytokines or chemokines (that are autoantigens) by DNA vaccination can prime autoreactive immune reactivities that neutralize the bioactivity of these factors. Repeated administration of DNA vaccines containing chemokine-encoding genes inhibited the development and progression of arthritis through the development of chemokine-neutralizing autoantibodies, even when administered after the onset of disease. However, the appearance of autoantibodies binding cytokines or chemokines is also a regular phenomenon in many chronic infections. It is unexpected that such a wide variety of cytokines with very different modes of action enhance priming of specific immunity by DNA vaccines. It is uncertain whether the reported findings have general validity for vaccination protocols in species other than the mouse. However, they certainly provided information on the molecular basis of ''adjuvant effects'' that until recently were largely empirically defined.

2.3.7 Codelivery of Transcription Factors

Proteins produced from DNA vaccines by transfected cells can include transcription factors or antiapoptotic molecules. An example is the codelivery of interferon regulatory factors (IRFs). Using an experimental DNA vaccination model, it was shown that IRF-3 had good activity for T cells, IRF-7 had good activity for both antibody and T cells, and IRF-1 had good activity for antibody. This opens a new field of manipulating intracellular signaling pathways to induce, enhance, or modulate inflammatory reactions to create a supportive milieu for the initiation of an adaptive immune response. A further option is to extend the life span of antigen-bearing APCs by codelivering antiapoptotic signals that prolong the period they can specifically stimulate T-cell responses. These strategies target the differentiation and the functional life span of APC, the key regulators at the interface between the innate and adaptive immune system that regulate priming, magnitude, and polarization of an immune response.

2.3.8 CpG-containing Oligodeoxynucleotides(ODN)

Motifs in DNA sequences containing cytosine/guanine (CpG) nucleotides flanked by 2 to 3 other nucleotides exert potent immune-stimulating signals through binding to the toll-like receptor (TLR) 9. Such motifs are present in many plasmid DNAs used for genetic immunization. It has been proposed that they provide a critical contribution to the immunogenicity of these constructs. This is not supported by the observation that TLR9-deficient mice are perfectly able to respond to DNA vaccines. The role of CpG-containing motifs in the immunogenicity of DNA vaccines is thus unresolved.

2.3.9 Stress Proteins

Heat shock or stress proteins (hsp) have been incorporated into DNA-, protein-, or peptide-based vaccines as either antigens, chaperones, or adjuvant. T- cell reactivities to many bacterial and protozoan

pathogens (e.g. mycobacteria, chlamydia, yersinia, malaria plasmodia, or leishmania) are directed against hsp epitopes. An immunogenicity-potentiating role of hsp is apparent in DNA vaccines in which antigen and hsp molecules are linked, either by fusing sequence encoding antigens to hsp-encoding sequences, or by fusing hsp-capturing domains to antigen-encoding sequences. This strikingly enhances the potency of the vaccine to elicit, for example, tumor-rejecting T-cell responses indicating a potent adjuvant effect of hsp molecules.

2.3.10 Copriming Specific "Help"

DNA vaccines can deliver large protein antigens that either contain naturally or are engineered to contain epitopes that stimulate $CD4^+$ T-cell "help." This specific T-cell reactivity can "help" prime either B cells (enhancing antibody responses), or $CD8^+$ T cells (cell-mediated cytolytic and/or cytokine response). This has been used to increase the potency of DNA vaccines for priming antibody or cytotoxic T-cell responses.

2.4 Production and Quality Control of DNA Vaccines

Traditional production methods used sophisticated methodology to separate DNA from contaminating organic components. In contrast, new processes for manufacturing plasmid DNA pharmaceuticals have been significantly improved and are shorter but also fulfill established GMP (*good manufacturing practices*) guidelines. The core elements used in manufacturing and quality control are nearly identical (generic) for plasmids <10 kb in size, but require modifications for the manufacturing and formulation process of larger plasmids. The first step in plasmid production is the stable transformation of a defined *Escherichia coli* host strain with the plasmid DNA vector, followed by cultivation in a bioreactor, alkaline lysis of the bacterial biomass, followed by several filtration and chromatography steps to obtain DNA pharmaceuticals of the required quality. The most important requirements for the plasmid purification process are:

1. separation of plasmid DNA from substances derived from the DNA isolation process or the bacterial host cell;
2. purification of the "supercoiled" (ccc) form from other plasmid DNA forms to obtain a homogeneous product; and
3. protection of the ccc form throughout the manufacturing, formulation, storage, and delivery process.

2.4.1 Quality Control and Safety in Plasmid DNA Vaccine Production

Plasmid DNA quality depends on manufacturing, storage, and application. Its safety depends on vector construction, characterization, and testing by toxicology before clinical trials. These parameters are well defined but subjected to ongoing improvements regarding analytical techniques. Table 2 shows relevant quality control tests for in-process-control (IPC) and product release. A safe, state-of-the-art manufactured, well-controlled product is usually requested, the relevant guidelines for the specification for clinical material are currently subject to continuous improvements.

2.4.2 Plasmid Identity

Plasmid DNA is tested for identity by digestion with a panel of restriction enzymes followed by agarose gel electrophoresis (AGE) to determine the length of the digestion fragments obtained. These have to

Tab. 2 Important physical and microbial specifications for quality assurance and quality control of plasmid DNA vaccines.

	Test	***Analytical method***
1.	DNA concentration	UV Absorption (260 nm)
2.	General purity	UV Scan (220–320 nm)
3.	Homogeneity (ccc content)	CGE (*capillary gel electrophoresis*)

conform to the calculated lengths of the fragments. The nucleotide sequence of the plasmid is determined by sequencing the plasmid DNA.

2.4.3 Animal-free DNA Production

Because RNA from *E. coli* is the major contaminant of the plasmid DNA produced, a typical and critical process in its purification is usually the treatment with ribonucleases (e.g. RNase A from bovine pancreas) to destroy RNA molecules. Current pharmaceutical DNA manufacturing technology avoids bovine RNase treatment to increase the quality of the product, even in large-scale production of GMP-grade DNA. To ensure product purity and safety, no enzymes should be used in the purification and cultivation processes that thus should be carried out without animal-derived substances.

2.4.4 Genomic DNA

A major impurity in plasmid DNA preparations is chromosomal and genomic DNA (gDNA) from plasmid-producing bacterial cells. The most critical step is alkaline lysis, in which gDNA as well as plasmid DNA are denatured by alkaline pH shift. As chromosomal DNA is extremely sensitive to shearing, this can result in its fragmentation. Some gDNA fragments can migrate as distinct bands in AGE while smaller fragments can be detected as undefined smears in overloaded AGE analyses. Sensitive assays, for example, Southern blot hybridization or quantitative PCR, are often used to quantify gDNA contamination. While contaminations of gDNA in plasmid DNA preparations were often in the range of 5 to 10% in the past, novel purification technologies allowed a significant reduction.

DNA species must be completely removed from the manufacturing environments at product change. This aspect of changeover is important if different DNAs are produced within the same facility.

2.4.5 Host Cell Impurities

Host cell–derived contaminants (e.g. proteins, RNA, lipopolysaccharides) should be reduced to minimal concentrations in the plasmid DNA purification process. Proteins can be detected by colorimetric assays. Quantification of residual RNA is performed by fluorescence assays after digestion of plasmid DNA with DNase. Lipopolysaccharides can be detected in the *Limulus polyphemus* lysate assay. A striking reduction of these impurities has to be achieved before the manufactured DNA can be used in research or clinics.

2.4.6 Importance of Supercoiled Forms

Structural homogeneity of plasmid DNA is usually determined by AGE. Different forms of plasmid DNA with an identical nucleotide sequence are present within a given DNA preparation from *E. coli* cells and can be assigned to different AGE bands. However, the assignment of bands to different plasmid topologies is complicated because the electrophoretic mobility of plasmids of different shapes changes with the electrophoretic operating conditions. In addition, the quantification of DNA plasmid forms based on signal intensity of stained bands in AGE may not be reliable due to nonlinear responses. It is well known that typically only one band (the ccc form) is observed when only a small amount of plasmid DNA is applied to AGE while two prominent bands (ccc and a slower migrating, nicked, open (oc) form), are usually revealed by standard AGE. Capillary gel electrophoresis (CGE) allows the identification and more reliable quantification of all forms of plasmid DNA. CGE is performed using thin (diameter 100 µm), coated capillaries with a length of 40 to 60 cm, filled with a liquid polymer, for example, a solution of hydroxypropylmethylcellulose. Electrophoretic separation takes place by applying a high 5 to 30 kV voltage followed by high-resolution detection using special intercalating dyes. This allows quantitative detection of all plasmid forms by laser-induced fluorescence. This automated system offers high reproducibility, reliable quantification, and short analysis time. In contrast to AGE, quantification of plasmid forms by CGE is possible in a wide range of linearity and needs only 50-ng plasmid DNA.

The ccc plasmid topology is the most compact structure and is expected to be the most active topology. Other plasmid topologies also appear often and have to be eliminated from the product. If one strand is broken (nicked), the oc form results. This is caused either naturally by processes within the plasmid-producing bacteria or during processing (enzymatic or mechanic degradation) of the biomass. Linear forms are generated if both strands are cleaved once at approximately the same position. In addition, plasmids may appear as oligomeric forms (e.g. concatemers) detectable in different topologies (Fig. 1a,b). The only intact, nondamaged form is the ccc supercoil DNA because linear forms and oc forms are randomly damaged at different gene locations and may be inactive if promoter- or antigen-encoding regions are destroyed. Any process development must therefore be subjected to IPC systems to assess the characteristics of the produced plasmid molecules. In particular, methods are required for obtaining supercoiled ccc plasmid DNA in pure form.

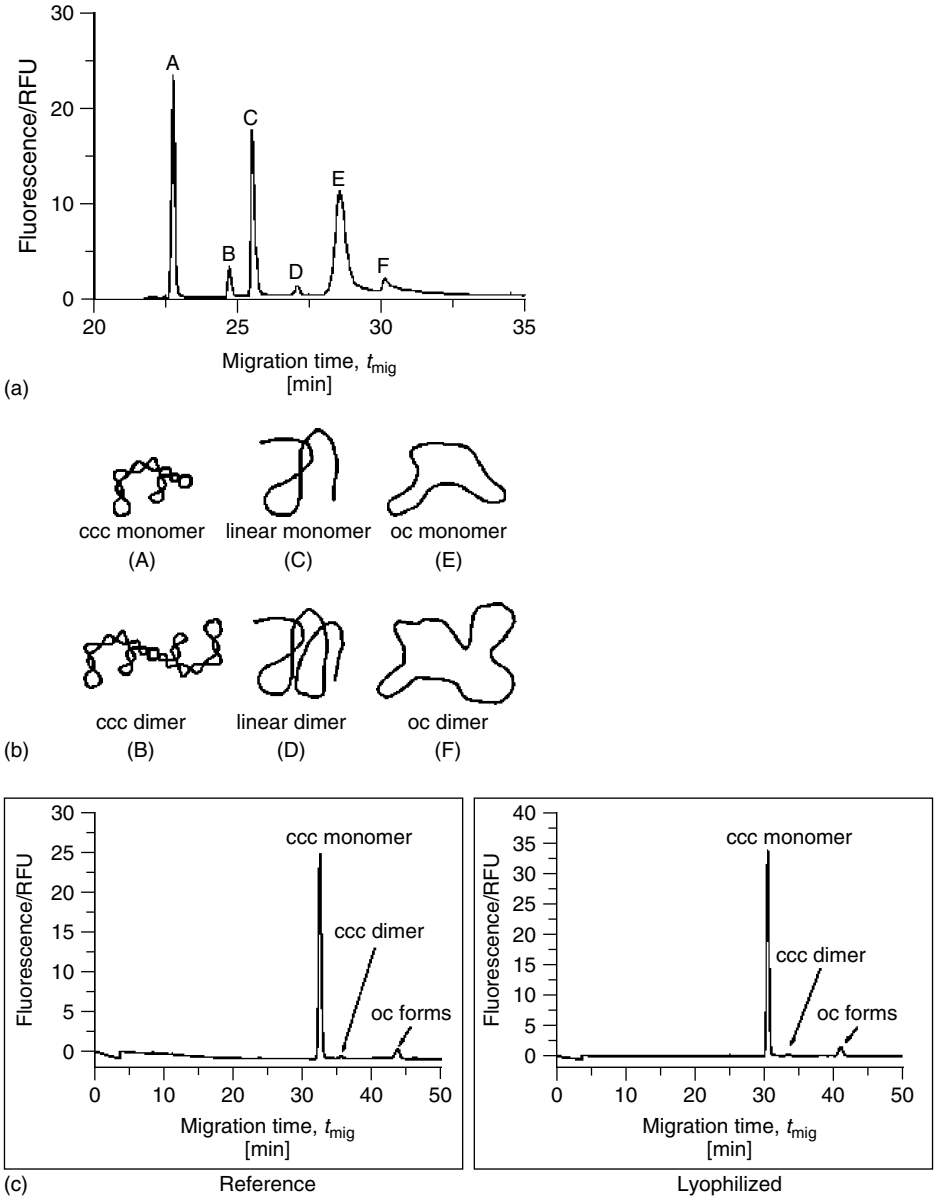

Fig. 1 (a) Electropherogram indicating individual peaks of (b) various plasmid topologies, (c) visualized in the corresponding graph (a and b from Schleef, M., Schmidt, T. (2004) Animal-free production of ccc-supercoiled plasmids for research and clinical applications, *J. Gene Med.* **6**, S45–S53). The comparison of the plasmid topology pattern in DNA before (reference) and after lyophilization indicated no difference ((c) from Schmidt, T., Voß, C., Schleef, M. (2005) From Bulk to Delivery: Plasmid Manufacturing and Storage, in: Schleef, M. (Ed.) *Plasmid Pharmaceuticals*, Wiley-VCH, Weinheim).

2.5 Stability of DNA Vaccines

Manufacturing, formulation, storage, and application of DNA vaccines should be easy and cost efficient. Physical and chemical stability of plasmid DNA is required for DNA-based pharmaceuticals that can be stored, shipped, and applied even under critical environmental conditions. DNA delivery sometimes requires protection of the active pharmaceutical ingredient, which is an issue of DNA formulation.

2.5.1 Storage Stability of Plasmid DNA

Recent studies have shown alterations of plasmid DNA stored at different temperatures (e.g. −80, −20, or +4 °C) over 13 to 30 months. Plasmid DNA stored at −20 or −80 °C shows no degradation of the intact ccc into the damaged oc form. In contrast, ccc plasmid DNA stored at +4 °C is degraded into damaged oc and linear forms within months. Hence, storage conditions are critical to maintain the bioactivity of plasmid DNA pharmaceuticals. An attractive option in plasmid DNA storage and shipment is lyophilization, a technology often applied to other vaccines or pharmaceuticals. Although lyophilization of plasmid DNA has been accompanied by damage to its ccc supercoil topology and insufficient reconstitution, recent improvements in lyophilization could be shown not to damage ccc supercoil plasmid DNA (Fig. 1c).

2.5.2 Stability in Plasmid Vector Applications

Very little is known about the *in vivo* fate of a formulated DNA vaccine after its injection. Complexing DNA with cationic agents provides some physical protection *in vivo* but raises the question whether plasmid topology is maintained during formulation. This can be determined by CGE analysis of small samples reextracted from the complexes.

2.6 Delivery of DNA Vaccines

DNA vaccines can be delivered either as nonpackaged (''naked'') plasmid DNA, or as formulated or ''packaged'' plasmid DNA. A single (intramuscular, subcutaneous, or intradermal) injection of a fairly high dose (50–100 μg/mouse) of ''naked'' plasmid DNA into mice usually primes an immune response. Unfortunately, this is not reproducible in other species, including man. Many formulations have therefore been used to formulate plasmid DNA in an effort to facilitate *in vivo* its half-life, its transfection efficacy, and the expression of an immunogenic product from the vector. These included incorporation into cationic liposomes, virosomes or lipoplexes; binding to cationic polymers, peptides or proteins; mixing with aluminum phosphate; *in vivo* electroporation; or treatment with chloroquine (to reduce plasmid DNA degradation in an acid endolysosomal compartment after uptake). Plasmid DNA vaccines can be introduced into invasive bacterial cells (from strains that are used for vaccination). Following infection after oral vaccination, the DNA vaccine is directly delivered to the cell. Another promising delivery technique is a biolistic system in which DNA-coated gold microprojectiles are directly propelled into cells in the living animal (''gene gun''). This technique has been successful in genetic vaccination of many animal species, and has been employed in clinical trials. The plethora of alternatives in this rapidly evolving field of delivery techniques is an indicator that the issue is not yet resolved

in a practical way. This is a major drawback in introducing this technique into clinical practice.

2.6.1 Combining DNA Vaccines and Protein Vaccines

Traditional protein antigen vaccines and DNA vaccines can be combined. Protein antigens and DNA vaccines emulsified together in aluminum phosphate can prime multivalent immune responses to both components of the vaccine. DNA vaccines, delivered as a complex with antigenic, cationic peptides, or proteins can prime immune responses to epitopes in the DNA vaccines and in the cationic antigens. These preliminary data suggest that DNA vaccines could be a part of multicomponent vaccines.

2.6.2 Routes of DNA Vaccine Delivery

Similar to the many formulation protocols, many different routes of plasmid DNA delivery have been described. These include intramuscular, subcutaneous, or intradermal injection of ''naked'' or formulated plasmid DNA, or intradermal and mucosal delivery of plasmid DNA by the gene gun. Finding a reliable, easy, safe, and accepted route for delivering DNA vaccines in clinical practice is a high priority in the field.

3 Applications

3.1 Priming Immune Responses by DNA Vaccination

DNA vaccines effectively prime and boost immune responses, which is evident by the generation of specific (B and/or T cell) reactivity and/or the specific induction of protective memory against pathogens. An immune response primed by a conventional (e.g. protein-based) vaccine can be boosted by DNA vaccination. A response primed by DNA vaccination can be boosted by alternative vaccine formulations of the relevant antigen (e.g. a protein antigen or a recombinant virus), a protocol apparently eliciting superior protective immunity to some clinically important pathogens. Most experimental studies have been performed on the mouse, in which immune responses can be readily primed by different DNA vaccination protocols and in which many specific readout assays are available. In contrast, DNA vaccination had mixed successes in species other than the mouse, including man.

3.1.1 Priming T-cell Responses

In contrast to most alternative vaccines, DNA vaccines are particularly potent in priming MHC class I-restricted CD8 T-cell responses and MHC class II-restricted CD4 T-cell responses. Priming CD8 T-cell responses by genetic vaccination can be indirect or direct. Antigens produced from a DNA vaccine by transiently transfected cells (myocytes, keratinocytes) seem to be transferred to professional APC that present their epitopes in an immunogenic way. This indirect way of antigen expression, processing, and presentation is called *cross-priming*. In contrast, resident dendritic cells (DC) in the targeted tissue may be directly transfected by a DNA vaccine and process the antigen it produces for immunogenic presentation. Direct priming may operate after intradermal delivery of low amounts of plasmid DNA with the gene gun. It is complicated by the finding that resident DC usually are immature and tend to elicit tolerogenic or regulatory rather than effector/memory T-cell responses. Engineering antigenic

constructs in DNA vaccines to target APC in lymph nodes, codelivery of factors that enhance their immunogenicity, and an increase of antigenic information they carry offer attractive prospects for optimizing potent T cell–stimulating vaccines. DNA vaccination could prime T-cell responses to nonstructural viral antigens that support cross-strain protection, and could override nonresponder status. The exceptional potency of DNA vaccines to elicit specific T-cell responses has generated the hope that it might contribute to solve some major current health issues, such as the development of vaccines to be used against, for example, HIV, mycobacteria, papillomaviruses, or cancer.

3.1.2 Priming B-cell (Antibody) Responses

DNA vaccines expressing secreted antigen readily prime antibody responses. In mice, injection of a high dose of a DNA vaccine induces high titers of specific IgG2a antibodies (indicating Th1 priming), while injection of a low dose of the same DNA vaccine induces preferentially specific IgG1 antibodies (indicating Th2 priming). Antibody responses have been elicited after DNA vaccination to subdominant (cryptic) epitopes of antigen fragments that were difficult to detect by conventional vaccination strategies. *In situ* production of native antigen with all post-translational modifications allows priming of neutralizing antibodies to conformational epitopes that are usually CD4 T-cell "help"-dependent.

3.2 DNA Vaccination as an Experimental Tool

Expression library immunization is a DNA vaccine–based tool to identify vaccine candidates out of a large number of gene products expressed by a pathogen. Although its usefulness has only been demonstrated in a few systems, it may gain in interest as more genomes of pathogens are sequenced. Owing to the ease of deleting or recombining fragments of open reading frames, DNA vaccines are furthermore useful in identifying antigenic domains or epitopes of complex antigens. Once identified, these antigenic determinants can be combined into polyvalent, chimeric vaccines that contain immunodominant domains from different antigens and/or different pathogens. The selective incorporation of an antigenic domain or epitope into a DNA vaccine has been used to generate monospecific immunological probes, either monoclonal antibodies, or T-cell clones.

3.3 Potential Advantages of DNA Vaccination

Genetic vaccination can provide long-lived immunity, and multivalent vaccines can be given by a single inoculation. As DNA vaccines to different pathogens are produced using similar or identical generic production techniques, the development of formulation, delivery, and safety issues are greatly simplified. A particular feature of DNA vaccination is its exceptional potency to prime T-cell responses. DNA vaccines have been shown to override low responder status in preclinical animal models to subdominant T-cell epitopes. It can prime T cells to nonstructural virus proteins, thereby extending the repertoire of vaccine candidates that can be used to control virus infections. Priming T-cell immunity to (nonvariant) internal viral antigens can establish cross-strain protection against pathogenic viruses, a goal difficult to obtain with conventional vaccines that rely on the induction of

neutralizing antibody responses against variant envelope proteins. Newborn mice immunized with DNA vaccines develop balanced Th1/Th2 immune responses. DNA vaccination is thus an attractive option to prime antiviral Th1 immunity in neonates or young children, overcoming the bias for specific tolerance induction of the neonatal immune system. Hence, this type of vaccine may have advantages for protection early in life, an objective difficult to achieve with most conventional vaccines currently available.

4 Perspectives

4.1 Achievement and Unresolved Issues of the Technology

The technology introduced only a decade ago has made striking progress in vector design, large-scale DNA production, and optimizing the antigenic information and the immunogenicity of antigens, their domains or selected epitopes. Major unresolved issues are the efficient delivery of the vaccine in man and the critical assessment of safety issues. While the former needs an easy, safe, and reliable technique soon, the latter will only be resolved with clinical experience accumulating over extended time spans.

4.2 Preclinical and Clinical Trials that Test Potential Applications of DNA Vaccination in Clinical Practice

In informative preclinical animal models of *infectious diseases*, DNA vaccination proved effective as a *prophylactic* vaccine against a broad spectrum of pathogens including, for example; influenza, malaria plasmodia, leishmania, mycobacteria, simian immunodeficiency virus, papilloma virus, and herpes viruses. Even more challenging is the development of therapeutic vaccines against HIV, hepatitis B and C virus, and malaria plasmodia or mycobacteria. DNA vaccine-based specific immunotherapy protocols against these and other pathogens that cause chronic infection are under investigation in various informative animal species.

The specific *immunotherapy of cancer* relies on induction of efficient cellular immunity to tumor-associated antigens by therapeutic vaccination. Because it efficiently primes T cells, DNA vaccination has played a prominent role in designing treatment schemes for the treatment of growing tumors in preclinical models.

DNA vaccination primes potent Th1 immunity. An established Th2 bias of an immune response can be specifically converted into a Th1 phenotype by boosting with the relevant antigen in conjunction with a strong Th1-driving stimulus. DNA vaccination has been successfully used in a preclinical model to specifically suppress established *allergy* by converting the pathogenic Th2 response into a harmless Th1 response.

These are some of the many potential areas of interest where DNA vaccination may find clinical applications. Clinical trials using either DNA vaccination alone, or DNA vaccine priming and boosting with recombinant viruses have been initiated. These include vaccination of uninfected volunteers to assess safety and immunogenicity, and therapeutic vaccination of chronically infected or cancer-bearing patients to assess safety and therapeutic efficacy. An infectious disease targeted with high priority is AIDS caused by the human

immunodeficiency virus (HIV). DNA vaccines containing >20 CD8 T cell–defined epitopes (polytope vaccines) of HIV, its envelope (gp160, gp40, gp120) protein or its antigenic fragments, its nucleocapsid gag (p17, p24), a fusion protein containing gag and polymerase, or its small regulator proteins (tat, nef) from different HIV clades have been tested in Phase I clinical trials using different formulations and different constructs, sometimes with selected cytokine adjuvants (e.g. IL-2). In addition, some clinical trials have been initiated to assess the efficacy of DNA-based vaccination for the specific control of herpes viruses; human papilloma virus, Ebola virus; *Plasmodium falciparum* (causing malaria), or mycobacteria. The therapeutic value of DNA vaccines is currently tested in melanomas, renal and prostate cancers, hepatocellular carcinoma, chronic lymphatic leukemia, and colon cancer. It is expected that these studies will generate a wealth of information on the safety, immunogenicity, and therapeutic efficacy of DNA vaccination strategies.

4.3 Risks and Safety Issues Raised by DNA Vaccination

Only limited experience on the long-term safety of DNA vaccination has been derived from preclinical animal models and their validity for the critical assessment of the risks under clinical conditions is uncertain. The following potential risks of DNA vaccination have been discussed.

Integration of plasmid DNA into coding or regulatory sequences of cellular DNA could lead to *insertional mutagenesis*. It is conceivable that insertion into the genome of the germline could occur as a rare event. The integrated ''foreign'' DNA could contribute to tumor development by activating oncogenes, inactivating tumor suppressor genes, or inducing chromosomal instability through the induction of chromosomal breaks or rearrangements. DNA vaccines usually produce only low amounts of antigen that may induce low zone tolerance rather than immunity. This possibility has not been verified experimentally up to now. In contrast, it has been shown that DNA vaccine-primed responses that were undetectable post-priming could be readily boosted. Some DNA vaccines were exceptionally potent raising the concern that they could induce autoimmunity specific for either codelivered, autologous costimulator molecules (cytokines, chemokines), or for the transfected cell. As autoantibody responses against cytokines regularly occur during tissue damage in the course of chronic infections, it is uncertain whether this is a complication typical for DNA vaccination. Anti-DNA antibodies have been only rarely induced by DNA vaccines in experimental animal models. As the *in vivo* transfection of cells by injected plasmid DNA of the vaccine is not controlled, and destructive Th1 immune responses are elicited, immune-mediated tissue lesions could occur. Whether this is an advantageous (deleting genetically altered cells) or deleterious event is uncertain. Antibiotic resistance genes are usually transferred with the DNA vaccine, but the stable induction of this resistance in vaccinated individuals is an unlikely event because resistance genes are expressed under prokaryotic promoter control in the bacterial backbone, and not expected to be expressed at high levels for extended periods of time by human cells. Furthermore, most of the antibiotics used for selection are not of clinical importance.

Keywords

AIDS
Acquired immunodeficiency syndrome.

CTL
Cytotoxic T lymphocytes; a type of white blood cells that can kill cells infected with viruses.

DNA
Deoxyribonucleic acid.

HIV
Human immunodeficiency virus.

SIV
Simian immunodeficiency virus.

Vaccine
An agent that stimulates an immune response in the body in order to prevent future infection.

Human immunodeficiency virus/acquired immunodeficiency syndrome (HIV/AIDS) has reached pandemic proportions globally. Currently, there are approximately 40 million individuals infected with HIV-1. The most likely solution for this disease is a preventive vaccine that can be distributed worldwide. Despite intense efforts, the development of a vaccine against HIV has not been realized. Here, we review the challenges that have impeded progress and the approaches that are currently under consideration. Vaccination results from human trials and animal models are also discussed.

1 Introduction

The first cases of Acquired Immunodeficiency Syndrome (AIDS) were described in homosexual men in the United States in 1981. Within three years after the initial reports, French and American scientists confirmed that the causative agent for AIDS was a retrovirus, the human immunodeficiency virus (HIV). Today, more than 20 years later, over 20 million

individuals have died of AIDS; and in 2004, approximately 40 million people globally are infected and living with HIV-1.

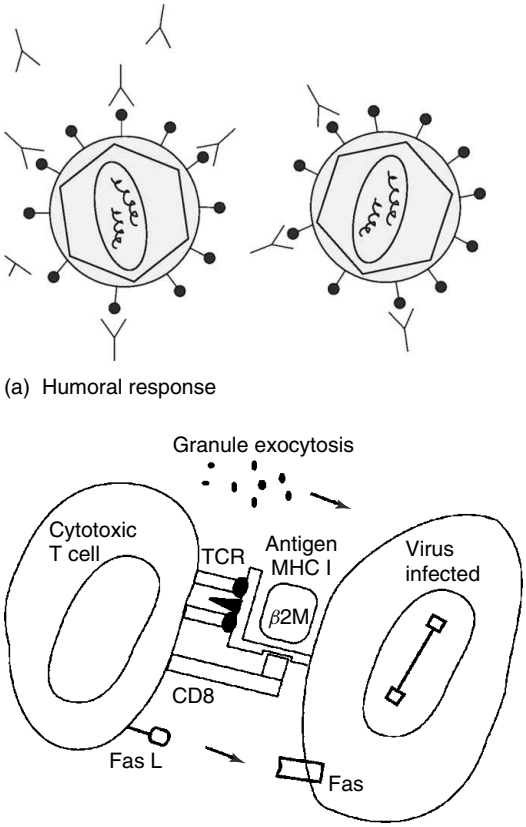
The worldwide trend for HIV/AIDS is not encouraging. In 2003 alone, 3 million individuals became newly infected with HIV-1 in sub-Saharan Africa; an additional 1 million new cases of HIV-1 infection emerged in Asia. Even in developed nations, HIV-1 infection remains on the rise. Today, more than 950 000 and 580 000 individuals in the United States and Western Europe, respectively, are seropositive for HIV-1. New advances in the treatment and prevention of HIV-1 also appear to be insufficient to halt the spread of HIV-1. The United Nations estimate that only 7% of people in developing countries have access to antiretroviral treatment, and that only 20% of people worldwide are reached by HIV-1 prevention programs. Indeed, data from countries with ongoing HIV/AIDS treatment/prevention initiatives have shown that such approaches have failed to effectively blunt the spread of AIDS. In this light, past vaccination successes in controlling viral epidemics such as smallpox and polio suggest that a cost-effective preventive HIV/AIDS vaccine is reasonably the best public health solution.

The development of an effective, prophylactic HIV-1 vaccine has proven to be extremely difficult. Despite an extraordinary devotion of time, effort, and money, the incremental advances in our attempts to generate immunogens, which offer protective immunity to HIV-1, have been discouraging. Nevertheless, this slow progress has to be viewed in the context that to date no effective vaccine against any retrovirus has been developed. Scientifically, we are just commencing our understanding of the *in vivo* immunological parameters that dictate durable control over retroviral infections. In this chapter, we summarize the approaches, the progress, and our current state of immunological knowledge in developing an HIV/AIDS vaccine.

2 Immune Responses Elicited by Viruses and Vaccines

Viruses come in different flavors. Smallpox, polio, and measles viruses cause acute infections. These viruses, after an episodic presence, are normally cleared by the host with no lasting sequelae. By contrast, other viruses like the herpesviruses, present and maintain chronic and/or latent infections. The latter pathogens establish a life-long parasitic relationship with their hosts, and likely survive in this relationship because they have evolved mechanisms for evading immune-mediated elimination.

The adaptive humoral and cell-mediated immunities are the prototypic responses mounted by human host to all viral infections (Fig. 1). In response to replication-competent viruses, humans are, in principle, capable of generating neutralizing antibodies (humoral immunity) and cytotoxic T lymphocytes (CTL) (cell-mediated immunity). Our current understanding of virology and vaccinology suggests that the key immune response, which clears an acute infection, preventing chronicity, correlates with virus-specific neutralizing antibody. On the other hand, cell-mediated immunity is generally deemed necessary to control a chronic viral infection, once established. The latter view does not, however, exclude a protective role for antibodies in chronic infection.



(a) Humoral response

(b) Cell-mediated response ($CD8^+$ T cells)

Fig. 1 The two major types of adaptive immunity triggered by replication-competent viruses in mammalian hosts. (a) Humoral or antibody responses are elicited. Antibodies represented by the Y symbol can target epitopes on the virus, ''neutralizing'' the virus and preventing infection of cells. (b) MHC class I restricted cytotoxic T-lymphocyte response can also be provoked. The diagram shows a cytotoxic ($CD8^+$) T-lymphocyte, which recognizes through its T-cell receptor (TCR) antigen (brown triangle) presented by the MHC class I molecule on the surface of a virus-infected cell. The cytotoxic T cell can kill the virus-infected cell via two mechanisms, exocytosis of toxic granules that perforate target cell membranes and induction of apoptosis using Fas ligand (Fas L)–Fas interaction. β2M = β-2 microglobulin. (See color plate p. xxvii.)

A requisite step in the lifecycle of all retroviruses is the integration of the viral genome into the host's cellular chromosome. Hence, infection by a retrovirus, if initial entry into permissive cells is not prevented by neutralizing antibody, has the potential to persist and spread chronically within the host so long as infected cells are not eliminated. Early infection studies of HIV-1 in the chimpanzee model showed that passive infusion of neutralizing antibodies can prevent the establishment of a chronic infection. However, should the body's initial opportunity to generate neutralizing antibody to prevent HIV-1 infection of cells fail, a chronic and progressive viral infection then takes hold. The natural viral history suggests that humans do not effectively respond with protective and sterilizing antibody to initial HIV-1 infection, and immunity against reinfection is never established. Indeed, HIV-1 does establish a chronic progressive infection and can rapidly mutate its genome to escape the restriction enforced by initial neutralizing antibodies. Because natural humoral correlates of protection are not observed, it has been reasoned that cell-mediated CTL response acts to control chronic *in vivo* HIV-1 replication and dictates the rapidity of progression to AIDS.

3 Challenges to HIV-1 Vaccine Development

How does one then go about developing a vaccine against HIV-1? A major obstacle to immunological success is the plasticity of the viral genome. Currently, HIV-1 exists in many different subtypes (clades), each differing from the other by about 10% in their respective genetic content. In this context, one also notes that HIV-1 turnover *in vivo* is astonishingly high with up to 10^9 virions being produced each day. Superimpose onto this number the fact that the reverse transcriptase enzyme of HIV-1 is highly error prone (mutation rate of approximately 1 per 10^5 bases), then one expects for a genome size of 10^4 bases, if all things were equal, that every possible mutation would occur at every position of the genome everyday. This mathematics argues that for each epitope to which a specific immune response is raised by the host, the virus could and would change the selected epitope and thus, rapidly affect immunological evasion. If this argument holds true, then it is very unlikely that a useful HIV vaccine can be developed. Accordingly, the foremost challenge for a successful vaccine is to identify critical viral epitopes, which the virus for reasons of functional constraint, cannot mutate for purposes of evading immune restriction. If such immutable epitopes are also broadly conserved across different HIV-1 clades, then success could be contemplated.

A recent report lends tangible credence to the concept for the existence of immutable epitopes to which neutralizing antibodies could be elicited against HIV-1. Hence, researchers recently showed that a caveolin-binding motif (CBD1) in gp41 is highly conserved across all HIV-1 clades, and that a broadly neutralizing antibody against CBD-1 halts virus infection in tissue culture. Building upon this new finding, logical next steps in vaccine development would be to uncover additional epitopes in Env and Gag, which are either linearly or conformationally conserved across clades and to test these for ability to elicit durable neutralizing antibody.

If a neutralizing antibody vaccine cannot be developed to prevent HIV infection, it still may be possible to develop a CTL-eliciting immunogen, which would control virus replication *in vivo* and delay or prevent the onset of AIDS. In general, HIV-1 infection in humans is not itself symptomatic, but rather it causes gradual immune system deterioration. Over time, $CD4^+$ T cells are depleted. The definition of acquired immunodeficiency syndrome or AIDS is when a person's $CD4^+$ T cells fall below 200 cells μL^{-1} of blood. A person with AIDS is susceptible to many opportunistic infections and malignancies, which do not occur in people with intact immune systems. These opportunistic illnesses are the causes of death. On average, HIV infection leads to AIDS within 8 to 10 years and has a plasma viral load of 10^4–10^5 copies mL^{-1} (Fig. 2). The level of viremia closely correlates with the rate of $CD4^+$ T-cell depletion. The higher a person's viral load is, the quicker that person loses $CD4^+$ T cells and advances to AIDS. The goal of a vaccine, which induces anti-HIV CTL, is to significantly reduce viremia by eliminating productively infected cells. A reduction in viremia will slow the rate of immune suppression and will decrease the rate of transmission to others. This approach contrasts with that of all other viral vaccines, which prevent or limit acute infection. In the same way, it eludes antibodies; HIV is facilely capable of generating CTL-escape mutants. The solution here rests on coming up with CTLs, which target immutable epitopes. There

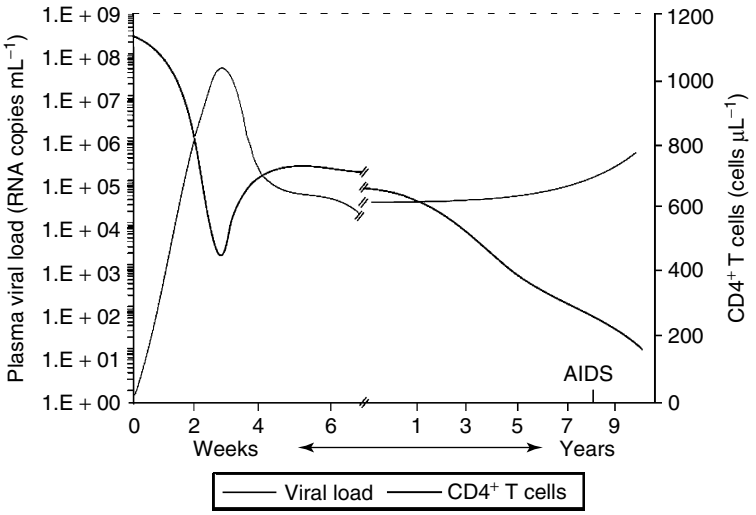


Fig. 2 Typical HIV-1 infection is characterized by acute-phase viremia followed by chronic intermediate levels of plasma viremia, a steady loss of peripheral $CD4^+$ T cells and the development of AIDS after 7 to 10 years. (Adapted from Feinberg, M.B., Moore, J.P. (2002) AIDS vaccine models: challenging challenge viruses, *Nat. Med.* **8**(3), 207–210.)

is emerging evidence that such immutable CTL targets exist in the HIV-1 genome. For example, we recently showed that a CTL epitope in the second exon of the viral Tat protein appears to fit that definition. Going forward, the scientific challenges are to induce high titers of neutralizing antibodies and potent cellular immune responses to conserved viral epitopes, which cannot be changed by HIV-1 in response to immune restriction without drastic loss of function for the virus.

4
Vaccine Development Stages

4.1
Preclinical Phase

Preclinical testing, which occurs in laboratories or animal models, of vaccine candidates takes years to decades (Fig. 3). Initial basic experiments defined HIV's proteins and its basic life cycle. HIV-1 is a retrovirus of the lentivirus genus. The HIV-1 RNA genome is ~9 kb and encodes 9 polypeptides. Posttranslation proteolytic digestion results in the formation of 15 discrete proteins. The major structural proteins are encoded by three genes, *gag* (group-specific antigen), *pol* (polymerase), and *env* (envelope) (Fig. 4), while the accessory proteins, Vif, Vpu, Vpr, and Nef, and the regulatory proteins, Tat and Rev, are the primary translation products of multiply spliced mRNAs. In vaccine development, each viral protein (15 separate proteins and many subtypes of each) represents a possible vaccine target. After selecting a viral target or targets, researchers next choose a delivery system or approach, such as recombinant adenovirus. Then, animal models are used to test the immunogenicity and the safety of the vaccine strategy. In many cases,

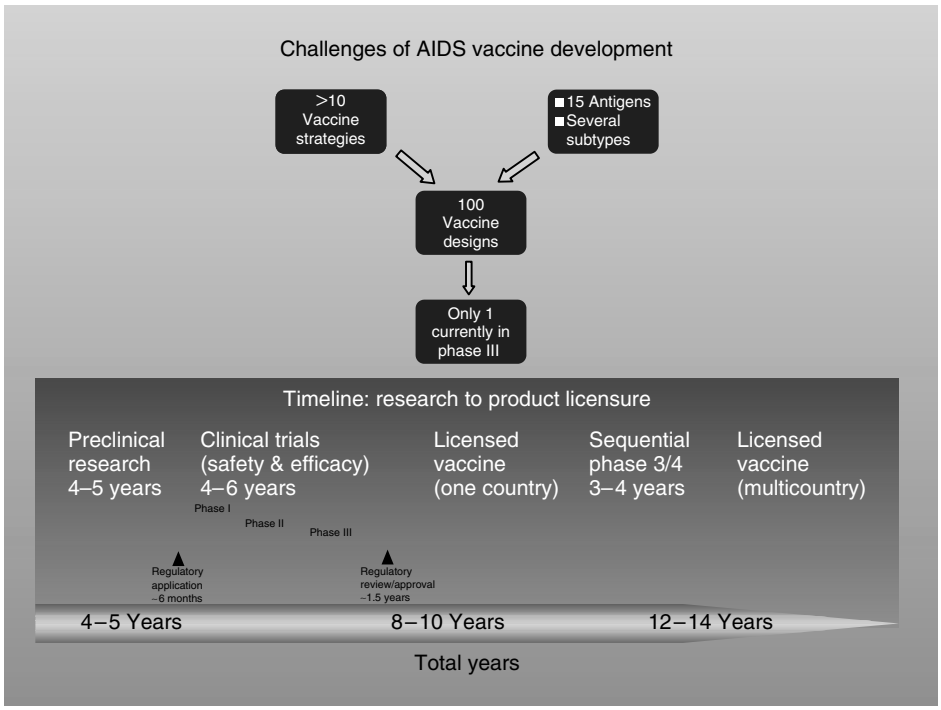

Fig. 3 Challenges to HIV vaccine development. Each stage of vaccine development takes years to complete. In the absence of an immunologic goal or target, researchers have attempted to raise immune responses against many viral antigens through several different approaches. Despite these efforts, only one vaccine type has been tested in Phase III trials in the 23 years of the epidemic.

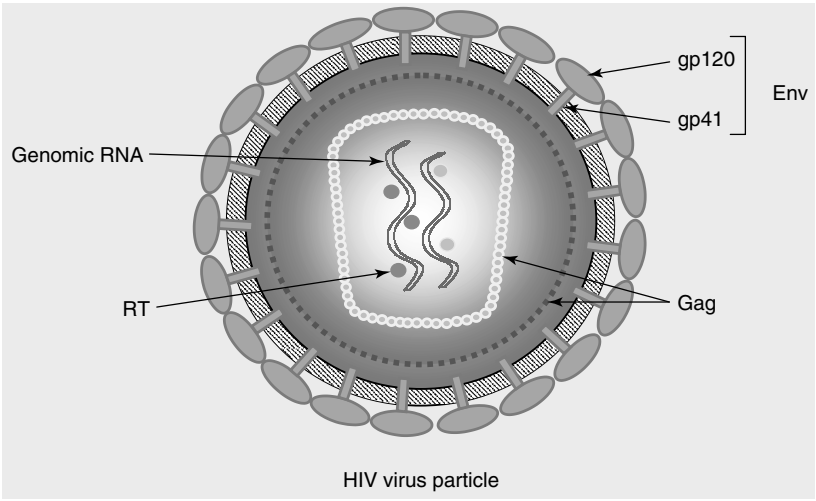

Fig. 4 Schematic of HIV virus particle.

small efficacy studies are performed in the macaque model of AIDS (see the following). Once a vaccine candidate successfully passes these tests, it can then be considered for human testing or clinical trials. Of the multitude of HIV vaccine candidates tested in preclinical studies, only one has been completely tested in an efficacy trial (Phase III), which, as discussed, failed.

4.2 Human Trials

Vaccines, like new therapeutics, are evaluated in three successive stages of clinical testing, referred to as Phase I, II, and III trials. In Phase I testing, the side effects and safety of a given vaccine are measured in a small number of healthy volunteers who are at low risk of infection. Typically, 10 to 30 individuals are inoculated with the vaccine at different doses and immunization schedules. Participants are closely monitored for the development of adverse reactions, and immune responses to the vaccine are evaluated secondarily. Phase I trials are usually completed in approximately 1 year. In Phase II trials, several hundred people are given the vaccine to collect additional short-term safety data and, more so, to measure the immunogenicity of the vaccine. Participants in Phase II trials are individuals who have varied rates of risk for acquiring the infection, and these trials typically take 1.5 to 2 years to complete. Once a vaccine has been determined to be safe and sufficiently immunogenic, it is tested in an efficacy, or Phase III, trial.

Several thousand volunteers must be enrolled in a Phase III vaccine trial. The study must be placebo controlled and double-blinded such that neither the researcher nor the volunteer knows whether he/she is receiving placebo or vaccine. Further, Phase III studies must be conducted in a population with substantial risk of HIV-1 infection and can take three years to complete. Combined, Phase I, II, and III trials for a candidate HIV vaccine may require up to 6 years to yield the necessary safety, immunogenicity, and efficacy data.

The National Institutes of Health in the United States has formed the HIV Vaccine Trials Network (HVTN) to help organize and sponsor vaccine research. The self-stated mandate of HVTN is to conduct ''all phases of clinical trials, from evaluating candidate vaccines for safety and the ability to stimulate immune responses to testing vaccine efficacy. The HVTN mission is to develop and test preventive HIV vaccines. This research is done through multicenter clinical trials in a global network of domestic and international sites.'' Other countries, including Great Britain, Thailand, Kenya, Uganda, South Africa, Australia, and Italy, actively support HIV vaccine trials. Several pharmaceutical companies have developed significant HIV vaccine projects, most notably Merck, Aventis, and Glaxo Smith Kline (GSK). For several years, the International AIDS Vaccine Initiative (IAVI), a nonprofit global organization, has been an advocacy group for HIV vaccine research and testing. Now, IAVI is directly supporting clinical testing. The HIV vaccine effort is not lacking for governmental, nongovernmental, or industrial support. Rather, the many institutions and foundations lack a clear immunologic target.

5 Animal Models

HIV-1 does not productively infect any other animal, with the possible exception

of chimpanzees. Small laboratory animals such as mice, guinea pigs, and rabbits have been used to evaluate the safety and immunogenicity of various vaccine preparations. These animals have also been used for testing the potency of adjuvants and immunostimulatory molecules (e.g. TNF-α, IL-2, IL-12). However, such animals cannot be used for evaluating the efficacy of candidate vaccines, since these animals are not infected by HIV-1. The lack of a good small animal model for HIV-1 infection and pathogenicity has been one of the major difficulties in AIDS vaccine development.

Macaques, which originate from Asia, are the animals, most often used in HIV vaccine development. Monkeys and apes from Africa harbor more than 30 lentiviruses, called *simian immunodeficiency viruses* (SIVs). The SIVs are related to HIV in their genomic organization and sequence homology. None of these viruses causes disease in its natural host; however, SIV causes AIDS when inoculated into Asian macaques. SIV does not infect macaques in the wild. This model was developed after researchers serendipitously discovered that macaques, which had been housed with African monkeys, developed AIDS via cross-species transmission of SIV. Infection in captive macaques is used as a disease model to study simian AIDS.

Laboratory-generated chimeras between HIV-1 and SIV, called *simian–human immunodeficiency viruses* (SHIV), have also been created to be used in pathogenesis and vaccine studies in macaques. SHIVs typically have gag, pol, vif, vpx, vpr, and the long terminal repeat (LTR) of SIV, while tat, rev, and env are derived from HIV-1. While not all SHIVs are pathogenic in macaques, a subset of pathogenic SHIVs have been identified and shown to cause rapid immunodeficiency and disease progression. As a result, several pathogenic SHIVs have been utilized as challenge viruses in vaccine studies.

Among the different species of macaques, rhesus macaques (Macaca mulatta), cynomolgus macaques (Macaca fascicularis), and pigtailed macaques (Macaca nemestrina) are most commonly used for pathogenesis and vaccine studies. Early studies focused on chimpanzees as the only nonhuman animal susceptible to infection with HIV-1; however, these animals are infrequently used today because of their failure to develop significant viremia and disease following HIV-1 inoculation. Moreover, legal and ethical issues have created mounting pressure for laboratories in the United States to discontinue research using chimpanzees. Consequently, SIV infection of macaques has become the most frequently used model to evaluate candidate vaccines. Despite the ability to establish SIV infection, this model is not without drawbacks. Owing to the high cost of macaques and limited supply, vaccine studies are often constrained to the use of a small number of animals (<20). Often, in the interest of economy, this initial group of animals is further divided into subgroups of 4 to 5 macaques to simultaneously evaluate several related strategies. An unfortunate consequence of such small group sizes is the loss of statistical power and the potential for misinterpretation of results due to inapparent biases. However, in the absence of an alternative, research in the SIV-macaque model has provided valuable information on the induction of immune responses and the efficacy against pathogenic virus challenge for many candidate vaccines. In the following sections, we will review data generated in this model encompassing several different

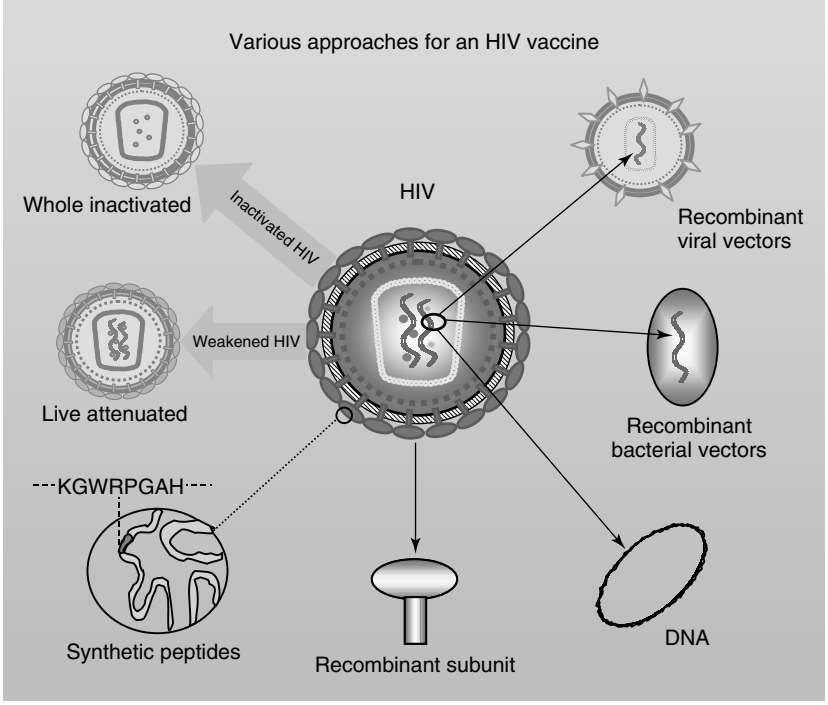

Fig. 5 Various approaches for an HIV vaccine are illustrated. (Please see text for elaboration.)

vaccine strategies (Fig. 5) and the limited work conducted in human clinical trials.

6
Vaccine Approaches

6.1
Inactivated Virus

Inactivated virus particles have been used successfully as vaccines against several human pathogens, including poliovirus, influenza, and hepatitis A virus. In this simple strategy, virus is grown in tissue culture or other vessel, such as chicken eggs. Next, virus is purified and chemically inactivated, while retaining the overall particle structure. The dead virus particles are then injected into the host. In response to such vaccines, humans develop a primary antibody or humoral response. In some viral diseases, these antibodies confer significant protection against infection and/or severe disease.

In the late 1980s and early 1990s, several researchers used this approach against SIV in macaques. This approach worked well in initial experiments. In the following years, whole-inactivated vaccines were shown to protect macaques from pathogenic SIV infection by intravenous, intrarectal, and intravaginal routes. The initial optimism of these results turned out to be based on false hope. SIV used for vaccine preparations was grown in human cells and the human cellular proteins were incorporated into the vaccine virus particles. Such vaccine preparations induced antibody

responses in vaccinated animals against the human cellular proteins and afforded protection against the challenge viruses, which were also propagated in human cells. High levels of antibodies against human cellular proteins were detected in the protected animals and the degree of protection correlated with the level of these antibody titers. This observation of xeno antigen–induced protection was further confirmed by experiments where macaques immunized with human cells alone, HLA-DR, or HLA class I proteins were protected against SIV grown in human cells, but not against SIV grown in macaque cells. Several researchers tried to exploit the finding of xeno-antigen responses by designing vaccine strategies based on alloimmunization, but concerns over inducing autoimmune responses rendered this approach unattractive.

6.2 Virus Subunit

With the advent of recombinant molecular biology, it is simple to express viral proteins individually and separately. The strategy has been extremely successful against many viruses, including hepatitis B virus. In this approach, the gene for a viral protein, usually the viral envelope, is expressed *in vitro*. The viral protein is purified and then injected into the host with an adjuvant. These protein-based vaccines illicit a strong humoral response, but a very limited cellular immune response. In some cases, the viral subunit approach induces a similar humoral response as the inactivated viral vaccine (i.e. influenza), but causes fewer side effects. Many attempts using the subunit approach were made in the macaque model to induce protective antibodies against pathogenic SIV. However, they were not successful. Most approaches used some form of viral envelope, typically gp120, since this is the only viral protein exposed to antibodies.

Despite the many failures in the macaque model with the subunit approach, the National Institutes of Health supported two large Phase III vaccine trials, which used this simplistic strategy. This vaccine, AIDSVAX, is a monomeric version of the normally trimeric HIV-1 envelope glycoprotein, gp120. The vaccine was found to induce a strong antibody response against linear epitopes on gp120 and a $CD4^+$ T-cell proliferative response. However, in two independent trials, which tested slight variations of the same approach, the vaccine failed to confer protection against HIV-1 infection and did not significantly alter virus replication, as measured by plasma viral load.

The first of two Phase III trials of AIDSVAX was conducted in the United States, Puerto Rico, Canada, and the Netherlands and enrolled 5109 men and 309 women at high risk for acquiring HIV-1 infection. The volunteers were randomized to either the vaccine (AIDSVAX B/B) or placebo arm of the study at a ratio of 2 : 1. Those in the vaccine arm received AIDSVAX B/B, which contains two forms of gp120 derived from subtype B virus; the most common subtype found throughout North America and Europe. Of those enrolled, 5009 participants completed the three-year study. While adverse reactions were minimal, the infection rates for the vaccine and placebo groups were 5.7 and 5.8%, respectively, and were not statistically different. The second efficacy trial was conducted in Thailand and enrolled 2546 injection drug users. For this study, the vaccine was changed to AIDSVAX B/E to reflect the subtypes of HIV more commonly found in Asia (subtypes B and E). This trial again

showed no protection against HIV-1 infection providing convincing evidence that immunization with monomeric gp120 is ineffective as a vaccine strategy. Secondary to its lack of efficacy, researchers currently use this approach in conjunction with another strategy and never alone.

6.3 Live-attenuated Virus

Inactivated virus particles are capable of inducing immune responses, which for some viral diseases can be protective. Live-attenuated versions, however, often produce stronger immune responses in a larger percentage of hosts than a comparable inactivated or dead version. The classic comparison of these two approaches is that between the Salk (inactivated virion) polio vaccine and the Sabin (attenuated viruses) polio vaccine. The Salk vaccine, while effective in many, does not stimulate the same degree of immune response as the Sabin vaccine. By replicating within the host, an attenuated vector more effectively mimics a limited natural infection and elicits humoral and cell-mediated immune responses. In general, attenuated virus vaccines are more efficacious than their inactivated counterparts. The major disadvantage of attenuated viral vaccines is the possibility or propensity to cause disease. The Sabin vaccine, for instance, causes 1 case of vaccine-associated poliomyelitis per 1 000 000 recipients, while the Salk vaccine causes none.

In HIV vaccine development, no attenuated virus candidate has been evaluated in clinical trials. Since HIV is a retrovirus, even an attenuated version would not be completely cleared from the host. While scientists can easily modify or delete each gene from HIV, no one knows how to attenuate HIV in such a way that it makes the virus safe and yet effective. In the macaque model, certain forms of attenuated SIV protect animals from infection with wild-type virus. Several researchers have confirmed this finding. Unfortunately, in neonatal macaques and even in some adults, this attenuated viral vaccine replicates efficiently enough to cause gradual depletion of the immune system. Forms of attenuated virus, which replicate less efficiently, fail to induce protective immunity in any animals. In conclusion, at least in the SIV-macaque model, attenuated vaccines, as currently conceived through gene deletion or interruption, are not capable of safely protecting a large population of animals. To improve the safety profile, some groups, like ours, continue to work on strategies that allow conditional control of the attenuated strain. In these models, the attenuated HIV's replication would be dependent upon the coadministration of a drug. Once the drug was discontinued, the attenuated viral vaccine would cease replicating. This approach has not yet been tested in macaques.

6.4 Viral and Bacterial Vectors

As mentioned earlier, attenuated viral vaccines have the benefit of replicating within the host and thus induce more potent immune responses. Investigators have used molecular techniques to produce viral and bacterial vectors, which express HIV proteins. Several recombinant viruses have been tested in macaques. These include adenovirus, different alphaviruses, various pox viridae, and even rhabdoviruses. As cellular parasites, each viral vector replicates within the cell and uses the cell's protein producing machinery. Intracellular expression of foreign or viral proteins leads to enhanced cell-mediated immune responses. In the macaque model, many different recombinant viruses have shown

promise and are able to induce an immune response that controls the replication of SIV. Unlike the Sabin vaccine against poliovirus, these recombinant virus vaccines do not protect the animals against infection, but rather against disease.

Recombinant viruses, which encode HIV proteins, are now being tested in human trials. A canarypox vector called ALVAC is currently in Phase III testing. ALVAC has been studied extensively in Phase I and II trials, and has been shown to have an excellent safety profile. This is because of the fact that canarypox infects mammalian cells, in which it completes a single cycle of replication but does not release infectious virions. In the current clinical trial (designated RV144), ALVAC is produced by Aventis and engineered to express HIV-1 subtype E env (gp120), subtype B env (gp41), gag, and protease (designated ALVAC-HIV-vCP1521).

Since protection against HIV has been impossible to achieve with any one vector or vaccine, researchers are now using two or more vaccines in what is termed *prime-boost strategy*. The first vaccine is given to prime the immune system's response against HIV antigens and then the second is administered to boost this response. In fact, most planned Phase II and III trials employ this approach. One prime-boost strategy is DNA vaccination (see the following) followed by recombinant poxvirus. Both vectors induce primarily a cell-mediated immune response. This approach has worked well in the macaque model against pathogenic SHIVs, but not against pathogenic SIV. In other prime-boost regimens, the first vector is given to raise cell-mediated responses, while the second, usually soluble protein, is given to induce a humoral response. This latter approach is currently in the Phase III study, RV144, in which ALVAC is used to prime the cellular immune response and soluble gp120, AIDSVAX, is administered as the boost to raise antibodies.

Recently, Phase I and II trials with another recombinant poxvirus, modified vaccinia Ankara (MVA) was completed. The immune response targets were not reached with this vector. Plans for a Phase III trial were scrapped. Recombinant adenovirus has been very effective in protecting macaques against disease and is being studied in humans in Phase II testing. Several additional HIV-1 vaccine strategies are now being tested in Phase I trials. A comprehensive list can be found on the International AIDS Vaccine Initiative or IAVI Web site (http://www.iavireport.org/trialsdb/).

Bacteria such as Salmonella and Listeria can survive well intracellularly. Researchers have used recombinant techniques to manufacture attenuated versions of these bacteria, which express HIV proteins, to deliver intracellular expression. In small animal models, these bacteria do elicit anti-HIV immune responses. These approaches have been extensively studied in the macaque model or in human trials yet.

6.5 DNA Vectors

Direct inoculation of purified preparations of DNA as a means of immunization has become an exciting area of research, stemming from an unexpected observation in mice. DNA, encoding antigens, or even adjuvant cytokines, can be delivered either intradermally, intramuscularly or mucosally, from where it is taken up by host cells. Host cell production of the encoded proteins may enhance presentation of antigenic peptides on major histocompatibility complex (MHC)

Class I molecules, and facilitate the development of antigen-specific CTL responses. Cytokine delivery by DNA allows for localized delivery to the same tissue in which antigen is being expressed and processed. DNA vaccination is currently being tested in early clinical trials. Early data suggest that human immune responses to DNA vectors are less than that seen in mice.

7 Conclusion

In the history of medicine, no vaccination effort has been as large or as extensive as that against HIV-1. Many different approaches and multiple attempts at each have not yielded a clear avenue to follow. From these efforts, we have learned that prevention of infection through vaccination (i.e. attenuated SIV) is possible. However, we also know that it is difficult to induce neutralizing antibodies by vaccination, despite the recognition that this approach offers the most promise for a truly preventive vaccine. CTL-based vaccines can protect against disease in some macaque models of HIV, but not in others, and escape from CTL can lead to vaccine failure. HIV-1 vaccine trials are expensive and the current scientific landscape suggests that a successful HIV-1 vaccine may still be years away. Until that time, widespread use of antiretroviral drugs offers a tangible hope to slow the epidemic.

subdivided into three phases, wherein Phase I denotes the earliest basic safety studies, Phase II means extended efficacy and safety studies, and Phase III encompasses large-scale trials under practical conditions. Clinical trials conducted after product licensing are often referred to as *Phase IV clinical studies*.

Preclinical Research and Development
Activities preceding the clinical testing of a medicinal product. The term is usually applied to summarize all technical work required to develop a medicinal product, including process and analytical methods development, formulation development, characterization, and safety studies.

Vaccine
A medicinal product, which is applied in order to confer protection against diseases, preferably against infectious diseases. Different types of vaccines are separated by the nature of their active ingredients or antigens as *inactivated vaccines*, consisting of inactivated (usually by chemically agents), whole microorganisms, *subunit vaccines*, consisting of one or few components of the whole microorganism, *live attenuated vaccines*, consisting of weakened or ''attenuated'' microorganisms, *conjugate vaccines*, wherein the desired antigen is linked or ''conjugated'' to a carrier that stimulates a more effective immune response to the antigen, and *toxoid vaccines*, consisting of inactivated bacterial toxins. *DNA vaccines* are using the genetic material encoding for the desired antigen rather than the antigen itself. Vaccines may contain mineral salts or more complex molecules and compositions as *adjuvants* to enhance the immune response of the vaccinated individual.

Vaccine research and vaccine development are commonly combined by the term R&D because, in practice, these two different disciplines cannot be easily separated. However, there are fundamental differences. Research is mainly motivated by, and aiming at, scientific publications, which are best achieved by new methods, inventions, and discoveries. Development is aiming at innovations, that is, new products that will have an impact on our daily life. In research, a vaccine could be an antigen or a preparation that has the potential of eliminating or inhibiting microorganisms. In order to convert this into a useful vaccine, developers must then add several other dimensions to the research product, namely, quality, safety, a specifically defined clinical efficacy, and practical utility. For a successful development not only scientific but also technological, commercial, and regulatory hurdles must be taken. Designing practical utility into a product encompasses and combines almost any aspect of the product, including a good tolerability, acceptable application schemes with only few vaccinations, a proven and perceived effectiveness, comfortable presentation forms, formulations that guarantee good stability and shelf lives, and, of course, adequate product cost.

1 From the Research Concept to a Development Candidate

Concepts for new vaccines arise from research and are based on combined scientific findings collected over many years and by various scientific institutions and disciplines. New vaccine concepts are regularly presented and proposed in large numbers by scientific publications or patent applications, but these concepts rarely result in new vaccines. After being tested in mice, most concepts slowly fade, since the original results cannot be reproduced under more practical conditions or turn out to be insufficiently effective to justify additional work. On the other hand, there are also organizational and financial aspects that represent serious hurdles. Most academic institutions and scientists simply do not have adequate resources to perform vaccine studies in specific models or even in monkeys or primates. Whereas vaccine antigen candidates can be designed and made by only one or a few individuals, studying these more intensively would normally require other specialists, specific facilities, and, of course, much more money. The initial research project now competes for scarce resources and needs very convincing data to make it to the next stage.

Scientific collaborations across institutional walls are an almost absolute prerequisite for continuing projects beyond testing in small laboratory animals and in order to proceed into a more intensive and application-oriented research phase. During this secondary research phase, promising concepts are taken up, reproduced, and improved until finally – and in only very few cases – a viable product and development concept can be put together. Almost invariably the efficacy of the candidate vaccine needs to be improved and made more reliable. For many new indications, even the tools and models must be established first, by which immunological effects or protection can be adequately measured.

For those few candidates that remain attractive after being studied in a more reliable way or in better models, it will then be important to assess the technical and economic aspects of the vaccine candidate very carefully. As these strongly depend on available facilities, general expertise, and specific experience with certain techniques needed, these aspects are normally evaluated by the developing organization during a project evaluation or ''predevelopment'' phase. At the end of this phase, a development concept should be available, which at least fulfills the following three criteria:

1. There should be sufficient evidence that the vaccine candidate is effective and protective in humans or in the target animal species. This normally presupposes that meaningful animal models have been established and that the vaccine has been tested successfully.
2. There should be a defined technical base or verified options by which the vaccine can be reliably and safely produced on a large scale. This includes, for example, cell culture or expression systems, purification schemes, and formulations that are qualified for the production of pharmaceutical products and do not contain hazardous components that cannot be removed during later process steps.
3. The expected product cost and the resulting sales prices must be in balance with the envisaged benefit of using the vaccine and expected revenues should be able to recoup the development cost in a reasonable period of time.

Thus, there should be rather clear ideas as to how the vaccine is to be manufactured and how it is characterized in its main qualities. If this base is not yet known or is based only on assumptions, a targeted product development in its strict sense is not possible, as neither the way to go nor the target or end result are known. In this case, the project should still be considered to be a research project. However, particularly in the case of vaccines, development projects are frequently started with many uncertainties, assumptions, and compromises, as vaccines are highly complex compositions, which cannot be characterized entirely and completely by analytical methods. Vaccines are products that are defined to a great deal by the process by which they are made, by the analytical tools by which they are tested, and even by the facilities in which they are manufactured. As a consequence, most vaccine development projects have no clear starting point and research and process development activities run in parallel. Although partly impossible, this should be avoided as far as possible, as development activities need many more people and are considerably more expensive than research. No developing organization has sufficient resources to run numerous complex development projects in parallel or to change the direction of a development again and again. By defining adequate criteria and by a proper project organization, critical aspects of a development project can be identified early, so that these are evaluated during the applied research phase prior to the onset of product development.

2 Vaccine Research Projects

An excellent overview of ongoing research activities for vaccines is provided by the Jordan Reports issued by the US National Institutes of Health. According to the latest issues of these reports, the number of vaccine R&D projects in the United States in the year 2000 and 2002 amounted to more than 500 projects. Almost one-third of these were various efforts to develop vaccines against AIDS. A list of the main target indications pursued by recent vaccine research and development efforts is given in Table 1.

The top positions of the vaccine research "hit list" have not changed very much over the past few decades. Well-known viral and

Tab. 1 Main infectious agents or targets for new vaccines in advanced R&D.

Viruses	***Bacteria***	***Parasites***	***Tumors***
HIV/AIDS	*Streptococcus*	Malaria	B-cell lymphomas
Hepatitis C virus	*Helicobacter pylori*	*Leishmania*	Melanomas
Herpes simplex viruses	*Borrelia*/Lyme disease	*Schistosoma*	Prostata carcinoma
Cytomegalovirus	*Salmonella*	*Toxoplasma*	CEA-tumors
HRSV	Enterotoxigenic *E. coli*	*Trypanosoma*	
Parainfluenza	*Shigella*		
Rotavirus			

Notes: HIV/AIDS: human immunodeficiency virus/acquired immunodeficiency syndrome; HRSV: human respiratory syncytialvirus; CEA: carcino-embryonal antigen: an antigen that is frequently found on colorectal, bronchial, and breast cancer cells.

bacterial infections continue to occupy the most prominent positions. However, the number of individual projects for many of these vaccine indications has increased considerably. The simple reason for this is that formerly complete microorganisms or subfractions thereof, but rarely purified single antigens, had to be used as vaccine candidates. Modern molecular biology and recombinant techniques result in individual antigens or even smaller immune response stimulating units, such as peptide epitopes, which may be varied or combined by almost endless options. Of course, this increases the number of candidates significantly and offers many new chances and possibilities, but it does not necessarily increase the chances of success for each individual approach. Molecular biology has opened up various new possibilities to approach antiparasite vaccines and tumor vaccines but also, in these particularly complex fields, the number of projects dealing with conventional ''whole'' organisms or cells is quite remarkable. Antitumor vaccine projects indicate that vaccines should no longer be regarded only as infection prophylaxis. Immunizations can and will in future also be used as therapeutic measures. Vaccine research even covers approaches that attempt to induce temporal infertility by the induction of antihormonal antibodies.

In comparison to current vaccine R&D projects, the number of newly licensed vaccines is extremely small. Most newly licensed products are improvements or combinations of existing vaccines; real vaccine novelties are very rare. Thus, the chances that a vaccine project in advanced research finally ends up as a vaccine product is minimal and is certainly far below 1%. These low success rates in research inevitably lead to long research phases. Short time intervals of around five years between the first publication or patent application of a new vaccine concept and the start of full development are an extremely short, applied research phase for vaccines. These may be applicable to some veterinary vaccines, for which vaccine protection of a candidate vaccine can be measured directly in the target species. For vaccines against human diseases, 10 or more years appear to be a more realistic average estimate for this phase. If one adds those further 10 to 12 years that it takes on average to develop a vaccine product, one must assume that after the basic concept has been published or patented for the first time, about 20 years are needed to successfully develop a new vaccine product. This is not different from the average time interval of two decades between concept and first appearance on the market for various innovative technical products developed during the past 100 years (including e.g. not only complex products, such as antibiotics, the pacemaker, and radar but also presumably simple products such as the zipper, dry soup mixes, powdered coffee, ballpoint pens, and liquid shampoo). At their times, all innovations had to overcome serious hurdles, such as scientific challenges, technical difficulties, and usually financial limitations also.

3 Scientific Challenges of Vaccine R&D

Science and technologies are the driving forces that enable us to develop new vaccines. Regarding the basic technologies, there are few discoveries to be named that had a significant positive influence and resulted in new vaccines. Cultivation of pure bacterial cultures is still the

fundamental base for most bacterial vaccines. A remarkable breakthrough came with the invention and development of cell culture techniques in the 1950s, which led to several new or significantly improved antiviral vaccines, including the current state-of-the-art vaccines against poliomyelitis, mumps, measles, rubella, and cell culture rabies vaccines. Current influenza vaccines are still all based on embryonated egg-derived virus antigen, but cell culture technologies are now also applied to develope new influenza vaccines. Compared to these fundamental bacterial and viral propagation technologies, molecular biology and recombinant techniques up to now had a rather limited success with essentially only one licensed recombinant human vaccine for hepatitis B. DNA vaccines may be regarded as yet another new and basic technology for new vaccines, but only a decade after their discovery, they certainly did not yet have enough time to mature to practical applications. Monoclonal antibodies or anti-idiotype antibodies, however, did not lead to new vaccines as expected, although these basic techniques were initially quoted as a major breakthrough in vaccine research.

Apart from a few essential technologies, continuous research in virology, microbiology, parasitology, and immunology are the foundations for vaccine research. However, even the most detailed knowledge about cytokines and their regulation of immune responses, or of fundamental genetic mechanisms controlling the growth and replication of microorganisms cannot be expected to bring any direct or immediate success. For the past and for the foreseeable future, it seems that it is more the pragmatic, application-oriented research that primarily fosters vaccine development. Complex immunological hurdles must be overcome in order to arrive at a new vaccine target, and that is mainly done by establishing suitable animal models and by testing all sorts of vaccine candidate antigens in these models in a very pragmatic way for their protective effects.

Recent efforts to develop a vaccine against AIDS serve as a good example of illustrating the importance of suitable models for vaccine development. In the United States in the year 2000, 135 different AIDS vaccine projects were known. Only 10% of these were considered to be basic research and development (R&D) projects, that is, they are mainly in a phase of selecting, constructing, and making the desired antigen. The rest of all these projects were allocated to preclinical testing phases in animals or to clinical testing in humans (compare Fig. 1). Less than one-third of these projects seemed to have passed small animal testing successfully and appeared to be worth testing in monkeys. Only 4.4% of the antigen candidates proceeded to trials in chimpanzees. A substantial proportion of 44% of vaccine candidates was tested in humans for safety and efficacy; however, only 1.5% were already in Phase III clinical trials, indicating that these two different vaccine candidates appear interesting enough to go into widespread field testing for efficacy. The low number of projects in basic R&D shows that after two decades of AIDS research, there are not too many new antigens or entirely new approaches to be discovered. In the absence of reliable animal models, the relatively high number of projects in early human clinical trials and the low number in later stage clinical trials very clearly demonstrate that in this case research is essentially performed in human clinical trials – with all the inherent limitations. Consequently, the

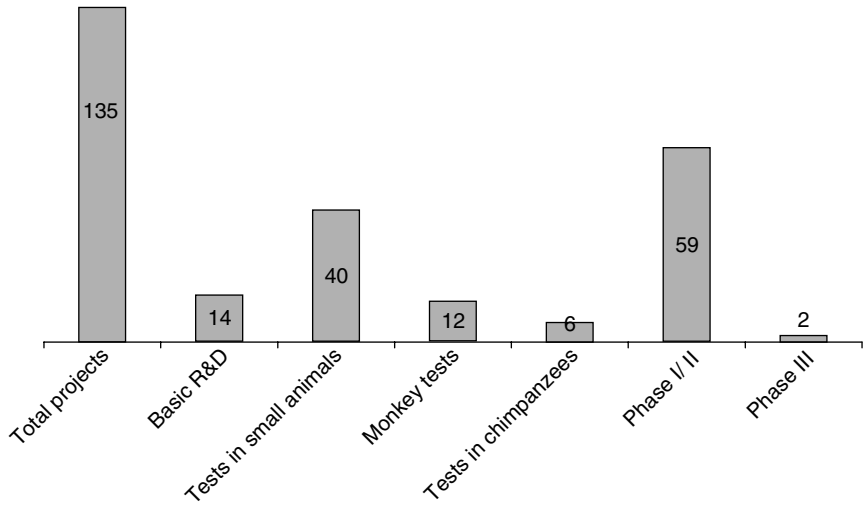

Fig. 1 AIDS vaccine candidates in research and development. The numbers apply to projects identified in the United States in year 2000.

chances of success are low, while at the same time the cost of such research is extremely high.

What are the scientific challenges and difficulties to be overcome on the way toward an effective AIDS vaccine? As summarized in Table 2, infectious microorganisms and parasites have developed various mechanisms by which they effectively prevent their elimination by the host's immune response. All of these negative attributes have been found to be associated with HIV infections. HIV does not only evade the immune responses by presenting itself by different subtypes, by varying its main immunogenic antigens during the protracted course of infection in an infected individual, or by hiding itself in a nonaccessible form by integrating its genome into host cell's genes, it even interferes actively with several important immune functions and modifies these for its own benefit and support. Of particular relevance is the selective preference of HIV for CD4 immune cells, as disturbance of their function can result in numerous deleterious effects. The ability of HIV to persist and replicate in macrophages enables HIV to convert the migrating immune cells into an efficient vehicle across normal barriers. HIV is not only insufficiently neutralized by antibodies, it even uses bound antibodies to get access to immune cells, such as macrophages, which carry receptors for the Fc fragment of antibodies.

Whereas AIDS and HIV was only chosen as examples that contributes any imaginable difficulty to vaccine development, Table 2 also lists many other current vaccine projects and their specific difficulties. A limited number of different serotypes may still be overcome by making and combining several similar vaccines, once a successful vaccine against one of these has been accomplished. Thus, vaccines against parainfluenza infections appear reasonably feasible. Other indications, such as malaria, herpesvirus infections or Lyme disease/Borreliosis, however, represent

Tab. 2 Immunological challenges on the way toward new vaccines.

Attribute	***Examples***	
Different serotypes or subtypes to be covered by the vaccine	Parainfluenza:	3 major pathogenic subtypes
	Dengue:	4 subtypes
	Malaria:	4 major pathogenic plasmodium species
	Borreliosis:	4 genetic and immunological types
	Hepatitis C:	6 major genotypes and >100 subtypes known
	HIV/AIDS:	>10 subtypes known
Antigenic variation of major immunogens	Malaria:	High variance of major antigens within the parasite
	HIV:	Antigens vary during the course of infection even within the same patient
	Trypanosoma:	Periodic switching of major surface glycoproteins
Genetic restrictions of immune recognition and immune responses	Malaria:	Multiple HLA restrictions for recognition of Plasmodium falciparum CTL epitopes even within the same individual
	HIV:	HLA-restricted CTL escape mutations associated with viral load and disease progression
Microorganism not accessible to immune responses	HIV:	Virus genetically integrated in host cell genomes
	Herpesviruses:	Virus persists in a latent state in neuronal cells
Microorganism persists in immune cells and may spread with these into tissues or across blood-brain barrier	HIV:	Persistence and active replication in, for example, macrophages
	Herpesviruses:	Can infect endothelial cells and macrophages
	Borreliosis:	Borrelia survive in macrophages. Complement membrane complexes and macrophages in the endoneutrium of Lyme neuroborreliosis
	Hepatitis C:	Macrophages and T cells found to be infected by HCV
Immune-enhancement and immune-mediated disease	HIV:	Antibody and Fc receptor–mediated enhancement of infection and disease
	Dengue:	Antibody-mediated enhancement of infection
	Borreliosis:	Immune-mediated neuropathology and arthritis
	Respiratory syncytial virus:	Inactivated vaccine induced high serum antibodies and aggravated disease upon infection

Notes: HIV/AIDS: human immunodeficiency virus/acquired immunodeficiency syndrome; HLA: human leukocyte antigens; CTL: cytotoxic T-lymphocytes; HCV: hepatitis C virus.

quite significant scientific immunological challenges, because the responsible microorganisms combine many unfavorable immunological characteristics. Finally, the example of a respiratory syncytial virus (RSV) vaccine developed and tested in the late 1960s may serve as an example to illustrate the difficulties and practical effects that some of these imponderable aspects can have. This RSV vaccine turned out to enhance a later disease, rather than preventing it. More than 30 years after those results were published, there is still no real explanation for the underlying mechanism and almost all further efforts to develop a new vaccine were stuck in a preclinical phase.

Another important aspect, which seems to be underrated in many current vaccine research projects, is the fact that most vaccines are not sufficiently effective if these are based on only single antigens. Controlled vaccine studies performed under ideal conditions in genetically homogeneous or inbred animals quite often lead to the false assumption that a fully protective vaccine antigen has been identified.

Tab. 3 Protectivity of different forms of vaccine antigens.

Type of antigen	*Amount of antigen [µg]*	*Vaccinations*
Purified whole virus particles	1	1
Virion subunits (12 S)	10	2
Virus protein 1	200	3
Oligopeptide (N-142-160-C)	200	1

Notes: Type of antigen, amount of antigen, and frequency of immunization required to achieve protection against foot-and-mouth-disease virus infection in the guinea pig model.

However, when the same vaccine is then studied under more practical conditions by fewer numbers of immunizations, in the presence of acceptable and better-tolerated adjuvants, it becomes evident that the selected antigen candidate alone is simply not effective enough. Table 3 summarizes the experiences made with different foot-and-mouth-disease (FMD) experimental vaccines. Results from model studies with this type of vaccine can be correlated reasonably well with protective response in the target species. The FMD virus consists only of three structural proteins and the most relevant virus-neutralizing antigenic epitopes are known to be located on virus protein 1. Thus, FMD vaccines appeared as an excellent target for new vaccines based on recombinant technologies. The standard vaccine, made of inactivated whole virus particles, required a relatively low amount of antigen and only one immunization in order to confer protection. Efforts to make smaller subunit or single-protein vaccines resulted only in a similar protection if several immunizations and/or massively increased antigen doses were given. These results had been established rather early in the molecular biology vaccine era, but, despite intensive further research, a commercially viable recombinant FMD vaccine has never been achieved. Meanwhile, conventional whole virus vaccines were successful enough to allow for measures to eradicate the disease completely in those countries where the vaccine has been used intensively.

4 Technical Aspects of Vaccine Development

In an ideal situation, vaccine development commences with a proven, protective, and well-defined antigenic composition.

Successful vaccine development then normally takes 10 or more years, but only a small proportion of all development candidates finally end up as a licensed product; the vast majority remains stuck in early development phases or is abandoned. Figure 2 summarizes the essential tasks of a vaccine development project and may give a rough impression of what is to be expected. For the sake of clarity, several time dependencies and overlaps have been neglected in this graphic overview.

An extensive range of national and international rules and guidelines exist, covering almost any aspect of pharmaceutical and vaccine development and registration. These guidelines describe standards that are not binding in a legal sense, but adherence to these is strongly recommended, as during later registration and licensing, the product will be judged by the same rules. Deviations from guideline recommendations may be inevitable for certain aspects and particularly for vaccines, but these should only be considered if convincing reasons for doing so can be presented. A summary of relevant guideline's requirements along with specific interpretations and applications for biopharmaceuticals and vaccines is quoted under Books and Reviews and may be consulted by prospective developers in order to get a reasonable understanding of the guiding principles.

4.1 Preclinical Development

Preclinical development comprises the technical and scientific elaboration of a process to manufacture the desired product on a large scale. Firstly, cell cultures and microorganisms to be used must be established as Master Cell Banks and Working Cell Banks, or as Master and Working Seeds, respectively. These ensure a constant supply of well-characterized, uniform, biological starting materials. Numerous tests *in vitro* and *in vivo* are required to guarantee the absence of undesired adventitious agents and to confirm the identity of these cell banks and microbial seeds.

Starting with a single aliquot of the Working Cell Bank and/or the Working Seed material, a process is then established and brought up to a final scale. The term "upstream process" typically means a cell culture or fermentation process up to some 100 L, but, for very common vaccines, larger scales may be chosen. Downstream processing summarizes activities during the purification process and typically includes recovery and concentration steps, followed by a secondary purification or "polishing" to remove specific impurities and process-related impurities introduced during earlier steps. Inactivation of bacteria or viruses or detoxifying steps for toxoid vaccines is usually included after an initial concentration step.

Formulation development includes the design of adequately buffered and well-tolerated, stable formulations, adjuvantation, the development of specific application forms, combination of vaccines into compatible vaccines, and, particularly for live attenuated vaccines, the development of a lyophilization process. Formulation development also extends to the selection or design of final syringes or other presentation forms and to filling and packing processes. Stability monitoring programs for intermediate and final products are of adamant importance for any development work and should be started as early as possible to avoid difficulties at a late development stage.

Analytical development encompasses all activities to design and use adequate methods to control and specify all parts of

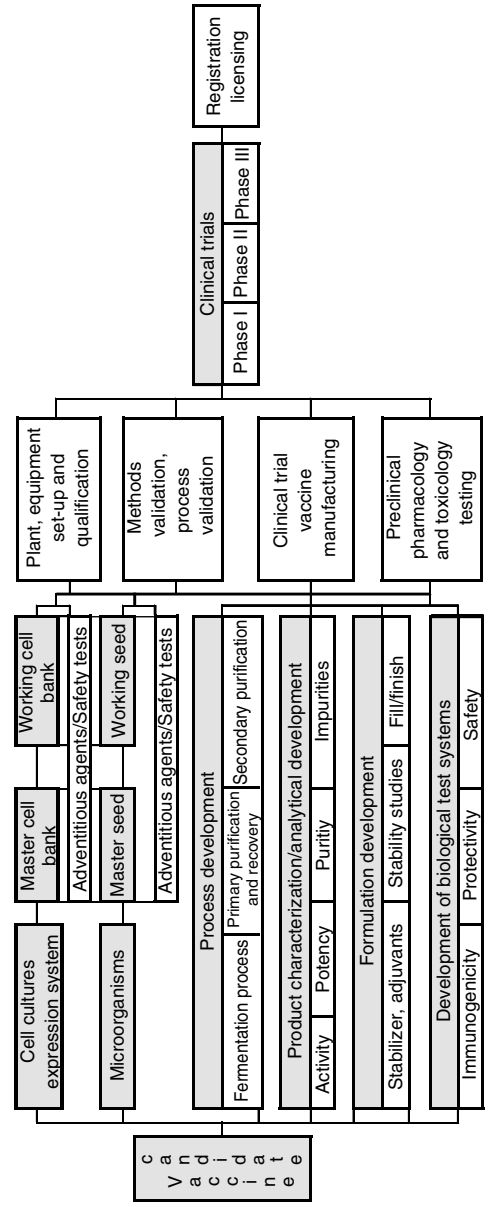

Fig. 2 Schematic diagram of a vaccine development process.

the process and the product. This includes testing of starting materials, intermediate products, and the final product, for example, for identity, specific activity, conformation, purity, and impurities. For a vaccine developed according to today's standards, a range of about 100 different tests and methods will be required. Most of these tests need to be validated for their specific purpose in order to assess the methods specificity, sensitivity, statistical exactness, and its limitations.

In parallel with process development, biological tests, and model systems must be available to monitor the vaccine's potency, immunogenicity, or protectivity at any stage, as vaccines are particularly labile products and minor modifications of the process can have a significant – mainly negative – influence on the vaccine antigen. Likewise, biological models must be at hand to study the vaccine's basic pharmacological, immunological, toxicological, and potential immunotoxicological characteristics. As far as this can be adequately studied, these include dose responses, characterization of induced humoral and cellular immune responses or of their major contributing protective mechanisms, longevity of immune responses, and potential immunological side effects. Although vaccines rarely present severe tolerability or toxicological risks, abbreviated classic toxicological testing is mandatory before the onset of studies in humans. Most vaccines need to be tested only in local and systemic tolerance studies and in repeated dose studies in standard toxicology models, but for new adjuvants and certain new excipients, representing a significant part of the vaccine composition, even a complete toxicology program, including two years of carcinogenicity studies, may be needed. Further toxicology and safety studies addressing specific risks, such as embryonal, fetal, or peri- and neonatal toxicity may be required for certain vaccines and applications or if risks are expected or known. The recent withdrawal of a newly licensed Rotavirus vaccine that was suspected to cause intussusceptions and fatal bowl obstructions in vaccinated children may serve as an example that such studies may be required not on entirely hypothetical grounds alone. In this particular case, however, the true reason for the fatalities could also be a mere coincidence and the higher medicinal attention and reporting of fatality cases in vaccinated individuals.

Owing to the biological origin of many starting materials, risks associated with prions and potentially contaminating viruses must be addressed. Organizational measures are to be put in place to avoid risk materials in addition to testing for adventitious agents. Potential risks by starting materials or process contaminants can further be evaluated and assessed by model studies with various viral and microbial agents. If specific risks are identified and if safety margins appear low, specific countermeasures are to be included into the process. As far as possible, within the technical limitations of these safety studies, a residual risk of less than 1 in 1 000 000 cases should be aimed for. In practical terms this means, for example, that an unnoticed contaminating virus is inactivated or eliminated by the process to a degree that no active virus would be found in a vaccine volume equivalent to 1 000 000 doses. For live attenuated vaccines, viral safety must also be assured by assessing the genetic and phenotypic stability of the vaccine virus and by evaluating the chances and consequences of transmissions of the virus to unvaccinated individuals.

4.2 Production Facilities

Facilities and equipment for the manufacturing of a vaccine are an immanent part of the registration dossier for the product. Any major change would have to be approved by the regulating authorities. Thus, at least for the later clinical phases, the product should be made in a specific plant and with dedicated equipment. For a development project, this means that after the process has been defined, large investments into buildings, facilities, and equipment are to be expected. Owing to the inherent risks of these investments, pilot plants should be available to produce initial clinical trial vaccine lots on an intermediate scale. A developing organization may even choose to go into Phase III clinical trials with a vaccine that has been produced in a pilot plant and to seek registration for this ''preliminary'' product. This approach delays the investment decision to a later point of time when all development risks have been abolished, but inevitably requires new clinical trials for the vaccine that is later on made in the final plant and extends the time to the market by several years. The sum to be invested greatly depends upon the scale of operation and dosage volume of the vaccine. For a complete vaccine plant including all auxiliary functions, the total investment may well accumulate to far above € or US$100 million. Vaccine producers who can use their existing infrastructure, such as buildings, filling and packaging facilities, raw material and media production areas, quality control laboratories, and so on, would have to invest significantly less. For small or start-up companies, outsourcing and outlicensing may be chosen to reduce risky capital investments, as only vaccines with high market expectations justify establishing a complete, own manufacturing operation.

4.3 Clinical Development

The clinical development of a new vaccine is done in three phases and normally lasts three to seven years. The duration mainly depends not only on the novelty and complexity of the vaccine indication to be explored but also on the availability of measurable immunological surrogate markers of protection. If the vaccine's efficacy must be evaluated by comparing randomly occurring cases of the disease in test groups and in alternatively treated control groups, clinical studies can be extremely long lasting, demanding, and risky.

Prerequisites of all clinical trials are adequate preclinical pharmacological and toxicological safety assessments, including animal studies, to justify tests in humans. On the basis of the available safety data and documentation, approval for clinical trials must be obtained by the relevant ethics committees and health authorities. Trials will only be admitted if these are conducted according to preestablished, systematic, and written procedures for the organization and conduct of the trials, for data collection, documentation, and statistical verification of the trial results. The ''informed consent'' of all participating trial subjects and medical personnel is essential. For trials involving children or mentally handicapped persons, the informed consent must be given by parents or by the person responsible. Clinical trials are to be planned and conducted according to ''good clinical practice'' standards that require controlled and randomized trials where possible. Control groups are to be treated by established products or treatments. Placebo treatments are

only admitted where no alternative treatment exists.

During the initial Phase I, the basic safety features of the vaccine candidate are intensively studied in a limited number (<100) of patients or healthy volunteers. The main purpose of these studies is to confirm the vaccine's local and general tolerance before it is applied in further clinical trial subjects, but Phase I vaccine studies can partly be used for a first dose finding, and immunological evaluations for adequate immune responses. During Phase I trials, vaccines rarely fail due to safety concerns, but quite frequently due to insufficient or inconsistent immune responses below expected levels.

Phase II clinical studies usually comprise no more than several hundred subjects and are normally done as controlled studies comparing the test vaccine along with an alternative prophylactic or therapeutic treatment. Clinical evaluations are mainly addressing the vaccine's effectiveness and safety, doses, application schemes, and possibly also different target groups selected by age, specific risks, countries, or by epidemiological criteria.

Phase III clinical studies are expanded, controlled, or uncontrolled trials on efficacy and safety in various clinical settings and under practical conditions. Altogether several hundred to several thousand trial subjects are enrolled at various trial sites, which are often distributed over several countries in order to study different epidemiological situations, ethnic populations, and deviating local medical practices. Phase III studies can also be evaluated for risk–benefit relationships and address practicability aspects as well as interactions by other products or concomitantly applied medical treatments. Postmarketing clinical trials of the licensed product, often referred to as *Phase IV clinical trials*, are, nowadays, rather often, also requested as part of a conditioned licensing of pharmaceutical products, mainly in order to specifically investigate those aspects that can only be assessed by large statistical cohorts.

For live attenuated vaccines, specific safety aspects must also be studied clinically. As live viruses or bacteria replicate in the vaccine and may be shed into the environment, the potential transmission of vaccine microorganisms to unvaccinated subjects must be studied. If transmission is possible or likely, the vaccine's genotypic and phenotypic stability must be carefully studied and confirmed.

4.4 Licensing and Registration of Vaccine Products

On the basis of previous experience and evaluations, the process of getting a vaccine through the evaluation at different national licensing authorities on average takes about two years, which includes time periods for working off and answering questions not adequately covered by the registration dossier. As vaccines and other biological pharmaceuticals are particularly complex compositions that cannot be adequately characterized by specific quality control methods, the entire process, manufacturing facilities, analytical methods used to specify the product and its starting materials, and all ingredients are considered as being an inherent characterizing part of the product. Any change to these affects the product's license and requires approval by the licensing authority. Changing essential elements, such as production cell substrates or microbial strains, critical test methods such as potency assays, purification methods, or

formulations would almost inevitably be seen as a change to the product that needs to be verified by new clinical trials. Furthermore, each individual batch produced must be approved and released by the authorities.

5
Economic Aspects of Vaccine Development

Without any doubt, the development of vaccines is a very costly and long-lasting process that bears a significant risk of failure. The following paragraphs intend to provide some deeper insights into the specific risks and chances, cost, and time requirements to develop a new vaccine, as the knowledge of those basics drawn from experience may by helpful in decision making. After all, successful vaccine development depends not only on good science and technical methods but also to a great extent on adequate management decisions.

5.1
Vaccine Development Cost

The number of successful vaccine projects is fairly low and retrospective evaluations of the specific cost incurred by these development projects over a time period of 10 or more years are difficult. However, cost evaluations covering developments from the late 1960s to the early 1990s exist, which summarize the development cost of various pharmaceutical developments. Although chemical drug products dominated these figures, several vaccine projects were also assessed. With all the inherent variability, we can reasonably assume that these figures also give adequate estimates for vaccine products. These evaluations show that pharmaceutical development cost during those years tended to increase by a factor of about 10 within a decade. As demonstrated by a simple graph (Fig. 3), the rising cost is only in part due to the normal inflation rate, but clearly correlates with the increasing regulatory demands,

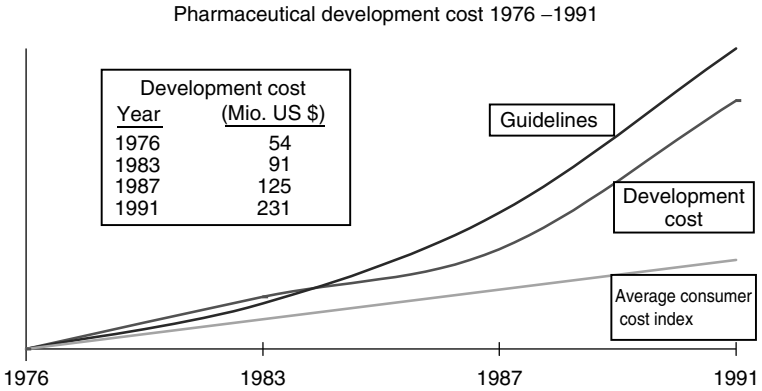

Fig. 3 Pharmaceutical development cost. Development cost denoted for various mainly chemical pharmaceuticals, including vaccine projects. Correlation with rising regulatory requirements as indicated by the counts of existing guidelines at the indicated point of time. Average consumer cost index for a household of four persons taken from figures released by the Feral German Statistics Office (Statistisches Bundesamt). Graphs show relative figures adjusted to a uniform scale.

as exemplified by the number of applicable guidelines.

The latest well-founded figure of US$231 million, published in 1991, was based on evaluations of 93 successful product developments. This sum has since been quoted on many occasions and has partly been willfully and generously projected to later dates. Thus, quoted sums of US$500 to 800 million may be encountered to describe the cost and risks of pharmaceutical development projects. However, these figures are misleading if several important details about the original calculations are not mentioned: those 231 millions include to a great extent, opportunity cost (calculated by an interest rate of 9% of the invested capital over a period of 12 years) and the cost of many unsuccessful or abandoned projects (assuming a success rate of 23%), furthermore, tax credits were not accounted for. All in all, the underlying ex-pocket expenses must be assumed to be about one-fourth of the total sum, and, according to today's standards, direct cost between € or US$ 60 and 100 million may be assumed as a realistic estimate for the development of an average new vaccine. If, however, there is no suitable infrastructure and if investments into completely new production facilities are to be made, this could easily double the cost.

Apart from capital investments, personnel is the most relevant cost factor to be considered. Owing to the high number of persons involved in the preclinical and technical development and to the long duration of these activities (on average about four years until the start of clinical trials and several years beyond until registration), preclinical and technical activities account for about one half or more of the development cost. Clinical development normally causes about one-fourth of the development cost; the remaining quarter is evenly spread throughout the developing organization and covers overheads, technical support functions, quality control, and quality assurance, as well as various other specialists, for example, for quality assurance, regulatory affairs, patenting, and market research.

Taken together, the average vaccine development project requires about 170 man-years of work with average total expenditures per person and workplace in the pharmaceutical industry being around €180 000 to 200 000 or for the United States around US$220 000 to 240 000. This results in roughly € or US$30 to 40 million for personnel and workplace expenses. External cost of around 20% and highly variable capital investments into plant and facilities are then to be added.

5.2 Risks and Chances

The success of a project during and for the entire development process can be estimated by the numbers of projects that make it until the next development phase and finally end up as a commercial product. On the basis of data for products developed during the preceding decades until 1994, one must assume that only 50% of the preclinical vaccine development projects enter the clinical phase and another 50% is abandoned during the clinical trials. Having passed all preceding hurdles, product registration seemed to be uncritical, as only a loss of 1 out of 100 vaccine projects was noted. For pharmaceutical drug products, overall success rates of 11% were found, that is, 100 product candidates entering the preclinical development resulted in only 11 licensed products. Vaccine projects appeared to be more successful with an average of 22% licensed products per 100 projects (compare

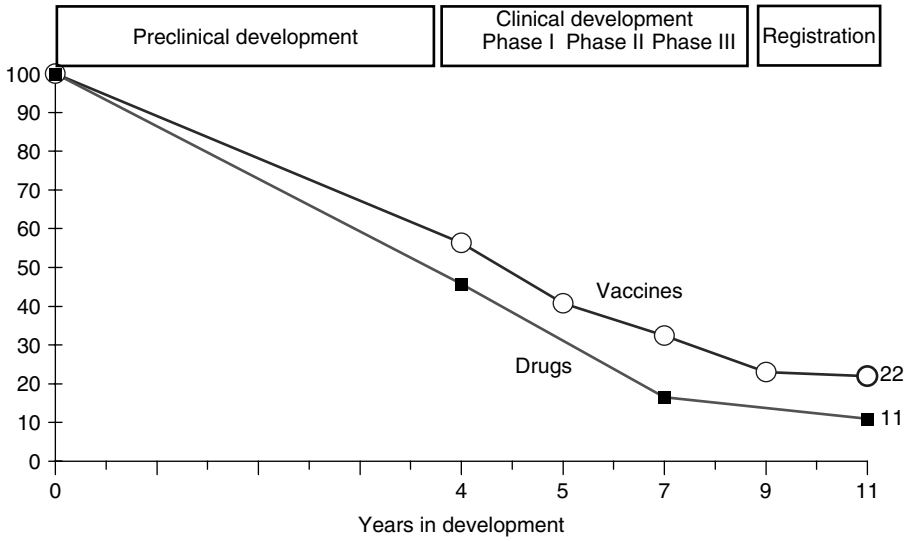

Fig. 4 Success rates of vaccine development projects in comparison with drug development. Data represent the percentage of projects, which successfully completed the respective development phase. Data summarized from assessments that mainly refer to projects of the 1980s. As discussed in the text, the success rates for vaccines developed today are most likely lower than shown here.

Fig. 4). However, the figures presented in Fig. 1 for AIDS vaccine projects of the recent past show that average figures can also be grossly misleading.

Most current vaccine candidates are dealing with quite "difficult" infectious diseases, which, under natural conditions, do not induce a lasting protective or sterile immunity, thus doubts about the applicability of those earlier risk evaluations to current vaccine projects are justified. Even if AIDS vaccine projects are not considered, a snapshot view on more recent vaccine developments supports the suspicion that success rates for today's projects and particularly for new vaccine indications are much lower. As shown in Table 4, the success rates of preclinical development in more recent times appeared to be below 50% and only 14 to 15% of all projects were found in Phase III clinical trials. Whereas preclinical projects represented a very wide spectrum of entirely new vaccines, the majority of Phase III clinical trials were covering alternatives to already existing vaccines, such as competitor's developments, combinations, or improved formulations. Less than 5% of these advanced projects were approaches to develop entirely new vaccines. These figures represent only a static view upon the vaccine development for a certain time period, but they clearly indicate that nowadays – and particularly for really new vaccines – development success rates clearly below 5% appear more realistic than earlier estimates that were above 20%.

6 Perspectives

Judged by the number of scientific publications in microbiological and biotechnology

Tab. 4 Human vaccine development projects in the years 2000 and 2002.

Project phase	*No. of vaccine projects*		
	Year 2000	*Year 2002*	*Percentage*
Preclinical development	349	331	100
Advanced to Phase I clinical development	158	154	45–47
Advanced to Phase II clinical development	102	106	29–32
Advanced to Phase III clinical development	51	47	14–15
Thereof alternatives to existing vaccines in Phase III	37	32	10–11
Thereof new vaccine indications in Phase III	14	15	4–5

Notes: Data extracted from listed vaccine projects in the year 2000 and 2002 in the United States without consideration of AIDS vaccine projects. Vaccine projects in Phase III clinical trials for new indications include vaccines against *Coccidioides immitis*, group B *streptococcus*/*Streptococcus pneumoniae*, *Plasmodium falciparum*, *Trypanosoma cruzi, Leishmania major*, *Mycobacterium leprae*, Meningococcus B and C, Rotavirus, *Vibrio cholerae*, and *Pytium insidiosum*.

journals, vaccine R&D appears to have a great attraction for scientists from all pertinent scientific disciplines. Whenever new methods and technologies became available, these have always and immediately triggered a huge number of new vaccine research projects and stimulated research into formerly hopeless vaccines. Along with the good reputation that vaccines enjoy, this scientific background is an excellent base for new vaccines. It also provides a favorable environment to attract the required capital that is needed to develop vaccines into marketable products. However, considering the high risks and the long duration of vaccine R&D, there must also be other reasons why investors and pharmaceutical companies invest in this field.

Vaccines represent only a small proportion of the pharmaceutical market, but, nevertheless, vaccines are extremely successful products. Firstly, vaccines effectively prevent diseases, rather than only curing these. Owing to these advantages, vaccines have often created their own markets and have even defended their market shares against competition by very effective therapeutics or antibiotics. Secondly, most vaccines are recommended by public health authorities and thus enjoy a rather safe position on the market. Furthermore, there are usually only rather limited numbers of competitive products because vaccines are far too complex to become an easy target for producers of generic imitations. And, finally, vaccines usually have a very long life span. As long as vaccine products are not neglected and become outdated, but are constantly adapted to a better state of the art, vaccines do not lose their market position, unless they are too successful and by and by eliminate the need to use the vaccine.

Thus, vaccine R&D can be very rewarding for both scientists and investors. Regarding the risks, however, the investor has a quite different perspective than the scientist. The investor may contain risks by putting capital into many different projects and enterprises, thus participating in the statistically very successful ''average vaccine.'' To a limited extent, large companies who develop vaccines can also apply the same strategy. However, small enterprises and individual scientists working for only

one or a few R&D projects have only few options to manage and reduce risks. They often choose a high-risk approach by aiming only for ''block buster'' products. In this case, they must be aware that competition in this field will be also very strong, which increases the risks even more. However, within the given financial limitations, risks could also be spread over a certain number of projects in early R&D phases, preferably by approaching different indications and concentrating on an attractive new or improved technology.

Scientifically and commercially, vaccine R&D is certainly not a playing ground for those who expect fast success and revenues. Any organization that intends to invest into vaccine R&D should be prepared – both mentally and financially – to endure for at least 10 to 20 years.

Keywords

Bilaterians
The bilaterally symmetrical animals, including all triploblasts, excluding the diploblasts and sponges.

Clade
A group of species linked by a common ancestral species. Also called *monophyletic group*.

Diploblasts
Animals possessing only two cell layers (the ectoderm and the endoderm). Includes the cnidarians (jellyfish) and the ctenophores (comb jellies).

Genetic toolkit
Set of genes necessary to construct an embryo. Contains mostly transcription factors and signaling molecules.

Homeobox
Conserved region of 180 nucleotides, translated in a 60 amino acid domain (the homeodomain). Homeobox genes code for transcription factors called *homeoproteins*. Examples: *Otx, Hox*.

Homologs
Genes sharing sequence similarity and inferred to have originally derived from an ancestral gene at an indeterminate point. Example: otx genes.

Orthologs
Genes in different species that are related to one another by speciation events. Example: *otd* in *D. melanogaster* is orthologous to *Otx1* and *Otx2* in mammals.

Paralogs
Paralogous genes are those that in different, or the same, species are related by a gene duplication event. Example: *Otx1* and *Otx2* in mice.

Promoter
Noncoding region of the DNA that lies near the start site of transcription. Contains binding sites for the transcriptional machinery.

Pseudogenes
Nonfunctional genes. A pseudogene can be transcribed.

Triploblasts
Animals possessing three cell layers: the ectoderm, the mesoderm, and the endoderm.

The body (or phenotype) of a multicellular organism has two histories. One is ontogenetic, which is the development of the adult body from a fertilized egg. The other is phylogenetic, which is the evolutionary history of the organism. These two histories are fundamentally connected, as evolutionary change to the shape and size of an organism's body occurs via change in the processes regulating embryonic development, while selection on the adult phenotype determines whether such changes persist or are eradicated. Evolutionary developmental biology seeks to understand how evolutionary change in developmental processes has occurred, and how it has led over evolutionary time to the wide diversity of body forms that exist today or have existed in the past. At the core of the subject is the study of the genes that regulate development, and how change in such genes results in evolutionary change of the phenotype.

1 Historical Perspective and Recent Developments

1.1 Relationship between Ontogeny and Phylogeny in Late Nineteenth/Early Twentieth Century

Throughout the later part of the nineteenth century and early twentieth century, the study of embryology and evolutionary biology were deeply intertwined. The comparative study of embryonic development provided authors such as Haeckel with the basis for evolutionary hypotheses, and helped to refine an emerging view of the phylogenetic relationship of living animal groups. This cozy relationship was essentially split in the 1920s and 1930s by the rise of a new biological discipline, genetics. Evolutionary biology embraced genetics, becoming increasingly quantitative in its approaches, and resulting in the birth of evolutionary and population genetics. Embryology became increasingly experimental, adopting both genetic

and manipulatory methods for perturbing embryos, and laying the foundations for the study of developmental processes that we now refer to as developmental biology.

With some notable exceptions, the two disciplines remained largely separate until the 1980s, when key technical advances opened the door to a reunited field; evolutionary developmental biology. Essentially, the technical advances relate to our ability to examine and manipulate DNA, the common bedrock on which both disciplines could be mounted (see Sect. 1.2). Developmental biologists were now able to examine the genes responsible for regulating embryonic development, and to determine the precise genetic lesions responsible for specific mutant phenotypes. A milestone was passed in 1984, with the discovery of Homeobox genes and the subsequent demonstration of the conserved role of Hox type Homeobox genes in the development of animals with widely divergent body plans. Homeobox gene conservation was soon discovered to be but the tip of an iceberg of conserved genes and pathways that regulate animal development.

The new techniques that allowed us to read gene sequences and understand the relations between genotype and phenotype were a giant step that transformed the study of evolutionary developmental biology, opening the door to detailed, rigorous examination of hypotheses often first posed over a hundred years ago.

1.2 Impact of Molecular Biological, and Other Techniques

Molecular biology techniques such as polymerase chain reaction (PCR), Southern blotting, and DNA library screening have facilitated the rapid isolation of genes. With the application of such techniques to multiple model species, it rapidly became clear that different animals had genes that share a high level of similarity in their sequences. Degenerate PCR could then be used to isolate related genes from different species on the basis of such similarities. This technique drastically accelerated the number of genes characterized in both model and nonmodel systems, freeing gene isolation from traditional genetic studies.

New techniques also allowed the visualization of gene products, enabling researchers to examine their distribution in embryos. The characterization of a gene expression pattern is performed using two main techniques to visualize the products of the gene: *in situ* hybridization for the visualization of mRNA transcripts and immunolocalization for the visualization of proteins. Both techniques can be performed either in whole fixed embryos, in dissected parts of embryos, or on sections. Expression domains can also be localized in living embryos and adults using Green Fluorescent Protein (GFP) technology.

All these techniques, however, do not give any insight into the function of a gene or the protein it encodes. This can be assessed in several ways. Historically, the most informative method has been by creating and analyzing mutants, though this is extremely time consuming and labor intensive. Of great interest is the recent emergence of antisense technologies, such as RNAi and morpholino oligonucleotides, which allow gene function to be assessed without the need for time-consuming mutant screening programs. Additional to these loss-of-function approaches, gain-of-function experiments can also be informative, and are usually undertaken by injection or electroporation of RNA or DNA constructs into embryos. Finally, genomic and postgenomic techniques for

examining genes and proteins on a large scale are playing an increasingly important role in evolutionary developmental biology. In this case, researchers can follow the impact of one change on the expression of thousands of other molecules at once, and thus better understand the real impact of each genomic modification. In the following, we address some of the key evolutionary developmental questions currently under investigation, highlighting recent advances in our understanding and suggesting how future developments in biology will impact on this field.

1.3 Important Questions

1.3.1 The Microevolution of Development

One of the central questions of evolutionary biology has been the relationship between microevolution and macroevolution, that is, how population and speciation level processes contributed to the evolution of diverse animal body plans. As discussed earlier, it has been demonstrated that genes act through development to create morphological structures, and from this, it follows that evolutionary change in morphology is linked to changes in developmental processes. To understand this, we need to know how variation in genes arises, the nature of variation in developmental processes in extant populations, and we need to be able to examine the effect of selection on this variation. These issues are addressed in Sect. 3.

1.3.2 Canalization and Constraint in the Evolution of Development

Animal evolution is constrained by physical laws, such as gravity, rates of diffusion, and rates of chemical interactions, which act to limit morphology and physiology in certain ways. An important question is whether developmental processes also provide constraints on the evolution of animal morphology. For example, all vertebrates share fundamental similarities in their body plans, despite hundreds of millions of years of separation. Does this imply that they are unable to ''undo'' their basic design (i.e. that certain phenotypic end points cannot be reached), or is it simply that radical changes are possible, but selection continually removes them? An answer to this question would help us determine whether canalization of developmental processes constrains the evolution of animal form. Similarly, are all processes and periods of embryonic development equally subject to evolutionary change, or is phenotypic variation more likely to arise and be subject to selection at specific times and places in development? 'Answers to this too would help us understand why body plans often appear to be highly conserved in the face of enormous finer-scale variation, as seen in highly speciose taxa such as the insects for example'? The consensus view is that development does constrain the evolution of morphology, but this is not proven and many researchers hold alternative views.

1.3.3 The Basis for Major Transitions in the Development of Body Form

Taxonomists divide the animal kingdom into some 30 phyla, each with a different body plan. Notably, the majority of such body plans appear to have evolved in a surprisingly short window in the Cambrian, the so-called *Cambrian explosion*. How did such body plan diversity evolve, and how do other major changes in development and morphology evolve? In particular, can such differences be explained by the cumulative effect of microevolutionary processes,

with the extinction of intermediates giving the illusion of major transitions, or do other factors, such as those discussed earlier in Sect. 1.3.2, affect body plan evolution? The discovery that homeotic mutations, in which one part of an animal's body can be completely replaced by a duplication of another part, such as an antenna by a leg, can be caused by changes in single genes of the Hox complex (see Sect. 2.3), was taken by many to indicate that major changes in body form could be produced by relatively small mutations. However most evolutionary biologists now dispute that such mutations and the "hopeful monsters" they produced could have contributed to the evolution of animal morphology in such a simple way. These issues are addressed here from two different standpoints, the evolution of new complex characters that define major groups of animals (innovations) in Sect. 4, and the loss of complexity in Sect. 5.

Related to this issue is the degree of underlying similarity that appears to be present in the basic developmental programs of different phyla. One example of this is the role of the *Pax6* gene in eye development in numerous phyla with quite different eye structures, for example, insects, nemertene worms, and vertebrates. At its basic level, this suggests that the common ancestor of these taxa (and by extrapolation all bilaterally symmetrical animals: see Sect. 2) had a photoreceptor whose development was regulated by *Pax6*. Similarly, while vertebrates and insects have nervous systems that are superficially very different, comparisons of neural patterning in *Drosophila* and mouse have suggested further conservation of more intricate mechanisms between widely divergent taxa (Fig. 1). These studies have demonstrated that the positioning of cell types along both the dorsoventral and anteroposterior axes of the nervous systems of these species reflects a similar underlying profile of gene expression. This suggests a degree of molecular similarity that underlies the different nervous systems of insects and vertebrates, and therefore that the common ancestor of these two animal lineages also used such mechanisms to pattern its nervous system. The evolution of the vertebrate and insect nervous systems, therefore, can be seen as elaborations built upon a complex, preexisting, molecular ground plan, indicating how such major differences might have evolved from a common ancestor.

2
Animal Phylogeny and Gene Ontology

2.1
The Critical Nature of Phylogenetics in Defining Taxonomic Relationships and Gene Classification

The "tree of life" is a pictorial representation of the relationships between living organisms. Early trees, such as that of Ernst Haeckel, tended to depict an apparent progression from what was regarded as simple organisms to those considered more complex, and ultimately, man. Formalization of the tree-building process began with the science of cladistics, founded by Willy Hennig. Numerous attempts have been made to reconstruct animal phylogeny using adult as well as embryological morphological characters, with the results differing in many details. While most agree on major relationships, such as the division of bilaterians into protostomes and

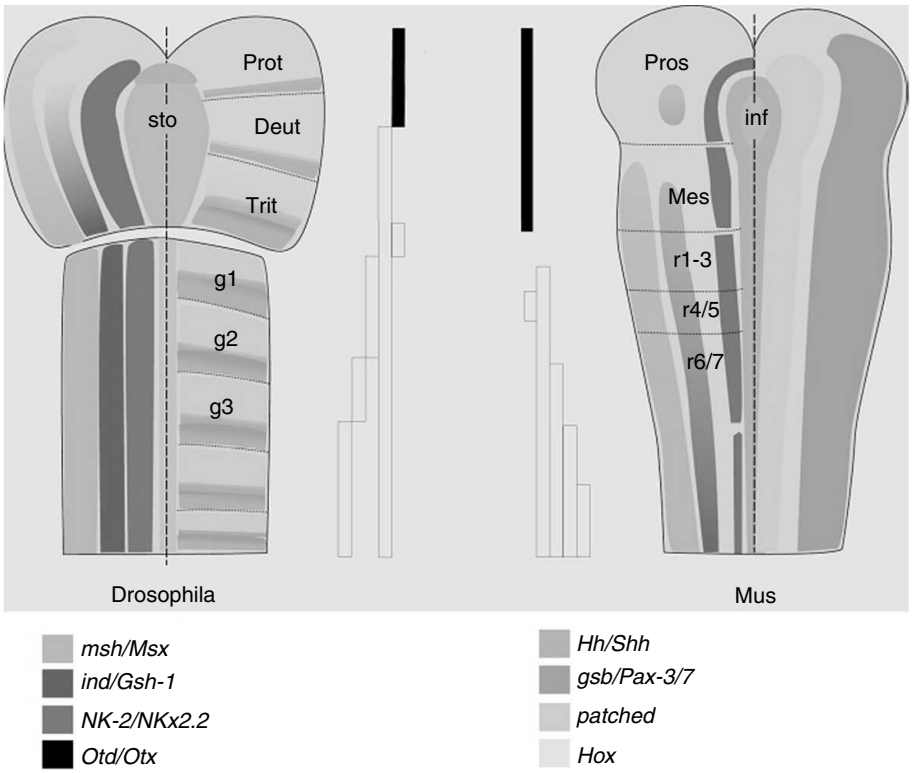

Fig. 1 Comparisons of gene expression patterns in the anterior central nervous system (CNS) of *Drosophila* and Mouse embryos. The expression of *msh/Msx* (blue), *ind/Gsh-1* (brown), *NK-2/Nkx-2.2* (red), *Otd/Otx* (black bars) and *Hox* orthologs (white bars) has a similar topological arrangement in the two species, despite the considerable differences in their nervous systems. The expression patterns of *Hh/Shh* (violet), *gsb/Pax-3/7* (green) and *patched* (yellow) differ between the two species. The similarities in gene expression are often considered to show that their central nervous systems derive from a single ancestral nervous system of considerable complexity (Reprinted with permission from Arendt, D., Nubler-Jung, K. (1999) Comparison of early nerve cord development in insects and vertebrates, *Development* **126**, 2309–2325. Copyright 1999 The Company of Biologists Ltd.) (See color plate p. xxviii).

deuterostomes, and the basal placement of diploblastic phyla such as the cnidarians, ctenophores, and sponges, such variability in proposed phylogenetic relationships between taxa is a real problem for those seeking to reconstruct the evolution of animal development, as interpretation of comparisons between taxa is entirely dependent on how they relate to each other.

Over the past 20 years, molecular phylogenetics, primarily based on shared derived similarities in the sequences of genes, has helped resolve some of these ambiguities. In theory, most molecular changes should not result in phenotypic change, and hence shared derived molecular characters should give a view of animal phylogeny that is independent of

morphology. In practice, debate continues over whether molecular or morphological phylogenetics gives the most accurate view of the tree of life. Despite this ambiguity, the use of molecular phylogenetics has proven to be a powerful tool that has been used to redraw relationships between animal phyla. A good example of this is the phylogeny of the animal kingdom based on 18S ribosomal RNA gene sequences and some *Hox* gene sequences. This agreed with the morphological consensus in dividing bilaterians into protostomes and deuterostomes, but further divided the protostomes into the ecdysozoa (including the arthropods and the nematodes) and the lophotrochozoa (including the annelids, molluscs, and brachiopods). This rearrangement of the phylogenetic relationships of animal phyla has had profound consequences for our interpretation of animal evolution, suggesting that some monophyletic groups previously created on the basis of shared morphological

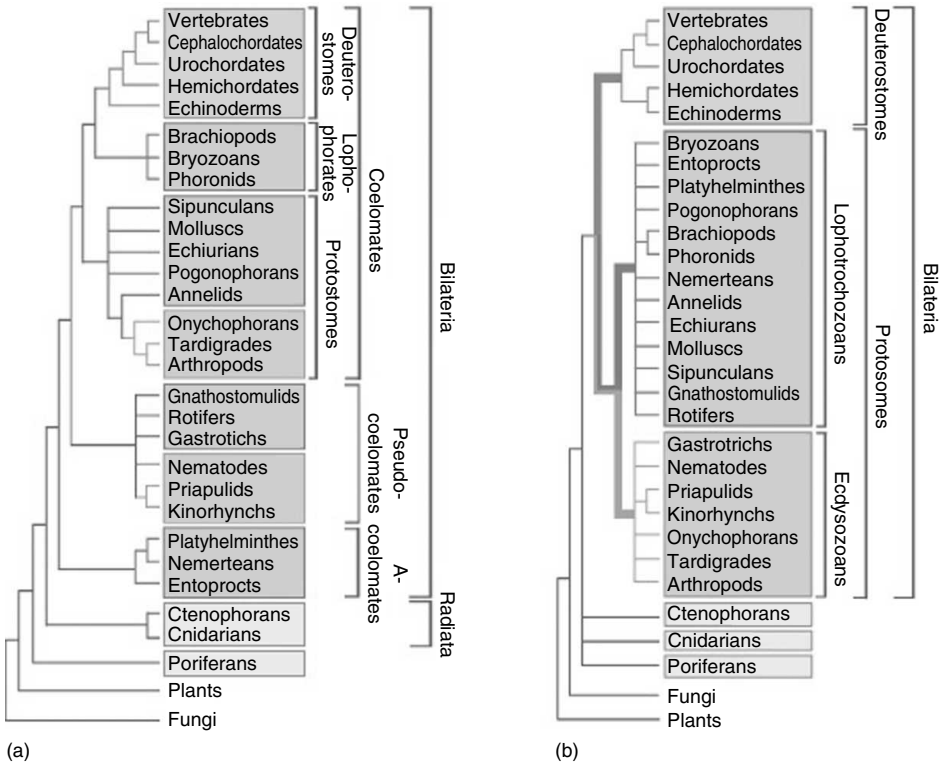

Fig. 2 A metazoan phylogenetic tree, based on morphology and embryology. The bilaterians are subdivided into three major groups: the coelomates, pseudocoelomates, and acoelomates. The tree in (b) is based on more recent DNA-based analyses. Under such an analysis, pseudocoelomates and acoelomates are included into the protostome clade, which is itself subdivided into lophotrocozoans and ecdysozoans (Reprinted with permission from Adoutte, A., Balavoine, G., Lartillot, N., Lespinet, O., Prud'homme, B., de Rosa, R. (2000) *Proc. Natl. Acad. Sci.* **97**(9), 4453–4456. Copyright 2000 National Academy of Sciences, USA).

resemblance were artifacts (Fig. 2) In turn, some researchers have taken this to suggest that the presumed shared morphologies were in fact convergently evolved.

2.2 Identification of a Conserved Developmental Genetic Toolkit in Animals

The developmental genetic toolkit can be defined as the minimum set of genes necessary to construct the embryo, and as such, excludes housekeeping genes that are necessary for the metabolic processes of the adult body. This is a loose definition and more of a working concept than a strict description of what makes a gene "developmental." At a practical level, these genes mostly encode transcription factors and components of intercellular signaling pathways. Transcription factors interact with DNA to regulate the expression of other genes. Differential expression of transcription factors is a fundamental part of cell differentiation. The most famous part of the genetic toolkit is the large family of transcription factors called *homeobox genes* that appear to have some functions conserved in most, if not all, phyla (see Table 1). Other major families of transcription factors in animals include the zinc finger, leucine zipper, basic helix-loop-helix, Tbx, and Fox families. Signaling pathway molecules include members of the TGFβ, Wnt, Hedgehog, Notch, and fibroblast growth factor (FGF) pathways. While transcription factors work inside a cell's nucleus and are essentially cell-autonomous, signaling pathways mediate communication between cells and are the key components in organizing the spatial distribution of differentiating cells. This is a critical step in building a multicellular organism. Many such genes were originally characterized in *Drosophila* and research over the past 20 years has demonstrated that most such genes are shared by many different animal phyla, and are therefore likely to have been evolved at an early point in animal

Tab. 1 Some examples from the developmental genetic toolkit.

Homeobox transcription factors	*Conserved roles*
Hox	Anteroposterior axis
Sox	Neural differentiation
Vnd/Gsx	CNS lateral patterning
Cad/Cdx	Posterior patterning
Otd/Otx	Anterior patterning
So/Six	Neural differentiation
Msh/Msx	Neural differentiation
Other transcription factors	*Conserved roles*
Fd1/FoxC	Dorsal mesoderm differentiation
Bin/FoxF	Visceral mesoderm differentiation
Achaete-Scute/Ath	Proneural differentiation
Tbx genes	Various
Secreted signaling molecules	*Developmental roles*
Wingless/Wnt	Various
Hedgehog	Various
BMP/chordin	Dorsoventral patterning
Notch	Various

evolution, before the radiation of the lineages that have given rise to most living animals. Key examples in this context are the *Hox* genes.

2.3 Hox Genes and AP Axis: A Detailed Example from the Toolkit

The *Hox* genes form a subset of the homeobox gene family. Originally isolated in *Drosophila melanogaster*, Hox orthologs have since been found in all animals. Of special interest is the conservation of the clustered genomic organization of *Hox* genes in several bilaterian lineages (Fig. 3), suggesting first that the common ancestor of both protostomes and deuterostomes had a complement of at least eight genes organized in a single cluster, and second that the clustered organization is important for the proper function of these genes. *Hox* genes are deployed in the developing embryos of several bilaterian lineages in

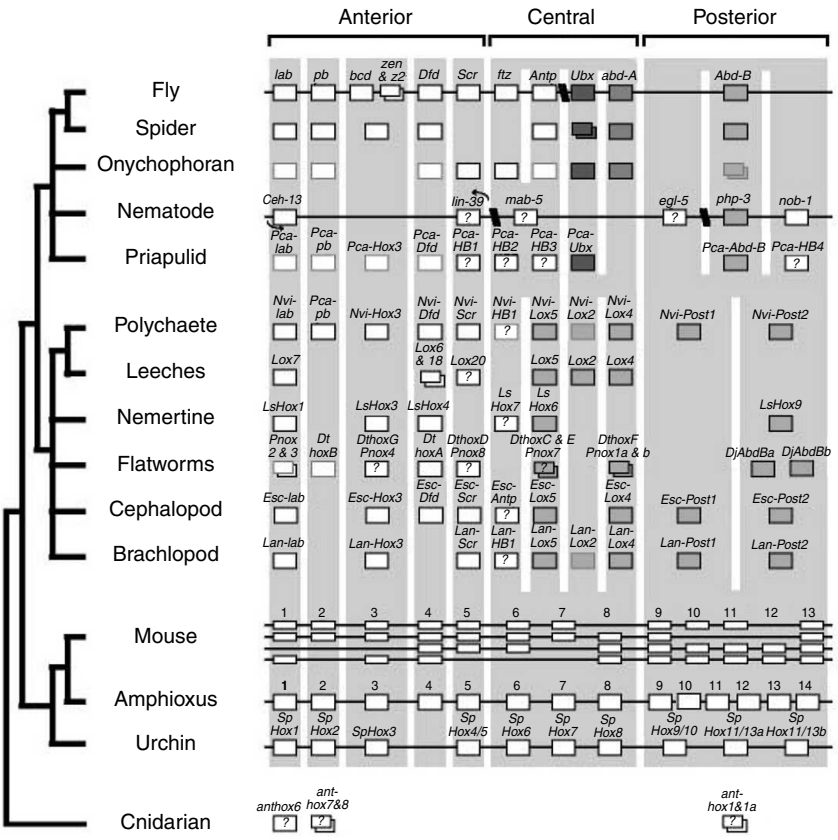

Fig. 3 *Hox* gene clusters in bilaterians. Each shaded column corresponds to an orthologous group. Genes are marked by a question mark when orthology is uncertain. Posterior *Hox* genes have been duplicated in the deuterostome lineage (lower three species) and are all related to the fruit fly gene *Abd-B*. Note that all mouse clusters lack several Hox orthologs (Reprinted with permission from Balavoine, G., deRosa, R., Adoutte, A. (2002) *Mol. Phylogenet. Evol.* **24**, 366–373.)

a strikingly similar way. Specifically, their role in the development of the anteroposterior axis of the early embryo correlates with their relative location within the cluster. Thus, genes located at one end of the cluster are expressed anteriorly in the embryo, while those toward the other end have more posterior expression. This conserved feature is named *spatial colinearity*.

In many taxa, *Hox* genes are also involved in other developmental processes, for example: the fine sculpting of bristle patterns on the legs of drosophilid flies, and the differentiation of the hematopoietic cell lineage in vertebrates. These probably reflect the recent co-option of the *Hox* genes to these new roles, reflecting a fundamental property of the evolution of genes and pathways involved in development: their frequent co-option in the evolution of new morphology.

2.4 The Evolution of this Toolkit via Duplication

When compared, the genomes of *Drosophila* and vertebrates show that, although they possess members of many of the same gene families, the number of members of each gene family is often different between the two lineages. Typically, the excess of copies is in favor of the vertebrates. Extra copies of genes arise by gene duplication, a phenomenon that is common in the evolution of genomes. A paradox is that, directly after the duplication event, the copies of the gene should be functionally redundant, suggesting a lack of selective advantage and rapid elimination of additional copies. Genome comparisons show, however, that many gene duplicates have been conserved for long enough to acquire differences in their patterns of expression. Such acquisition of different spatial or temporal expression patterns is one of the accepted explanations as to why duplicates have been preserved. A model, called the *Duplication-Degeneration-Complementation* (DDC) model, provides the most thorough and satisfying explanation of this process, and takes into account not only variations within the coding sequence but also modifications in regulatory sequences. The DDC model proposes three possible fates for a duplicated gene (Fig. 4): degeneration, when a copy is eliminated or made nonfunctional (pseudogene); neofunctionalization, in which the duplicates diverge by one acquiring a new function (which was not present with the ancestral gene); subfunctionalization, in which the duplicates diverge by reciprocal loss of some of the parental functions. Evidence so far suggests that all three fates happen depending on the gene. In summary, duplication is clearly an important force in evolution of the gene families that regulate development, and will be discussed in combination with gene loss in Sect. 5.

3 Microevolution of Developmental Processes

Loosely defined, the microevolution of development includes the study of within-population variation in developmental processes, and the contribution of development to speciation level processes. There are several key questions in this field that remain to be answered, including, for example: How much genetically determined variation is there in natural populations which gives rise to developmental changes? What is the nature of this

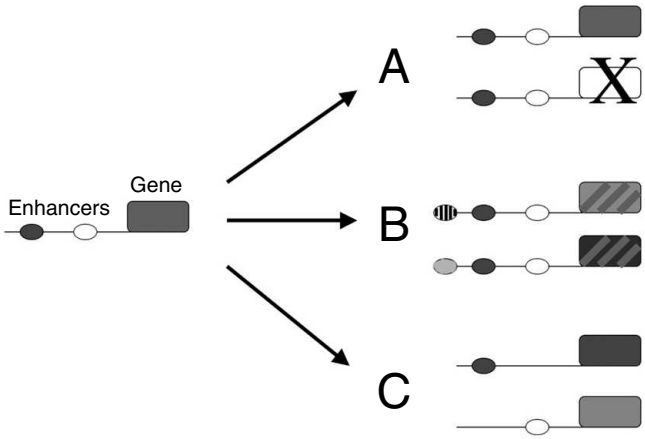

Fig. 4 Fates of duplicated genes as proposed by the DDC model. (A) Degeneration. One copy is eliminated after duplication. (B) Neofunctionalization. Each copy acquires a new expression that can replace or complement the ancestral one by acquisition of new regulatory sequences in front of each gene. (C) Subfunctionalization. Each duplicate becomes essential to the development of the embryo because of reciprocal loss of the original regulatory sequences. Note that these models are not mutually exclusive.

variation; does it primarily involve coding sequences or noncoding sequences? How does this yield phenotypic variation on which selection can operate? Do gene networks or other processes insulate individuals from phenotypic change by buffering developmental processes? Does convergent evolution of morphology tend to involve parallel genetic changes in different lineages? This section illustrates how answers to some of these questions are emerging from recent studies.

3.1 Evolution via Changes in Coding or Noncoding Sequences

While mutation rate can vary substantially across the genome, there is no evidence to indicate that different regions of genes, such as introns, exons, promoters, or enhancers, have generically different mutation rates. Thus, at a basic level, genetic variation can arise in all parts of a gene. When comparing orthologous genes from different species, however, translated exons usually appear more highly conserved than noncoding sequences. This implies that variation in coding regions, specifically of a sort that affects the amino acid sequence of the encoded protein, may be under tighter restraint than other regions of genes. With respect to developmental genes, several studies have demonstrated functional conservation of protein sequences over immense evolutionary distances. For example, the *Otx* genes encode homeobox genes expressed in the anterior of the developing embryos of several phyla. Nagao and colleagues were able to rescue the defects of fruit flies mutated for the gene *Otd*, by inserting the human orthologs, *Otx2* and *Otx1*, demonstrating that the human proteins could replace the *Drosophila* protein despite over 500 hundred million years

of evolutionary separation. Indeed, such studies form the basis of the concept of a conserved developmental toolkit, outlined in Sect. 2. This is not to imply that protein-encoding sequences do not evolve. They do, and this can have functional consequences, for example, some insect *Hox* genes have acquired new roles linked to the evolution of new protein motifs. However, it seems that variation between species is concentrated in noncoding sequences. While much of this may reflect genetic drift of nonfunctional sequence, it also includes the regions responsible for regulating the spatial and temporal deployment of gene transcription, the promoters and enhancers.

A small number of studies have addressed the evolution of the regulation of developmental genes at a functional level. One of the best-studied models in this regard is the fruit fly *Drosophila*. A key example of this is the *Ultrabithorax* (*Ubx*) gene of *Drosophila* and its role in the evolution of leg trichome pattern. Trichomes are small protrusions of the cuticle that cover adults and larvae in patterns that are typically species specific. Stern demonstrated that regulatory changes controlling transcription of the *Ubx* gene resulted in subtle differences in the distribution of the Ubx protein, and were the cause of subsequent subtle differences in leg trichome patterns between species of *Drosophila*. Such subtle changes in gene regulation are presumed to be responsible for the differences in the expression patterns of orthologous genes between species, and are presumed to underlie much of the evolution of developmental processes.

There are also other factors that affect the evolution of enhancers. The *Drosophila even-skipped* (*eve*) stripe 2 enhancer is one of the best-studied regulatory elements. *eve* is expressed in stripes in a pair rule pattern in the *Drosophila* blastoderm embryo, with expression in different stripes controlling a distinct enhancer. Ludwig and colleagues addressed the question of the relationship between genotypic and phenotypic variation in the stripe 2 enhancer. Comparison of the sequence of this enhancer between different *Drosophila* species showed considerable sequence variation, despite the ability of each sequence to direct correct spatiotemporal gene expression in its endogenous setting. By moving the enhancer between species, they then showed that a heterologous enhancer could essentially work in another species, despite the differences in primary nucleotide sequence.

This shows that function can be preserved despite high levels of sequence change in the enhancer region. This raised the possibility that the way enhancers work permits substantial genetic variation without this impacting on the phenotype. At a practical level, this makes understanding enhancer evolution from sequence information extremely problematic, and it is yet to be definitively established whether similar forces operate in species other than *Drosophila*, although, as gene regulation seems to be fundamentally similar between taxa, there is no *a priori* reason to think they should not.

3.2 Parallelism in Morphological Evolution

Similar selective forces, provided by similar ecological conditions, tend to drive the evolution of similar adaptive morphologies in different lineages. Recent studies have raised the surprising possibility that such changes in morphology may often reflect independent evolution of the same developmental pathway. A good example of this is the role of the *shavenbaby* (*svb*) gene in the evolution of larval trichome patterns in

Drosophilid flies. Most *Drosophila* species have been found to have a distinct pattern of trichomes on the larval cuticle. In addition, some species such as *Drosophila sechellia*, have lost trichomes, adopting what is known as a "naked" morphology. These naked species are scattered through *Drosophila* phylogeny, clearly showing that the morphology has evolved, convergently, on several occasions. Shavenbaby performs a key regulatory function in determining where trichomes will develop, and recent studies show that selection for naked morphology has targeted this locus in the evolution of different naked species. This is a clear case of genetic parallelism in the evolution of a convergent phenotype, and raises the possibility that other developmental traits that vary between species may in fact reflect parallel genetic changes.

4
Developmental Basis of Innovations

Innovations are characterized by novelty, with the suggestion that innovations provide some adaptive advantage to a taxon. In many respects their definition is somewhat subjective. Characters described as innovations are often inferred to have evolved at the base of a lineage comprising the taxa in which they are found. In reality, a clear distinction between species that possess a particular innovation and species that do not is probably only apparent due to the extinction of intermediate forms. Examples of such innovations include, in the bilateria, the presence of the mesodermal layer and bilateral symmetry of the body, and, in vertebrates, the neural crest cells and the internal skeleton. Each have been proposed to be the defining features of major animal lineages whose evolution endowed descendants with considerable adaptive advantage.

4.1
The Diploblast/Triploblast Divide: Evolutionary Hypotheses and Key Data

The origin of the mesoderm is often considered as key to the evolution of the complex organs and body plans of the triploblasts. All bilaterians possess this cell layer, and as such are sometimes called the *triploblasts*. In contrast, the members of the cnidaria and ctenophora (jellyfish, anemones and allies, and comb jellies respectively) are usually referred to as *diploblasts*, in that they lack a mesodermal cell layer. They also do not have obvious bilateral symmetry, instead possessing overt radial symmetry organized around an oral–aboral axis. Both morphological and molecular phylogenies agree in placing the diploblasts as basal to the bilateria. Hence, the cnidarians and ctenophores are considered good systems to investigate how the mesoderm evolved. Three basic possibilities exist in this regard. First, mesoderm may be a genuine innovation, the origin of which cannot be traced in diploblasts. Second, there may be a tissue in diploblasts that can be considered as a predecessor to the mesoderm. Third, the diploblasts may be secondarily simplified, and have lost the mesoderm.

The characterization of several cnidarian genes, orthologous to genes known as *mesodermal* markers in triploblasts, sheds light on this issue. Many such cnidarian genes are expressed primarily in the gastrodermis, an endodermal cell layer, in agreement with the hypothesis that the mesoderm is of an endodermal origin and can be traced to a diploblastic tissue. One scenario is that among the genes specifying the endodermal cell layer in

the common ancestor of diploblasts and triploblasts, some were recruited for the specification of the new mesodermal cell layer. The data do not, however, exclude the possibility that diploblasts are degenerate.

4.2 Gene Duplication and Vertebrate Origins

Vertebrates are members of the chordate phylum, characterized by a dorsal neural tube, a notochord and an endostyle. In addition, all vertebrates possess several distinct characters usually considered to be novelties, including migrating neural crest cells, a large regionalized brain, and the endoskeleton (cartilage and bone). The evolution of the vertebrates from an invertebrate chordate ancestor remains a mystery for a key reason: there is no evidence of a living or fossilized animal that shows evidence of a morphological transition state. However, it is possible to trace the origins of some of these new structures by comparing the morphology, developmental processes, and genetics of the vertebrates with their closest living relatives, such as the amphioxus and the ascidians. These organisms are classified with the vertebrates in the chordate phylum, and their embryonic and larval stages share many similarities with vertebrate embryos.

Molecular comparisons have proven to be a popular way to investigate the invertebrate vertebrate transition. A fascinating finding from these studies is that vertebrates possess more members of most transcription factor and signaling molecular gene families than does any invertebrate studied to date. Ohno in 1970 first raised the idea that large-scale gene duplication, via duplication of the whole genome may have played an important role in early vertebrate evolution. Currently, while the mechanism of duplication is still debated, it is widely accepted that some major duplication events happened at the dawn of the vertebrate evolution. As discussed earlier, the direct consequences of gene duplication for a specific gene can vary. What is the consequence of simultaneous duplication of numerous or even all of an organisms genes? This is not known; however, many researchers consider the co-occurrence of such gene duplications with the emergence of vertebrates as indicative that the extra genetic material may have played an important role in the evolution of vertebrates.

5 Loss of Complexity in Animal Development

Much of the earlier discussion focused on the evolution of new characters in animal lineages. However, loss of complex structures and genetic mechanisms is also a powerful force in the evolution of developmental processes and morphology. The two sides of such loss, the genes and the structures that they regulate, are discussed here.

5.1 Phylogeny Suggests Loss of Genetic Complexity is Widespread

When comparing the gene complements of two species, the presence of a specific gene in one species but not in the other can result from two processes. First, it may have evolved specifically in the lineage leading to one species. Second, it may have evolved earlier but been lost by the other species. Mapping the gene complements of species onto a phylogeny reveals some surprising results: it

is apparent that loss of genes that are highly conserved in other taxa is extremely common. Critical examples include the apparent loss of the hedgehog intercellular signaling pathway by the nematode *Caenorhabditis elegans*, and of Hox cluster cohesion in several lineages including *C. elegans* and urochordates. Furthermore, a recent large-scale analysis of the expressed genes in the cnidarian *Acropora millepora* (a coral) identified many genes shared with vertebrates but missing in both *Drosophila* and *C. elegans*. This indicates the loss of these genes in the lineage leading to these species, as their presence in a basally diverging lineage such as a cnidarian clearly demonstrates their early origin in animal evolution. Similarly, the urochordate *Ciona intestinalis* lacks several genes found in both protostomes and vertebrates. Because of the position of urochordates close to the vertebrates in the metazoan tree, we can infer that *Ciona* has lost these genes. In conclusion, there are several examples of lineages having lost genes. In most cases, the direct consequences of such losses to development is unknown, however, many animals that show this feature, including *Drosophila*, *Ciona*, and *C. elegans*, also show a drastic reorganization of early developmental programs, suggesting a fundamental association between gene loss and such evolutionary change.

5.2 Examples of Developmental Regulatory Changes Associated with Loss: Snakes and Sticklebacks

Considerable diversity in animal evolution is associated with the loss or reduction of structures. However, these modifications are not usually due to the loss of a gene, nor are they a restoration of ancestral, simpler morphology. Instead, a loss of body complexity can often be related to the modification of expression of key developmental genes. In vertebrates, for example, the invasion of new ecological niches and the origin of new locomotor adaptations like burrowing or swimming have repeatedly involved the loss or partial reduction of limbs. Obvious examples include whales (which have lost their hindlimbs) and snakes (which have essentially lost both sets of limbs).

Snakes evolved from tetrapod lizards. Their axial skeleton consists of up to hundreds of morphologically similar thoracic vertebrae, while the forelimbs are absent and the hindlimbs are severely reduced or absent. Because *Hox* genes are involved in the patterning of the vertebrate limbs as well as their morphological antecedents, the fins, a logical step was to analyze the expression of these transcription factors in snakes. The genes *Hoxb5*, *Hoxc6*, and *Hoxc8*, expressed in the region where thoracic vertebrate form in other tetrapods, have been examined in a species of python that has no forelimbs, and has hindlimbs reduced to rudimentary outgrowths (Fig. 5). The expression of the genes was found to be altered in a way that prefigured the expanded thoracic zone, thus eliminating the axial territory in which forelimbs usually develop. Hindlimb buds were initiated, but the signaling pathways that are normally required for limb development were not properly activated, stalling further outgrowth and development.

In sticklebacks, a large spine in the pelvic region serves to limit predation in marine populations; however, in some freshwater stickleback populations, this spine is reduced or lost entirely. Shapiro and colleagues performed genome-wide

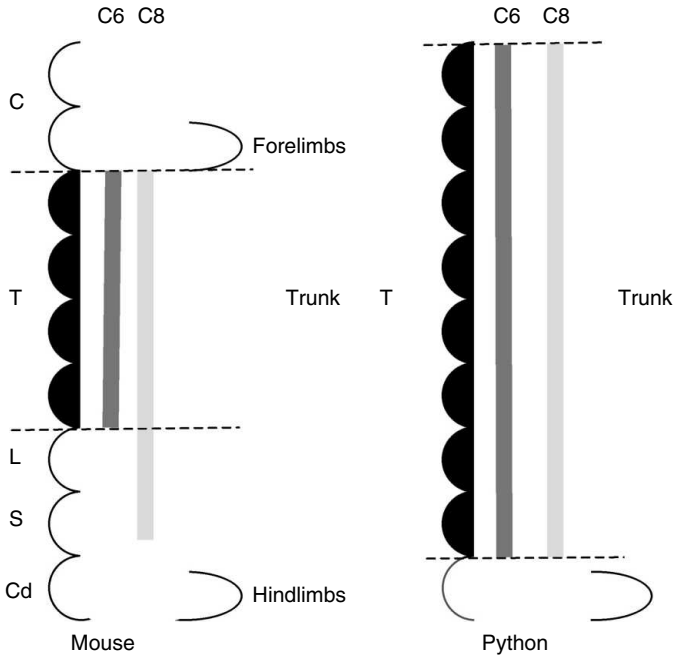

Fig. 5 In limbed vertebrates, the coexpression of *Hoxc6* (in dark gray) and *Hoxc8* (in light gray) in the mesodermal derivatives correlates with the thoracic-type vertebrae (T) and with the forelimb/brachial plexus region. In python, both domains are extended anteriorly and posteriorly changing the identity of the vertebrae and most likely inhibiting the induction of the forelimb development. Rudiments of the hindlimbs are still present in the python and the morphology of the vertebrae at the same level is of an intermediate type. C: cervical vertebrae, T: thoracic vertebrae, L: lumbar vertebrae, S: sacral vertebrae, Cd: caudal vertebrae. See Cohn, M.J., Tickle, C. (1999) Developmental basis of limblessness and axial patterning in snakes, *Nature* **399**, 474–479 for more details.

mapping of several natural populations of stickleback fishes and deduced that the modification was related to the alteration of the expression of the gene *Pitx1*. The experimental manipulation of *Pitx1* does indeed affect pelvic appendage development; however, *Pitx1* is also known to be involved in the development of numerous morphological features, including the proper development of some craniofacial structures. The loss of this gene thus affects multiple parts of the developing embryo, and indeed, no silencing mutation of the gene itself was detected in the mutant sticklebacks. This lead to the hypothesis that the mutation instead affects a regulatory region specifically involved in driving *Pitx1* expression during the late development of the pelvic area, with other regulatory regions remaining intact. This highlights the probability that such subtle changes in gene regulatory elements have the potential to bring about startlingly large changes in morphology, while preserving other essential gene functions.

6
Future Prospects

6.1
The Impact of Genomics and Postgenomics

Clearly, genomics will play an increasingly important role in evolutionary developmental biology, as in many other areas of biology. The current bottleneck in applying genome-scale approaches to nonmodel organisms is financial rather than technical, and this hurdle is beginning to be jumped, with genome sequences of several nonmodel taxa (including the mosquito, honey bee, and sea squirt) already completed, and others (including a sea-anemone, flatworm, mollusk, and annelid) following close behind. How can this wealth of sequence data be utilized to understand animal evolution?

First, the generation of whole genome sequences and expressed sequence tag (EST) sets allow the entire gene complement of an organism to be assessed, giving a full picture of gene family diversity. When plotted onto a phylogeny, this can indicate global patterns of gene loss and gene family expansion over evolutionary timescales. Interesting examples in this context are the lineage specific expansions of nuclear hormone receptor genes in the Caenorhabditid nematodes, and the Krab-like C2H2 zinc finger transcription factors in mammals. Such lineage specific differences will be a prime source of information, detailing how the diversity of genomes and resultant morphologies have evolved.

Second, genome resources allow the rapid isolation of clones for experimental studies, either via clone libraries or via PCR. Many studies of nonmodel taxa published over the past 15 years have concerned single genes in single species, reflecting the time-consuming nature of generating such data. Genome resources greatly shorten the time-consuming gene isolation and characterization stages, allowing more ambitious projects focusing on multiple genes, pathways, and networks.

Third, and perhaps most exciting, a genome sequence provides instant access to potential regulatory elements, at least *in silico*. Modeling of regulatory networks within organisms is a rapidly moving area of research, most advanced in model taxa such as yeast and the nematode *C. elegans*. As the principles governing network function are deduced from these model data sets, it will render possible their application to nonmodel systems. Ultimately, the changes in developmental programs that give rise to different morphologies are translated via such networks from mutations in an organism's DNA.

6.2
Understanding Regulatory Evolution: Computational and Empirical Methods United

The development of computational models raises the possibility that we may eventually be able to fully understand the evolution of animal from genotype to phenotype. The wealth of data means that statistical analyses become possible and mathematical models simulating evolutionary processes are now under construction.

Although the experimentation *in vivo* will still be necessary, developmental biologists and clinical biologists can now compare data concerning the decoded genomic sequences and apply them to their own research. For instance, it is possible to access large data sets of regulatory sequences and thus to infer the

possible regulatory pathways for any given gene in any given genome.

Keywords

Angiogenesis
The process by which new blood vessels are originated through the sprouting of endothelial cells from preexistent vessels.

Vasculogenesis
Differentiation of endothelial and precursor cells from the mesoderm and their coalescence into tubes to form a primary vascular plexus.

The development of the vascular system is initiated by the local differentiation of mesenchymal cells into hemangioblasts. These are pluripotent progenitors for both endothelial and hemtopoetic cells. Subsequently, endothelial cells form vascular channels that coalesce and circulation begins thereafter. Recruitment of smooth muscle cells and pericytes contributes to the remodeling stage characterized by the emergence of a hierarchical tree of vessels. Concomitantly, a second array of vessels emerges from the cardinal vein, the lymphatic vasculature. The use of molecular biology and genetics has allowed us to identify the key signaling pathways involved in the specification, differentiation and homeostasis of both the vascular and lymphatic systems. Here we have discussed the details associated with the formation of the vasculature in concert with the key signaling pathways responsible for these events.

1 General Overview

The vascular system develops shortly after gastrulation. The formation of the embryonic vasculature is initiated by the appearance of blood islands from progenitor cells (hemangioblasts) in the visceral yolk sac. Within the blood islands, hemangioblasts differentiate into either hematopioetic or endothelial cells, with the former located within the channel space and the endothelial cells lying on the edges. This first phase of blood vessel formation is known as *vasculogenesis*. A second phase then begins, which is referred to as *angiogenesis*, involving active sprouting of vessels from preexisting blood vessels. Interconnection of these primitive vessels results in the formation of a primary vascular plexus, which undergoes a complex process of remodeling. Eventually, the fetal vasculature emerges from angiogenic growth, selective fusion, and regression of primitive vessels. Figure 1 illustrates the major processes in blood vessel formation and highlights the key signaling pathways required for each step.

The morphogenesis of the heart is concomitant with the differentiation of blood islands. Cardiac progenitor cells migrate to the ventral midline, forming a linear heart tube. As the inflow and outflow tracks are formed, the heart is joined to the yolk sac and flow begins. All subsequent vascular development occurs in the presence of blood flow.

The circulatory system is the first functioning organ system to develop in vertebrate embryos and it is essential for viability and survival. This dependency has been advantageous to investigators. The unsuspected contribution of several regulatory molecules has been revealed by hemorrhage and embryonic lethality. During the last two decades, the use of homologous recombination to ablate gene function has provided major breakthroughs in our understanding of vascular development. Key signaling pathways to vascular morphogenesis include vascular endothelial growth factor (VEGF), Notch, angiopoietins, ephrins, transforming growth factor (TGF)-β, and platelet-derived growth factor (PDGF).

The identification of genes involved in embryonic vascular morphogenesis is important to gain a concrete understanding of how vessels are formed. Many of the events that take place during development are recapitulated in situations of neoangiogenesis in the adult. Thus,

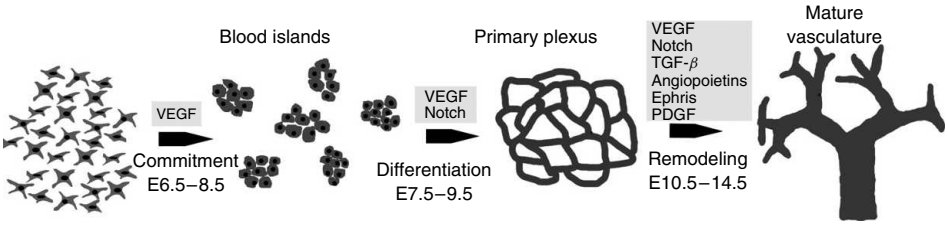

Fig. 1 Development of blood vessels: initially, undifferentiated mesenchymal cells under the instructive signals of VEGF become committed to hematopoietic and endothelial cell fate originating small groups of cells, known as *blood islands*. These clumps of cells gain lumen, coalesce, and form a primary plexus. Subsequently, a series of remodeling events takes place with selective fusion and regression, as well as active expansion by sprouting of new vessels. The end result is a hierarchic mature vascular plexus.

this information is central to the generation of novel and more effective therapies for the manipulation of vascular growth during pathological conditions in the adult.

2 A Stem Cell for the Vascular System: The Hemangioblast

The notion of a common progenitor for both endothelial and hematopoietic cells was first suggested in the early part of the twentieth century by Florence Sabin, based on her studies of vessel formation in the chick blastodisc. Those initial observations were morphological and based on the proximity between endothelial cells and hematopoietic cells in the embryos. Today, we know that endothelial and hematopoietic progenitors share expression of many genes, including VEGFR1, VEGFR2, Tie1 and Tie2, Tal1/SCL, and Runx1. We also know that genetic ablation of VEGFR1 and R2 affects both hematopoietic and endothelial development. Although these findings did not provide a concrete lineage link, they were consistent with at least an interdependency of both cell types.

Subsequently, the utilization of ''ES cell *in vitro* differentiation assays'' offered an opportunity to further explore the lineage association between endothelial and hematopoietic cells. Using a subpopulation of embryonic stem (ES) cells that expressed VEGFR2, Choi and colleagues demonstrated that under appropriate culture conditions those cells could give rise to both blast-colony forming cells (BL-CFC) and endothelial cells. Subsequent analysis demonstrated that not all VEGFR2 cells could generate BL-CFC, but cells coexpressing both VEGFR2 with Tal1/SCL are enriched for BL-CFC. Tal1/SCL is a transcription factor required for the initiation of primitive and definitive hematopoietic development. Overexpression of Tal1/SCL in Flk1-expressing ES cells significantly increased the number of BL-CFCs in culture. Consistent with those observations, ES cells lacking Tal1/SCL do not differentiate into endothelial cells or hematopoietic cells. However, some degree of endothelial cell development has been noted in Tal1-null mice.

Additional evidence for the existence of a common link between endothelial and hematopoietic cells comes from the finding that during development, certain endothelial cells give rise to hematopoietic progenitors. Functional evaluations *in vivo* have demonstrated that definitive hematopoietic stem cells (HSC) can arise from yolk sac, and in the intraembryonic aorta-gonad-mesonephros (AGM) region. A large morphological body has also noted budding of hematopoietic progenitors from the ventral region of the dorsal aorta, umbilical, and vitelline arteries in chicken, mouse, and human embryos. This potential of endothelial cells to give rise to hematopoietic progenitors is temporally restricted to early developmental stages. Currently, there is no evidence that mature endothelial cells can give rise to hematopoietic progenitors.

Primordia of blood vessels form by the interconnection of hemangioblast clumps that coalesce into blood lakes, and subsequently give rise to a primitive network of endothelial tubes. The process, known as *vasculogenesis*, marks the initiation of vascular development. While, initially confined to an extraembryonic location (yolk sac), shortly thereafter (8–12 h) vasculogenesis is also noted within the embryo proper.

3 Development of the Vascular System

3.1 Early Vascular Morphogenesis

The primitive vascular plexus is composed of differentiated endothelial cells that initiate their function as barrier between the bloodstream and tissues. The main characteristic of this plexus is its uniformity. Channels of the vascular plexus are of the same width, and are separated by similar distances, with no evidence of vascular hierarchy. The vascular plexus is transient and must be altered to accommodate the physical forces associated with the pressures of blood flow. Failure to differentiate this primitive vascular plexus results in embryonic death, generally by E9.5 to E12.5, a feature that has enabled the identification of several genes critical to vascular remodeling.

The vascular plexus expands by vascular sprouting (angiogenesis). During angiogenesis, endothelial cells migrate and proliferate in response to various stimuli, assembling into tubules containing cell–cell tight junctions characteristic of the endothelium. Recently, studies in the developing retina have indicated that the column of cells forming a sprout is heterogeneous. The leading cell, referred to as the *tip cell* within a vascular sprout, does not proliferate in response to growth factors. The tip cell responds to VEGF signaling by sending cellular processes (filopodia) and sensing its environment. The presumption is that, much like the neurons, these cells act to provide directionality to the sprout and the location of the future vascular bed. Recruitment and differentiation of supporting cells associated with mature vessels, such as smooth muscle cells, fibroblasts, and pericytes is also initiated at this time, but is not as prevalent in this stage. Recruitment events are highly regulated and require the coordinated action of a large number of molecules. However, the main group of signaling pathways that is essential to the early morphogenetic events include: VEGF and Notch. Genetic inactivation of molecules within these two signaling pathways results in lethality at E10.5. In addition, haploinsufficiency has been noted in VEGF and delta4 (ligand for Notch) embryos, suggesting that dosage of these ligands is critical to vascular morphogenesis.

3.2 Vascular Patterning and Remodeling

As it develops, the vascular system forms stereotypical blueprints reproducible within the same species and in a few cases even conserved across ontogeny. Patterning results from the combined effect provided by directionality of sprouting, selective vascular fusion, and apoptosis. Thus, some vessels are eliminated, while others increase in size providing the typical treelike structure of blood vessels. Although in both events, patterning and remodeling occur concurrently, for didactic they will be addressed sequentially.

3.2.1 Vascular Patterning

The remarkable conservation of vascular patterning suggests that specific genetic programs coordinate its formation. Interestingly, there is a growing body of experimental evidence to indicate that many of the signaling pathways involved in neural pathfinding also guide endothelial cells during development. The interconnection between neural and vascular patterning has been demonstrated by the finding that

sensory nerves instruct arterial differentiation and blood vessel patterning in the skin. There is an expanding list of neural guidance gene families that regulate migration and proliferation of endothelial cells, suggesting that developmental similarities coupled with physical associations between the vascular and nervous system rely on common molecular mechanisms.

Recently, the sprouting and selective fusion of growing capillaries has been documented by recording zebra fish embryos labeled with fli-EGFP, a construct that enables visualization of endothelial cells. This method has shown that tip cells in sprouts exhibit numerous active filopodia, which extend and retract in an intermittent fashion. Their directionality is guided by the combined set of attractive and repulsive cues, which, in turn, determine the selection of the branching site, the direction, and the fusion. Elucidation of the signaling pathways involved in this process is still in its infancy; however, a subset of these has been identified. Clearly, VEGF plays an important role in the guidance of sprouts, but more specifically the VEGF isoforms that bind to matrix proteins (VEGF188) are responsible for stimulation of sprouts and guidance cues.

Neuropilin, a receptor initially identified for its ability to promote axonal guidance, was later found to bind specific splice isoforms of VEGF. Genetic experiments later confirmed that ablation of neuropilin 1 resulted in abnormal vascular development. In particular, these mice exhibit poor branching in the subventricular zone of the brain indicating that neuropilin 1 is necessary for tip cell guidance, at least in the brain.

Another important group of signaling molecules in patterning are the plexins. In particular, loss of plexin D1 in both zebra fish and in mouse result in abnormalities in pathfinding. Plexin D1 null mice showed abundant branching in the intersomitic vessels with concomitant loss of the normal vascular pattern. The results indicate that disruption of plexin D1 signaling removes the repulsion signals that are necessary for correct guidance during vascular sprouting events. The ligand for plexin D1, Semaphorin 3E has also been inactivated in mouse and reveals a very similar phenotype.

3.2.2 Vascular Remodeling

Remodeling is best understood in the retina. The relatively planar distribution of the capillaries combined with postnatal development make this an excellent system to study vascular morphogenesis. In this system, it is easy to note how specific vessels fuse to form larger vascular channels and others regress giving the vasculature its typical hierarchical structure.

Several pathways have been implicated in vascular remodeling. Essentially, an interruption in the evolution of the primary plexus into the hierarchical vascular tree is considered as a remodeling defect. Signaling molecules, which contribute to the recruitment of mural cells, such as Tie2 and Angiopoietin-1 result in remodeling defects. Also, pathways that affect the lumen and the stability of vessels have also been implicated in remodeling, such as Notch 1. These signaling pathways and their specific contributions will be described later in this chapter.

The contribution of extracellular matrix molecules appears to be extremely important in vascular stabilization and, consequently it can play a role in remodeling events. There is experimental evidence, for example, that type XVIII collagen, a component of basement membranes, is

required for the regression of hyaloid vessels in the developing eye. The hyaloid vessels are formed to provide nutrients to the lens capsule. After this structure differentiates, these vessels regress as part of the normal development of the eye. Absence of type XVIII collagen prevents this regression. The specific mechanisms that drive the regression of these vessels by type XVIII collagen are yet to be determined. It is likely that the signals from matrix molecules are conveyed through integrins. Several integrin proteins have been inactivated and some have revealed important roles in vascular stability, including α v, $\alpha 5$, and $\beta 3$ among others. Thus, it appears that extracellular matrix proteins, through integrins, are important contributors to vascular remodeling and stability.

3.3 Arteries and Veins

A functional vascular circuit requires the separation of arterial and venous networks that only interconnect within the capillary beds of distal target organs. Whereas the endothelial tubes that makeup primitive vascular plexus are morphologically indistinguishable, mature arteries and veins differ in their arrangement of extracellular matrix, smooth muscle cells, and other supporting cells that provide specialized mechanical and physiological properties. Thus, it is conceivable that the formation of arterial and venous networks might differ from one another. Indeed, it appears that during differentiation, endothelial cells become committed to either arterial or venous identities. However, their specific timing of differentiation and segregation during vascular morphogenesis is poorly understood.

Acquisition of arterial or venous features was previously attributed to local environmental factors. Specifically, hemodynamic forces such as blood pressure and blood flow imprinted arterial or venous character to vessels, depending upon the pressure load imposed. During development, however, this was not to be the case. Genetic predetermination drives fate of arterial and venular endothelial cells before any physical regulatory event takes place. Evidence of a genetic program that directs the development of arterial–venous identity comes largely from the characterization of gene-targeted mice and mutational analysis in zebra fish. The first compelling data arose from the observation that the transmembrane ligand, ephrin B2, and its cognate tyrosine kinase receptor, EphB4 are differentially expressed within the arterial and venous endothelium, respectively, of embryonic and extraembryonic vessels prior to the onset of circulation. Genetic inactivation of either ephrin B2 or EphB4 disrupts angiogenic remodeling of arteries and veins that is likely due to inappropriate interactions between arterial and venous angiogenic sprouts. As a result, animals die at midgestation from vascular anomalies and lack of remodeling.

More recently, the Notch signaling pathway has been implicated as an important mediator of arterial differentiation in zebra fish. In fact, inactivation of Notch in zebra fish blocks arterial differentiation, as determined by the expression of arterial-specific markers. Supporting these findings, expression of Notch ligands and receptors in mice is restricted to the arterial vasculature. Similarly, expression of neuropilin 1 and 2 is also segregated in arteries and veins, respectively. Combined, the findings support a critical role for genetic programs regulating arterial and venous fates. However, these genetic programs do not explain how arterial and venous endothelial cells are guided to common

distal targets along parallel but distinct paths.

Failure to establish or maintain proper arterial–venous boundaries in mutants may partially relate to a disruption of normal sprouting mechanisms during angiogenesis. Normally, arteries and veins sprout from the primitive vasculogenic vessels to form parallel but distinct vascular networks that only interconnect at the capillary beds of the target organs. Patients afflicted by hereditary hemorrhagic telangiectasia (HHT) suffer from multiple arteriovenous malformations, direct, and abnormal connections between arterial and venous vascular beds. As will be discussed in more detail, HHT is caused by haploinsufficiency in either activin receptor-like kinase 1 (ALK-1) or endoglin, both are members of the TGF-β superfamily of receptor and ligands. Mice lacking Akt1 or endoglin lose the morphological, molecular, and functional distinctions between arteries and veins. These observations led to the hypothesis that genes responsible for guiding endothelial tubes to their appropriate destinations might be differentially expressed in mutant mice lacking Akt or endoglin. Differential evaluation of these mice resulted in the identification of Robo-4, an endothelial-specific member of the Robo family of proteins. Combined, it appears that establishment of arterial and venous identity has to occur in parallel to patterning and selective fusion of new sprouts.

Finally, it is important to stress that arterial and venous molecular signatures, although established early during development, may not be sufficient to maintain the arterial–venous identity. It has been experimentally demonstrated that after transplanting the arterial endothelium into veins and vice versa, the transplanted endothelium adopts the specific molecular programs of the host vessel, suggesting that local cues modulate vessel specificity. The specific identity of these cues is unknown; however, it is also likely that mechanical forces, including flow and pressure might play important roles.

4 Lymphangiogenesis

In addition to blood vessels, the circulatory system also includes a group of lymphatic vessels. Unlike the circulatory loop formed by the heart and blood vessels, the lymphatic vasculature consists of blind-ended capillaries that permeate most tissues to drain interstitial fluid and proteins, and return them to the blood circulation by large lymphatic conduits (thoracic duct) that drain into the left subclavian vein. Lymphatics are also responsible for fat uptake from the gut and play an essential role in the immune system by directing leukocytes and antigen presenting cells to the lymph nodes. The blood and lymphatic systems complement each other to maintain tissue homeostasis; an interdependence that is also reflected in their coordinated development during embryogenesis.

As first described by Florence Sabin in 1901, the lymphatic vessels arise in midgestation (E10.5 in mouse) after the development of the blood vascular network from progenitor cells in the cardinal vein. Subsequent to the formation of the lymph sacs, progressive expansion of lymphatic vessels occurs by active sprouting, in a manner similar to blood vessel sprouting, but under regulatory control of a different cast of molecules. Prox-1, a homeobox gene related to the Drosophila Prospero, is one of such molecules. Mice lacking this transcription factor fail to develop lymphatics and die

at midgestation from generalized edema. It appears that Prox-1 is essential for the commitment and differentiation of endothelial cells from the cardinal vein to the lymphatic lineage. Figure 2 illustrates the process of lymphangiogenesis from the budding of endothelial cells from the cardinal vein to the organization of lymphatic capillaries. In the absence of Prox expression, cells that bud from the cardinal vein continue to display a cell-surface marker profile of the blood vascular system suggesting that expression of Prox-1 is sufficient for the specification of lymphatic endothelial cells. In fact, overexpression of Prox-1 is sufficient to reprogram cultured blood vascular cells into lymphatic endothelial cells.

Maturation of the lymphatic vascular system, as well as homeostatic function of lymphatics vessels requires expression of VEGF-C and VEGFR3. Activation of VEGFR3 by either VEGF-C or D leads to enhanced proliferation, migration, and survival of cultured human adult lymphatic endothelial cells. In addition, activation of VEGFR3 by overexpression of VEGF-C in adult transgenic mice results in lymphangiogenesis, and blocking of VEGFR3 signaling *in vivo* by expression of a soluble form of the receptor leads to lymphedema in adult. Finally, the association of missense mutation of the human VEGFR3 gene in patients with chronic lymphedema (Milroy's disease) supports a requirement for VEGFR3 signaling in the adult. It should be stressed that expression of VEGFR3 is initially not restricted to lymphatic vessels. In fact, VEGFR3 is highly expressed in vascular endothelium during development and mice die from disruptions in the morphogenesis of the vascular system. After E13.5 in the mouse, VEGFR3 is downregulated in blood vessels and becomes highly expressed in lymphatic endothelium.

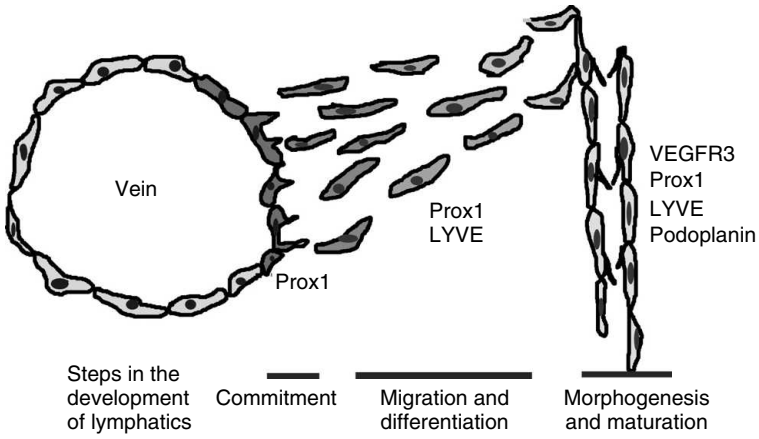

Fig. 2 Lymphangiogenesis: the initiation of lymphatic vessels occurs by the specification of subdomains within veins. These showed commitment to the lymphatic fate by expressing Prox1, a transcription factor that regulates expression of certain lymphatic genes. Subsequently these cells depart from the parental veins and migrate to organize a parallel vascular system that only drains its contents into major veins, but it is otherwise completely independent from blood vessels. Markers for lymphatic endothelial cells include: VEGFR3, Prox1, LYVE, and podoplanin.

VEGFR2 is expressed in lymphatic endothelium, as well as in blood vascular endothelium. In lymphatic vessels, VEGF-C is able to activate both VEGFR2 and VEGFR3. However, mice deficient for VEGF-C display a defect in the formation of the initial lymphatic vessels sprouts from veins, but specification of the lymphatic lineage is not impaired. Evaluation of heterozygous mice for VEGF-C revealed that dosage of this ligand is critical for normal lymphatic function in the adult. In fact, VEGF-C +/− mice display lymphedema in the lower limbs as well as chylous ascites from impaired lymphatic function in the gut.

The angiopoietin-Tie2 signaling pathway is also important in lymphangiogenesis. The contribution of Ang-Tie, however, appears to be more important for the function rather than to the development of lymphatics. Mice lacking Ang2 develop chylous ascites, an accumulation of interstitial fluid in the gut that is associated with a loss of gut lymphatic function. This requirement for Ang2 in the lymphatic system can be substituted by Ang1, as demonstrated by gene replacement. In addition, a subset of embryos deficient for Tie1 displays severe tissue edema that is independent of placental or cardiac dysfunction.

Abnormal development of peripheral lymphatics results in severe edema and impairment of lymphatic development in mouse models can be lethal. Equally importantly, lymphatic vessels are created by tumors and these vessels are used by tumors to metastasize from their site of origin. Growth of lymphatics in some tumors even appears to be rate limiting for metastasis. Thus, identification of molecular pathways regulating lymphatic growth may provide new strategies to treat vascular and neoplastic diseases.

5 Key Signaling Pathways in Vascular Morphogenesis

The molecular nature of the signaling pathways involved in blood vessel development has become an intense area of investigation, and great strides have been made toward elucidating the functions of the required genes. The mouse has proven to be a robust model system for studying vascular morphogenesis, not only because its developmental processes are similar to humans but also because of the wealth of available methods to manipulate the genome and create mutant animals. Many mutant mouse lines with a multiplicity of early and late vascular defects are currently available and allow for detailed analysis of the role of single genes or combination of genes during development, homeostatic functions, and under pathological conditions.

There are four most extensively studied ligand/receptor families that are essential for vascular morphogenesis: VEGF-VEGFRc; Notch-DSL; angiopoietin(Ang)-Tie2, and ephrin B2-ephB4. Their critical roles during development have been established by diverse ranges of approaches including the use of genetically ablated mouse lines for each gene. In addition, the TGF-β and PDGF pathways are also essential and will be discussed. Figure 1 provides an overall assessment of the impact of each of these pathways during vascular maturation. While we will constrain our comments to these major signaling pathways, it is important to stress that a large number of extracellular matrix proteins and their receptors, adhesion molecules, and other growth factors contribute extensively to the overall process of vascular maturation.

5.1
The VEGF Signaling Pathway

Initially identified for its ability to mediate vascular permeability, VEGF was later found to be a mitogenic agent for endothelial cells. Today, VEGF is recognized as an essential cytokine for the development and homeostasis of the cardiovascular system. Inactivation of a single VEGF allele results in embryonic lethality at midgestation due to severe cardiovascular defects. Interestingly, increase of VEGF in the heart, also leads to embryonic lethality. In the adult, overexpression of VEGF by basal epidermal cells (expressing keratin-14 promoter) results in increased microvascular density, leukocyte adhesion, and hypersensitivity to inflammation. Together these results indicate that unlike most genes, alterations in VEGF levels can result in significant pathological outcomes.

Although the major focus of interest has been on VEGF-A (or simply VEGF), this molecule is only one member of a family of proteins that also comprises VEGF-B, VEGF-C, VEGF-D, VEGF-E, and PlGF (placenta growth factor). These proteins interact with three major tyrosine kinases: VEGFR1, VEGFR2, and VEGFR3 and two nonreceptor tyrosine kinases; neuropilin 1 and neuropilin 2, which also bind to other ligands. Figure 3 provides a schematic view of these receptors and their respective specificity for each ligand. While this chapter will focus mostly on VEGF-A, referred herein as VEGF, much research has been done in the biological functions of the other family members.

The biologic activities of VEGF are mediated principally by two related

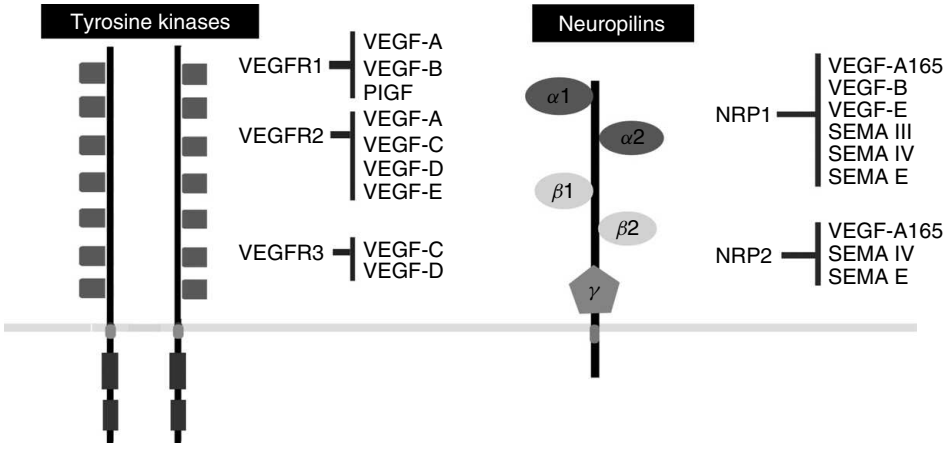

Fig. 3 VEGF receptors and ligands: VEGF signaling is essential for blood vessel development and homeostasis. This pathway includes a series of tyrosine kinases: VEGFR1, VEGFR2, and VEGFR3 that belong to the class III receptor tyrosine kinases of the platelet-derived growth factor receptor superfamily. All three receptors are characterized by the presence of seven immunoglobulin homology domains (in the extracellular region) and two intracellular kinase domains. The relative binding affinities of each receptor for the ligands is indicated. Neuropilins and accessory receptors to the VEGF pathway. The structure of neuropilin (NRP) 1 and 2 comprise two α, two β, and one γ subdomains, in addition to a short intracellular tail that does not show significant homology to any known proteins. The interaction of NRP 1 and 2 with their respective ligands is shown on the right.

cell-surface receptors, Flt1/VEGFR1 and KDR/Flk-1/VEGFR2 with extracellular ligand-binding domains and intracellular protein-tyrosine kinase domains. It has been determined that VEGFR1 is the high affinity receptor, while VEGFR2 is the low affinity receptor. In addition, some VEGF isoforms can bind to neuropilin receptors; these receptors will be discussed separately. VEGFR2 is the main signaling receptor for VEGF. Activation of this receptor has been shown to promote differentiation of progenitors, migration, mitogenesis, survival, nitric oxide release, and vascular permeability. In contrast, the biological role of VEGFR1 remains enigmatic. Treatment of VEGFR1-expressing endothelial cells with VEGF typically does not stimulate migration or DNA synthesis. Other reports using chimeric receptors or neutralizing anti-VEGFR1 antibodies to distinguish VEGFR1 and VEGFR2-mediated pathways suggest that VEGFR1 may indeed transmit signals that downmodulate endothelial cell responses to VEGF via VEGFR2. VEGFR1 appears to suppress both VEGF-stimulated chemotaxis and proliferation in endothelial cells.

Other evidence indicates that VEGFR1 performs important functions during vascular development. These might be mediated by VEGF, but could also be directed through activation by placenta-derived growth factor, another ligand for VEGFR1. Furthermore, in the adult, VEGFR1 appears to regulate monocyte function.

In situ hybridization reveals that patterns of VEGFR1 expression partially parallel those of VEGFR2 and VEGF in the developing mouse embryo. Moreover, homozygous knockout of VEGFR1 in mice results in embryonic lethality between days E9.5 and E11.5 characterized by a superabundance of endothelial cells and their hemangioblast precursors and the failure to form vascular channels. It was postulated that VEGFR1, as a buffer for embryonic VEGF, serves to keep endothelial cell expansion within limits appropriate for efficient vascular channel assembly. The VEGFR1-null phenotype is distinct from that seen in VEGFR2 homozygous knockout mice, which died *in utero* between days E8.5 and E9.5 with marked deficits in hematopoietic and endothelial cell numbers. Intriguingly, transgenic mice homozygous for tyrosine kinase–null VEGFR1 containing intact extracellular and transmembrane domains developed a normal, functional vasculature, but showed defects in monocyte chemotaxis. These findings reinforce the concept that, in endothelial cells, VEGFR1 may serve a modulatory function by virtue of its ligand-binding activity and potential to interfere with VEGFR2 or neuropilin 1, in addition to a signaling function.

While in neonatal mice expression of VEGF is required for survival, the function of VEGF signaling in adult vessels is less clear. There is evidence that activation of this signaling pathway is required for the maintenance of fenestrations in certain vascular beds. Blockade of VEGF signaling in adult mice has resulted in reduced capillary density and proteinuria.

5.1.1 Soluble VEGFR1, an Endogenous VEGF Antagonist

In addition to the major VEGFR1 mRNA species of 6.5 to 8.5 kb (presumed to encode the full-length receptor protein), Northern blotting typically detects other VEGFR1 hybridizing mRNA, originally detected in human placenta and endothelial cells, which arises by alternative RNA splicing. This mRNA encodes a protein, termed *soluble* or *secreted* VEGFR1 (or

sFlt1), in which a unique intron 13-encoded C-terminal peptide replaces the membrane-anchoring and tyrosine kinase segments, resulting in release of VEGF-binding receptor fragment from cells. Mouse VEGFR1 gene structure reveals that sFlt-1 mRNA is generated by the failure to excise intron 13 and the use of a presumed intronic polyadenylation signal. Recombinant sFlt1 binds VEGF with high affinity (Kd 20 pM) and acts as a potent inhibitor of VEGF biological activities *in vitro*. sFlt1 binds heparin, which may favor its retention close to sites of release in tissues containing heparan sulfate proteoglycans. Additional soluble forms of VEGFR1 have been described although their origin and properties remain unclear.

sFlt1 and chimeric analogs have been used experimentally as potential therapeutic agents and to test the role of VEGF in a variety of physiologic and pathological processes *in vivo*. For example, sFlt1 has been investigated as an experimental therapy for neoplasms that constitutively produce VEGF. Increased expression of sFlt1, either via transfected or infected tumor cells or administration of adenoviral vectors can dramatically inhibit vascularization and/or growth of tumor xenografts in mice. Similarly, virus-directed expression of sFlt1 reduced subretinal neovascularization in rats and ischemia-induced retinal neovascularization in mice. In a small-scale study, sFlt1 protein in the systemic circulation was marginally increased in patients with proliferative retinopathy compared to healthy controls.

Although it is clear that sFlt1, when overexpressed, can effectively inhibit biological actions of VEGF *in vivo*, little is known about the physiological function(s) of sFlt1 or the mechanisms controlling its biosynthesis. Since sFlt1 expression can occur only where the parental VEGFR1 pre-mRNA is produced, the fundamental level of control is transcriptional, governed by the endothelial-selective promoter elements for VEGFR1. In cell cultures or tissue explants, expression of mRNAs for VEGFR1, but not for VEGFR2, can be induced by hypoxia. This pattern of VEGFR1 inducibility can be recapitulated in animals exposed to systemic hypoxia.

Neuropilins and semaphorins. Neuropilins are transmembrane receptors best understood for their interaction with semaphorins. However, recently it has become clear that in addition to semaphorins, neuropilins also bind to VEGF isoforms 164 and 188. Eight classes of semaphorins have been identified and most of these appear to be specific to the neural system. They provide negative neuronal guidance cues: repel axons and collapse growth cones. Class-3 semaphorins, however, bind to neuropilin receptors also expressed by endothelial cells, in addition to neurons. There are six members of class-3 semaphorins (sema A–F) and they exhibit some relative degree of specificity. Thus, sema-3A activates neuropilin 1 and sema 3F activates neuropilin 2.

Clear demonstration of the impact of semaphorins in the cardiovascular system has been obtained from genetic knockout studies. Sema-3A–null mouse in 129/SV background die from cardiac failure approximately 3 days after birth. In the CD-1 background, they also exhibit a number of vascular defects in the head and abnormalities in trunk vessels. At E9.5, cranial blood vessels of the mutant embryos fail to remodel and the formation of the anterior cardinal vein is disrupted. Neuropilin 1–null mice also showed vascular remodeling defects with onset of lethality at E12.5 to E13.5. They also display agenesis of some branchial arch-derived vessels and

transposition of aortic arches. Overexpression of neuropilin 1 in mice also results in vascular defects. These include: vascular dilation, excess of vascular growth, and cardiac malformation.

Sema-3C–null mice die just after birth due to aortic arch malformations and septation defects in the heart. Interestingly, these were not noted in neuropilin 2–null mice. Instead, neuropilin 2 deficiency showed reduction of small lymphatic vessels and capillaries.

Interestingly, removal of both neuropilins showed a more severe vascular phenotype than either receptor alone. Embryonic lethality occurs at E8.5 with defects in yolk sac and embryonic vasculature. Overall, there seems to be a decreased number of endothelial cells in a manner similar to the one observed in VEGFR2–null mouse. Together these findings indicate that activation of neuropilins by semaphorins is an essential component of vascular morphogenesis.

5.2 The Notch Signaling Pathway

The Notch signaling pathway impacts a large variety of cell types including hematopoietic, neuronal, muscle, epithelial, and more recently, endothelial. It has been shown to participate in cell fate decisions either by initiating differentiation processes or by maintaining the undifferentiated state of cells. The contribution of Notch to the vasculature was initially recognized by the association of ligands and receptors with hereditary vascular anomalies. CADASIL (cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy), is a disease of adult onset manifested by strokes, migraines, and progressive dementia. CADASIL has been linked to mutations in notch 3 resulting in a progressive degeneration of the smooth muscle layer surrounding cerebral and skin arterioles. Alagille syndrome has been attributed to mutations in jagged 1. Patients suffering from this syndrome exhibit abnormally formed blood vessels, arterial stenosis, and heart disease, in addition to hepatic lesions and skeletal defects.

In mammals, there are four distinct Notch receptors (notch 1–4) and five ligands (jagged 1–2 and δ1, 3, and 4). Unlike the VEGF signaling pathway, Notch receptors and ligands are transmembrane, thus interaction requires cell–cell contacts. Most frequently, associations occur between cells (homotypic or heterotypic) resulting in trans-signaling events. However, activation of receptors in cis can also occur. There does not appear to be ligand specificity between the ligands and receptors; however, recent experimental evidence suggests that not all receptor/ligand pair results in signaling. Activation of Notch requires a series of proteolytic events that are trigged by binding to receptors. The enzymes implicated in processing include members of the ADAM family (ADAM10/Kuzbanian and gamma secretase). Interestingly, genetic inactivation of both these enzymes has resulted in embryonic lethality with vascular anomalies similar to those found in Notch mutants. Once released, the intracellular domain of Notch (ICD) translocates to the nucleus where it binds to the transcription factor RBPJ-k (also known as *CBF-1/RJBk* in mammals, and Su(H) in Drosophila). The complex then activates a cohort of specific downstream effectors. The best characterized direct targets of Notch activation include the Hairy genes in Drosophila and the related bHLH transcription factor genes, Hes/Hey in vertebrates.

Targeted inactivation of notch 1 has confirmed its relevance to the development of the cardiovascular system. Embryos homozygous for a null allele of notch 1 die by day 9.5 with clear defects in somitogenesis and severe cardiovascular anomalies. Targeted mutation of another Notch receptor, notch 4, showed no defects in homozygous mutant mice, but compound homozygous for notch 1 and 4 had a more severe vascular defect than embryos homozygous for the notch 1 receptor alone. Interestingly, gain of function of notch 4 in the endothelium has an abnormal vascular development and early lethality. Like VEGF, it seems that vascular morphogenesis is extremely susceptible to levels of Notch signaling.

Several Notch ligands have been inactivated by homologous recombination. Embryos lacking a functional jagged-1 gene die at embryonic day 10.5, with vascular defects including lack of vascular remodeling and absent vitelline vessels. More recently, inactivation in delta4 results in haploinsufficiency with lethality at E 9.5. Mice die from lack of remodeling of the primary vascular plexus, a finding that was evident in both the yolk sac and in the embryo proper.

While all Notch receptors and ligand mutants do not link this pathway in hemangioblast or endothelial cell specification, a possible contribution in Notch signaling in cell fate choice might occur in the lymphatic system. Activated Notch appears to directly transactivate VEGFR3, and thus, it might contribute to the specification of lymphatic endothelial cells from veins.

5.3 Angiopoietins – Tie Signaling Axis

Initially isolated through a secretion-trap expression strategy aimed at identifying the ligand for Tie2, Angiopoietin-1 belongs to the family of ligands currently comprising four members (Ang 1–4). From these, Ang 1 and 2 are more understood with respect to their roles in developmental and pathological angiogenesis. Although these two ligands bind to the receptor tyrosine kinase Tie2 with similar affinities, Ang2 can inhibit Ang1 under some specific physiological contexts. Some studies *in vitro*, however, have shown that Ang2 can induce Tie2 phosphorylation in endothelial cells depending on dose, duration of exposure, and whether the source is autocrine or paracrine. Interestingly, Ang2 is expressed at angiogenic and vascular remodeling sites and it contributes to the detachment of smooth muscle cells. This enables the exit, migration, and proliferation of endothelial cells during the process of angiogenesis. These findings explain why Ang2 can either participate in the regression of the formation of new blood vessels, since destabilization of vessels is also a requirement for angiogenesis.

Inactivation of Tie2 by homologous recombination results in embryonic lethality by midgestation (E12.5) from cardiovascular abnormalities. Mice exhibit lack of remodeling of the primary plexus and sprouting deficiency. Genetic ablation of Ang-1 results in a similar phenotype, indicating that at least during development, these two molecules are codependent. Gain of function of Ang1 results in increased vascularization and abnormal permeability.

Although ligands for the related kinase, Tie1, are yet to be identified, inactivation of this receptor is also embryonically lethal (from E13.5 to neonates). Deficiency in Tie1 results in edema and microvascular fragility with hemorrhage. Together the data indicates that Tie1 is not required for the early differentiation of endothelial cells

and, unlike Tie2, is not necessary for initial patterning.

In adult settings, it is clear that Ang1 is a natural antipermeability factor protecting against excessive plasma leakage and counteracting the pathological permeability induced by VEGF.

5.4 Ephrins and Eph Receptors

The family of Eph receptors includes a large group of receptor tyrosine kinases (14 in total) that regulate an impressive array of biological effects, including: embryonic patterning, neuronal targeting, epithelial differentiation, and vascular development, among others.

Activation of Eph receptors by their ephrin ligands requires cell–cell contact, as ephrins are also membrane bound. Signaling between ligands and receptors is bidirectional and dependent on the dimerization state of the ligand. The effects of ephrins have been well studied in neurons. In this system, ephrins provide guidance by repulsion of contact of the growing axon. There have been eight ephrin ligands identified thus far; however, only a subset of these appear to impact the cardiovascular system.

The first indication that Eph signaling was involved in vascular morphogenesis came from genetic inactivation analysis. In fact, removal of either ephrin B2 or EphB4 results in early embryonic lethality (E10.5) with alterations in vascular remodeling and lack of arterial and venular identities. Interestingly, expression analysis of LacZ reporter mice under the regulatory control of ephrin B2 and EphB4 revealed complementary expression patterns, with ephrin B2 in arteries and EphB4 in veins. Expression of ephrin B2 and EphB2 is also found in mesenchymal cells, suggesting a possible role for this signaling system in the recruitment of mural cells during remodeling events.

The signaling consequences initiated by Eph-ephrins have been also explored *in vitro*. Thus, signaling of EphA2 by ephrin A1 in aortic endothelial cells attenuates proliferative signals mediated by VEGF, through what appears to be the Erk pathway. In addition, this system regulates cell–cell recognition, as was anticipated by the defects noted in the null mouse.

5.5 TGF-β Signaling

TGF-β is a member of a large superfamily that includes: bone morphogenetic proteins, activins, inhibits, and Mullerian inhibitory substance all relevant to developmental processes. Three members of the TGF-β family (TGF-β1–3) have been identified all with partially overlapping expression, but distinct functions. The growth factors are secreted as latent forms and its activation is dependent on either proteolytic processing or binding to thrombospondin-1. Signal transduction by TGF-β requires a series of serine/threonine receptors, accessory receptors, Smad proteins, and Smad transcription factors that convey these signals to specific genes.

Because of its early expression and broad distribution, it was extremely surprising to find that targeted disruption of the TGF-β1 gene does not necessarily lead to embryonic lethality or congenital anomalies and mice tend to die 3 weeks after birth from immunological deficiencies. Initially, the potential issue of redundancy was a plausible explanation. Subsequently, it was shown that TGF-β could be transferred from mother to fetuses by the placenta

and to pups through the milk. This transfer is likely to account for the lack of a more severe phenotype, as the transfer would rescue the lack of endogenous production of the growth factor. While the maternal source of TGF-β could rescue some animals, still only about 50% of homozygous mice were recovered. The lethality was associated with defects in both hematopoiesis and vasculogenesis resulting in lethality around E9.5 to E11.5.

Genetic inactivation studies have clearly shown that TGF-β signaling is important for differentiation of endothelial cells. However, a further understanding of its contribution has been difficult to ascertain, particularly since the effects of TGF-β appear to be multiple and altered by other factors. In two-dimensional cultures, TGF-β has been shown to inhibit endothelial cell proliferation. Interestingly, in three-dimensional cultures, TGF-β does not affect proliferation, but appears to modulate differentiation. More recently, these opposing results have been conciliated by a more concrete understanding of TGF-β signaling pathways.

TGF-β signaling is mediated by its type I and II serine/threonine kinase receptors. There are two type I receptors: ALK-1 and 5 and one type II receptor, also known as TGF-β receptor II (TGFβRII). By activation of Smad1/5, it has been shown that ALK1 is responsible for the stimulation of endothelial cell proliferation and migration; while ALK5 through activation of Smad2/3 results in inhibition of cell proliferation and migration. Consequently, the net expression of these two receptors and their respective target Smads dictates the end result of TGF-β response in endothelial cells.

Mutations in ALK1 or on its accessory receptor, endoglin, have been linked to HHT. Consistent with these findings, ALK1-null mice die at E10.5 to E11.5 with defects in smooth muscle cell development and angiogenesis. ALK1 knockout animals also display vascular branching defects, dilations, and abnormal vascular connections (arterial–venular fusions). Mice lacking either TGF-βRII or ALK5 die at E10.5 due to defects in vascular development clearly seen in the yolk sac. Mice lacking endoglin also display embryonic lethality, with defects in vascular remodeling and abnormalities in arterial–venous boundaries. The contribution of this signaling pathway to vascular development has also been reinforced by the experimental inactivation of several Smad proteins in mice.

5.6 Platelet-derived Growth Factor

The PDGF family of dimeric growth factors shares a significant degree of sequence similarity to VEGF, yet its expression patterns and functional properties are clearly distinct. PDGFs and their tyrosine kinase receptors are expressed and impact a large number of tissues including fibroblasts, smooth muscle cells, neurons, and endothelium. This expression pattern explains why deregulation of this pathway has been associated with a myriad of human diseases, including atherosclerosis, fibrosis, and cancers.

The classical PDGFs include homo- and heterodimeric associations of the A and B chains, forming PDGF AA, BB, and AB respectively. The A and B polypeptides share similar protein domains, and are secreted as fully active factors. Like VEGF, these classical PDGFs also contain ''retention matrix'' motifs that allow them to interact with extracellular matrix proteins and regulate their biological availability to specific sites. Signaling occurs by

three receptors resulting from the association of two transmembrane polypeptides: PDFGR-α and β that also function as homo and heterodimers.

The contribution of PDGFs to the vasculature has been revealed by gene inactivation in mice. Phenotypic analysis of null mice implicated PDGF-B in the maturation stages of vascular development. PDGF-BB is expressed by endothelial cells and its receptor, PDGF-β, is located in vascular smooth muscle cells and pericytes. Absence of PDGF-B results in reduced pericyte association with capillaries, vascular fragility, and hemorrhage with subsequent lethality. Both PDGF-B and PDGFR-β-null mice had decreased numbers and proliferation of smooth muscle cells/pericytes progenitors. This was more noticeable in the brain, heart, and brown adipose tissue.

Recently, two additional growth factors have been identified in this family: PDGF-C and D. In contrast to A and B, the novel PDGFs are secreted as zymogens and require activation by proteolytic cleavage of their N-terminal CUB domains. Following proteolytic processing, PDGF-C binds as a homodimer to PDGFR-α, whereas active PDGF-D interacts with PDGFR-β. Both are also able to activate PDGFR-α and β heterodimers in cells that expressed these two chains. Genetic inactivation of PDGF-C results in defects in secondary palate formation and the dermis. The contribution, if any, of PDGF-C and D in the vascular system is yet to be elucidated.

6 Multiple Forms of Vascular Expansion

Angiogenesis is also a vital and dynamic process in adult vertebrate organisms. Vascular expansion is essential for normal tissue growth, wound healing, endometrial cycling, and pregnancy. Moreover, angiogenesis can be a beneficial adaptation to myocardial ischemia and peripheral vascular insufficiency.

Postnatal neovascularization has been thought to occur by a sprouting mechanism, that is, angiogenesis. While this process has been well studied and characterized during development, additional modes of vascular expansion have been recently proposed. In particular, the contribution of circulating endothelial cell progenitors (ECPs) has been clearly documented in a wide array of models and the existence of "resident-cell progenitors" that contribute to the growth of vessels upon injury has also been recognized. In addition, it appears that a mechanism of intraluminal bridging of vessels, known as *intussusception*, has also been noted as a mode for vascular expansion. These processes are discussed in greater length in the following sections.

6.1 Circulating Endothelial Cell Progenitors

The growth of blood vessels in adult animals has been traditionally considered to occur only as the result of angiogenesis, sprouting from preexisting vessels, rather than *de novo* endothelial recruitment from progenitor cells. Recent studies, however, have documented the existence of bone marrow–derived endothelial cells that participate in adult vascular growth, particularly in the context of rapidly generated tumor vasculature. Characterization of these circulating endothelial precursors has demonstrated that they are likely hematopoietic in origin and are recruited by VEGF signals to home in sites of vascular growth.

Similar to embryonic progenitors, adult bone marrow–derived endothelial precursors, including Sca1, appear to share antigenic determinants with hematopoietic progenitors. They also respond to similar factors, prominent among them is VEGF, which mobilizes Sca1+ cells, and stimulates their proliferation and migration, and probably their differentiation. ECPs have been detected in the peripheral blood and have the capacity to differentiate *in vivo* and *in vitro*. Their incorporation into sites of neovascularization has also been documented. Specifically, bone marrow–derived endothelial cell precursors (BMD-ECP) have been shown to participate in neoangiogenesis after postmyocardial ischemia, limb ischemia, wound healing, atherosclerosis, endothelialization of vascular grafts, retinal neovascularization, and cardiac impaired neovascularization during aging. Furthermore, the growth of at least certain tumors appears to be dependent on the recruitment of ECPs from bone marrow. Transplantation of wild-type marrow into *Id3/4* knockout mouse was reported to rescue the otherwise impaired tumor neovascularization of *Id3/4* deficient animals. At least in this model system, tumor vascularization was dependent on bone marrow–derived endothelial cells.

Contributions of bone marrow cells to the vascular smooth muscle cell compartment have been examined as well. Smooth muscle cells from arterioles in the infarcted heart were found to have bone marrow origin. Furthermore, smooth muscle–like cells can be derived from cultures flk-positive ES cells. These studies indicate that bone marrow cells can contribute to smooth muscle cell formation in pathological conditions, but do not address their potential role in normal vascular formation.

While investigators have agreed on their presence, the relative contribution of vascular progenitors to sites of neovascularization in the adult has been a point of heated debate, mostly because the assessments are not equivalent. Engraftment of ECPs, either from blood circulation or adult tissues have been reported to range from 3.5 to 10%. The information contrasts other studies that indicate progenitor contribution of up to 95%. Again, the source of bone marrow (or purified subpopulation) and the experimental models have been variable, therefore, this question remains to be answered.

If, indeed, the contribution of bone marrow–derived progenitors to the growth of the tumor vasculature is significant, manipulation of the ECP population might result in suppression of angiogenesis and tumor expansion. Consequently, several groups have now initiated significant efforts to ascertain the potential value of ECPs for therapeutic intervention. However, progress in this arena has been hampered by lack of a solid means to identify these cells.

The cell-surface makeup and full characterization of ECPs is still unclear and the subject of active investigation. Experiments using CD34+ sorted precursors have shown that ECPs display this marker, both while in the bone marrow and also in the circulation. In contrast, other studies have reported the presence of tissue-resident CD34 negative cells that can contribute to endothelial cells. These latter studies were performed with local progenitors, so it is possible that there are indeed multiple precursors, some bone marrow–derived; and some resident. More consistently, CD34+, AC133 (CD133 or prominin A in mouse) and VEGFR2 are the markers most agreed upon in the literature. Why has it been difficult to

fully characterize this population of bone marrow–derived cells? Models that can identify these cells are currently missing, and the isolation of ECPs using CD34 is challenging, with low yield. Other investigators have used a combination of markers, yet the proof of principle for their identity relies on vascular integration. This adds another layer of difficulty, as once they become incorporated, the differentiation pathways are initiated and the makeup of the precursor population is lost. Thus, the transient nature of the phenotype has hindered progress in this area. Clearly, genetic markers that could trace this population of cells can add a strong advantage to this research.

6.2 Vascular Intussusception

The term *intussusception* is used to describe the process of intravascular growth by the formation of transendothelial cell bridges. These bridges are subsequently reinforced by tissue columns that grow into the lumen of these vessels. Subsequently the bridges gain mural cells, that is, pericytes and/or smooth muscle components, and undergo remodeling. Through this process a large vessel can branch, or be subdivided into smaller daughter vessels. Little information is available in the literature about this process. At this point, it is difficult to ascertain the frequency of intussusception *in vivo* and its relevance to vascular expansion.

7 Mechanical Forces and Angiogenesis

Mechanical factors, such as shear stress, wall tension, and stretch, have long been implicated in vascular growth. Ligation of vessels and subsequent interruption in flow results in severe disruption in normal vascular patterning and morphogenesis. However, caveats in the interpretation of these experiments include the possible contribution of oxygenation.

Technological advances have allowed the application of laminar, pulsatile, and circular shear stress on cultured endothelial cells to study the effect of these forces on gene expression. There is increasing experimental evidence that shear stress, and other consequences of vascular activity, modulate gene expression and that different types of stress activate distinct gene programs. Stretch of cardiomyocytes activates several second messenger pathways including Ras/MAP kinase, tyrosine kinases, and protein kinase C. Stretch has been shown to activate all three MAP kinase family members. Furthermore, it has been shown that stretching of skeletal muscle results in transcriptional activation of VEGF.

In vivo evidence also indicates a role for stretching in angiogenesis. Stretching the left ventricle for 30 min via an intraventricular balloon resulted in nearly a sixfold increase in VEGF message level. Stretching of endothelial cells also precipitates changes that activate and facilitate angiogenesis. They include rearrangement of the cytoskeleton and the release of plasminogen activators and metalloproteinases, which disrupt the basement membrane thus enabling cell migration, proliferation, and activation of ion channels with consequent mobilization of calcium. These factors modulate the relative generation of cellular force by the cytoskeleton and integrins, which combined with the relative rigidity offered by the matrix results in either thinner or wider capillary tubes *in vitro*. Clearly, a concrete understanding of how mechanical

forces are interpreted by cells during angiogenesis is precarious; however, this is an active area of investigation that is likely to reveal important functions of hemodynamics forces in the vasculature.

8 Angiogenesis Inhibitors

The concept that tumor progression could be regulated by pharmacological and/or genetic suppression of blood vessel growth has engendered a long-standing interest in the identification of molecules or synthetic compounds that block angiogenesis. Among recognized angiogenesis inhibitors are: platelet factor 4 (PF4), thrombospondin-1 (TSP1) and 2 (TSP2), angiostatin, endostatin, pigment epithelial-derived factor, and more recently proteolytic fragments of type IV collagen. Interference in the signaling pathways of specific stimulators, such as VEGF/VPF (vascular permeability factor) has proven effective in blocking blood vessel growth. In addition, blockage of integrin binding, in particular, $\alpha_v ß_3$, has been shown to suppress angiogenesis in several tumor types.

Antiangiogenesis has been appealing for cancer therapy for three main reasons: (1) it is likely that most tumors are dependent on angiogenesis, thereby providing a common target in the treatment of widely heterogeneous disease; (2) endothelial cells are considered to be less likely to develop adaptations to bypass drug effects (i.e. drug-resistant phenotype, as seen in some tumors); (3) it is anticipated that tumor vessels are proliferative providing a differential target than the quiescent vessels present in normal tissues.

Results from angiogenesis research during the last decade have questioned some of those earlier assumptions. Clinical trials designed to test antiangiogenic therapy have met with variable and rather disappointing success. In particular, not all tumor vessels appear equally susceptible to a single modality of antiangiogenic therapy. The reasons for this outcome are likely multiple. For example, the participation of tumor cells to the vascular wall (''vascular mimicry'') has been demonstrated in uveal carcinoma, and more recently in melanoma. How responsive are these cells to antiangiogenic therapy? The molecular nature of tumor microvessels appears to be more variable than anticipated and differences in the tumor microenvironment will likely influence therapeutic outcome. It has been well acknowledged that the ''context'' poses a direct (and reciprocal) effect in the tumor cells. Additional reasons for the ''disconnect'' between bench and clinical results have been attributed to poor design of trials and efficacy of some of the tested drugs. More recently, the evaluation of ''combination therapy'' (antiangiogenic and ''metronomic'' chemotherapy) has received experimental attention with a higher degree of success than either therapy alone. Regardless, the relative success of therapeutic approaches using VEGF has engendered hope for this modality of therapy both in cancer (to block vessels) and in cardiac ischemia (to enhance angiogenesis).

VEGF has shown experimental success in animal models to treat vascular insufficiency in the heart and in peripheral blood vessels. Accordingly, clinical studies have been undertaken in which VEGF has been administered as recombinant protein or expressed from plasmids or viral vectors for stimulatory reasons. The situation is particularly complex in diabetic patients, where the potential benefits of

proangiogenic therapy for peripheral vascular disease must be weighed against the risks of exacerbating the progression of ''diabetic retinopahy,'' a condition characterized by excessive vascular proliferation. Inhibition of VEGF signaling has been used for suppression of vascular growth during cancer progression. In addition, the role of VEGF in other processes, such as atherosclerosis, arthritis, and retinopathies has engendered a lot of interest in attempting to block this signaling pathway in pathologies other than tumors. The efficacy of these treatments is currently under evaluation. It is clear that understanding the control of cellular events associated with VEGF-dependent angiogenesis will facilitate the rational design of therapeutic interventions.

Acknowledgment

I would like to acknowledge members of my laboratory for stimulating discussions and thank Dr. Tim Lane for important inputs and suggestions.

Keywords

Gene Therapy
A therapeutic technique to eradicate genetic malfunctions by introducing new gene or repairing defective gene in the host cell. The therapy, initially aimed toward treating inheritable disorders, is also used in treating acquired disorders such as AIDS, cancer and so on.

Lipoplex
A charged complex made of DNA and cationic lipid. The complex is formed by electrostatic combination of negatively charged DNA with positively charged cationic lipids. Preformed cationic liposomes made of cationic lipids and/or colipids interact and condense DNA by cooperative interaction of positively charged head group of aggregated surface of lipids with negatively charged DNA.

Lipopolyplex
An entity formed by mixing the preformed liposomes made of cationic, anionic or neutral lipids, and/or colipids with cationic polymer induced precondensed DNA. Electron microscopic studies revealed a lipid-based envelope, carrying the polyplex-containing core.

Nonviral Gene Delivery
A special gene delivery technique, which does not use viral mechanism to deliver genes to cells. It involves various physical techniques, chemical methods, and biomimetic synthetic agents to introduce genes to cells.

Polyplex
Another charged complex as lipoplex, but here the cationic entities are polymers. Cationic polymers associated with net positive charges also condense negatively charged DNA by electrostatic combination to form polyplex.

PAMAM:	polyamidoamine
PEG:	polyethyleneglycol
PEI:	polyethyleneimines
PLL:	poly-L-lysine
PO:	phosphodiester
PS:	phosphorothioate
TC-Chol:	3β-[*N*-(*N*′,*N*′,*N*′-trimethylaminoethane)carbamoyl] cholesterol

In gene therapy, nonviral gene delivery has earned a special position on its own right. This delivery system enjoys several favorable properties, such as, the delivery efficiency is not limited by the size of the genetic cargo, and it is less immunogenic and less toxic than their viral counterpart. One of the methods of delivery is direct injection of naked DNA to the organs of interest. Plasmid DNAs (pDNA), which carry recombinant genes of interest, are used for introducing genes to cells and organs. Various physical methods, for example, gene gun and electroporation, increase the efficiency of the naked DNA incorporation. Lipid-based vectors have the advantage of protecting the DNA against degradation by endogenous DNase *in vivo*, and can be targeted to a specific cellular site in some special cases. Varieties of lipid-based systems have been designed, mostly containing cationic lipids of different structures. Second-generation vectors containing polymers are more stable and more targetable than the first generation vectors. Although significant progress has been made, nonviral vectors are still limited in their efficiency and by some cytotoxicity inherited in the bacterial pDNA, which hosts the gene of interest. Understanding mechanisms and means to overcome the cellular barriers for the DNA delivery will undoubtedly promote further development of pDNA mediated gene delivery.

1 Overview of Plasmid-mediated Gene Therapy

Postgenomic era has thrust new responsibilities on humankind. Many defective genes responsible for various disease phenotypes have already been discovered. It now becomes a daunting challenge for multidisciplinary field experts to think of strategies to introduce normal genes efficiently into the target cells and/or tissues to complement the defective genes. Hence, gene therapy faces new tasks. This methodology originally designed to correct inheritable disorders, is now being considered for treating acquired disorders, such as cancer and AIDS.

Gene therapy is largely classified into two modes of gene delivery, it either utilizes viruses or it does not. Replication defective viruses such as retrovirus, adenovirus, adeno-associated virus, herpes simplex virus, papilloma virus, Sendai virus, and so on with part of the genes replaced by a therapeutic gene are used to transduce cells with very high efficiency. They are in use for various gene therapy approaches either clinically or experimentally. There are several drawbacks, which have partially eclipsed or limited the widespread use of viral vectors albeit their excellent transducing efficacy in cells and tissues. For example, induction of strong host-immune response followed by toxicity is common in adenoviral vector–based treatment, which limits the duration of the transgene expression. Additionally, the imposing immunogenicity makes repeated dosing impossible. Retroviral vector requires dividing cells for gene expression, but it poses the risk of random integration into the host genome, leading to mutation and neoplastic transformation. A large, industrial scale production of viral vectors is difficult. There is limitation for the size of the gene cassette to be included in viral vectors. These concerns have prompted

the development of nonviral vectors as a less toxic and more scalable alternative for gene therapy. However, nonviral vectors still need improvement, both in efficiency as well as in the duration of the transgene expression. These aspects are the central concerns of the current nonviral vector development.

Nonviral vectors often use recombinant plasmid DNA (pDNA) as the carrier of the therapeutic gene. Recombinant DNA is an artificial, synthetic DNA-based recombinant molecule, made by addition of several DNA fragments obtained from different sources, whereas pDNA is an extrachromosomal, circular, predominantly supercoiled bacterial DNA, which can be produced on a large scale by fermentation in bacterial cultures. Through simple recombination techniques, any therapeutic or marker gene of any size can be introduced into pDNA. Nowadays with the help of existing advanced technologies, a single lot can produce multigram quantities of pDNA, which can be finally purified using simple physical and chemical methods. Generally, standard pDNA is 4–10 kbp in size (molecular weight: 1×10^6 to 3×10^6). Other than the usual bacterial sequences, pDNA for gene therapy contains an expressible sequence of genomic DNA, popularly known as *complementary DNA* (cDNA) that codes for a specific protein. This genetic sequence, also called *transgene,* remains under the controlling influence of another gene sequence called *promoter*, located upstream of the coding sequence of transgene. This promoter sequence controls transcription, that is, transgene to messenger RNA conversion. A transcription termination gene is often inserted downstream of coding sequence to ensure proper termination of transgene transcription. A polyadenylation sequence and sometimes an intron, that is, a nonexpressible gene sequence, is also added to ensure proper processing of the m-RNA product of the transgene (see Fig. 1). The major advantage of plasmid expression vectors is that the cells upon transfection produce homogeneous, correctly folded, posttranslationally modified proteins within itself. This thwarts the attempt to purify and isolate proteins, which often leads to partial degradation or inactivation of the protein.

This chapter is, however, intended to summarily emphasize the role of pDNA as a gene-carrying cask, which finds its role in gene therapy using nonviral-based delivery techniques toward deciphering various biological functions, and use

those facts in finding gene therapy–based therapeutically useful tools against various disease pathologies.

2
Direct Delivery with Naked Plasmid DNA

2.1
History and Recent Efforts Toward Attaining Long-term Expression

The simplest of all DNA delivery systems is the injection of naked pDNA to the organ or tissue of interest. Skeletal muscle was first transfected by intramuscular (IM) injection of naked pDNA. Since then, a plethora of tissues such as, the interstitial space of liver, thyroid, heart muscles, brain, urological organs, and so on have been transfected with direct gene transfer. The delivery by direct injection of naked DNAs containing one or more anticancer genes was also tested against various tumors with mixed efficacies.

This technique of direct injection of pDNA was thoroughly used in several other experimentations as well. This technique of direct injection has become a useful tool to analyze the gene expression and promoter function in the respective organ. Utilizing viral promoter, such as that from cytomegalovirus (CMV), a high level of initial expression was attained, which, however, declined sharply to near background within two to three weeks. Although within two days of pDNA injection the maximum decrease in the expression level was observed, but the pDNA continued to be scantily detected till the end of 12 weeks (0.2 copies per genome). The major cause of this early decline was believed to be because of viral promoter activated immune responses, and this fact was later corroborated by experimentations in immunosuppressed mice that showed extended levels of transgene expressions.

Sustained therapeutic benefit needs assurance for long-lasting gene expression of pDNA associated therapeutic genes without eliciting any expression related cytotoxicity. Classically, several experimentations were performed, with fewer cases showing chances of extended expression time. For example, high-expressing human factor IX (hFIX) pDNA upon transfection in mouse liver yielded therapeutic-level gene expression over $1\frac{1}{2}$ years, eliciting no transgene expression–related cytotoxicity or long-term therapy related toxicity. However, with liver regeneration, there was a decline in transgene expression, which suggested the possibility of decline in maintenance of plasmid, rather than the possibility of transgene integration into the host genome. Hence, sustained gene expressions required a transcriptionally active vector DNA that could persist for a long time in the organ. Let us also not forget that a random genomic integration in host genome is contrary to health benefit. Therefore, with the help of this transcriptionally active vector, pDNA nonviral gene transfer could lead to extended life of transgene-expression level without leaving scope for genomic integration.

For extended transgene expressions of conventional plasmid vectors, a new technique was involved. The plasmid vector was modified to contain Eppstein–Barr virus (EBV) episomal vectors that consisted of *EBNA1* (EBV nuclear antigen-1) gene, and oriP element. Interestingly, nuclear localization and transcriptional upregulation of the oriP-bearing plasmid was assisted with the help of EBNA-1. This enabled efficacious transgene expression and long-term maintenance of the expression in cells transfected with the EBV/lipoplex. EBV plasmid vector played an important

role in various disorders such as congenital, malignant, chronic, and infectious diseases. This plasmid was used in gene therapy against tumor malignancies, such as in reducing tumor size by intratumoral injection of EBV plasmid vector encoding *HSV1-TK* anticancer gene. *EBV* plasmid-based interleukin genes, *IL-12* and *IL-18* gene transfer to tumors elicited natural killer (NK) cell activities and cytotoxic T-cell (CTL) responses, which lead to tumor retardation. Cardiomyopathic animals experienced extended cardiac output upon intracardiomuscular transfer of EBV-based β-adrenergic receptor gene. EBV-based plasmid gene transfer was also used for genetic vaccination against acute viral infections.

Another school of thought sprouted while developing and fine-tuning the conditions for long-term transgene expression. We know that virus-mediated gene transfer lead to random integration into the host chromosome. This often leads to abnormality in gene expression. However, site-specific genetic integration into inconspicuous genomic sequence might be one of the most-sought-after preconditions for stable, long-lasting, and powerful transgene expressions mediated through recombinant plasmids. This became possible with phage integrases. These enzymes mediate unidirectional site-specific recombination between two specific DNA sequences, one containing phage attachment site (attP) and the other bacterial attachment site (attB). These DNA sequences are short, yet specific on a genetic scale. A plasmid containing the bacterial attachment site flanking the gene of interest in both the ends was transfected into cells. The integrases of the serine family showed efficient recombination in mammalian cells. They mediated efficient integration at introduced att sites or native sequences with partial att sites (pseudo-attP). Human α_1-antitrypsin and hFIX gene associated with attB cassette, coadministered with integrase plasmid, upon liver delivery to mice showed elevated long-term expression (therapeutic level of protein obtained for about 8 months). Upon partial hepatectomy, the expression did not decline, indicating that the DNA was integrated to the mouse genome. Similar results were obtained during the functional restoration of human type VII collagen protein in skin cells obtained from recessive dystrophic epidermolysis bullosa (RDEB) patients. Additionally, this technique could be useful in developing big transgenic animals dedicated to the preparation of therapeutic proteins on large scales.

2.2 Recent Therapeutic Uses: Treating Cancer

Nonviral gene therapy had become a useful tool in generating various therapeutic effects in diverse animal models. One of these effects is to induce anticancer response in tumor models by introducing anticancer genes. NO synthase II (*NOS II*) gene that catalyzes nitric oxide (NO) production was incorporated in plasmid under CMV promoter control. This plasmid, upon injecting in medullary thyroid cancer (MTC), elicited anticancer effect in tumorigenic cells. The gene triggered a suicidal effect (apoptosis) on the tumor cells by the production of NO, which specifically activated the macrophages against the fast dividing tumor cells, leaving normal cells untouched. NO was also observed to mediate bystander antitumor effect: The activated *NOS* gene in a tumor cell induced the cytotoxicity in the neighboring tumor cells. The fact that NO mediated tumorogenic effect does not require transfection of all neoplastic cells promised a

capable suicide gene therapy approach to human cancer.

Fas ligand is another apoptotic inducing molecule that showed similar bystander effect. The membrane protein receptor Fas and its ligand FasL mutual interaction initiate an apoptotic signal in Fas-bearing cells. pDNA could be used to deliver these apoptosis-inducing genes to initiate killing of transfected and nontransfected surrounding cells. On direct injection of FasL encoding pDNA vector into the inflamed thyroid, pathogenic lymphocytes were inhibited to enter into thyroid, leaving the already infiltrated T cells dead. Thus, FasL expressing in thyroicytes might lead to potential remedial therapy for the experimental autoimmune thyroiditis (EAT).

2.3 Understanding Physiological Role of Protein-transduction Pathways

Direct pDNA transfer technique could find its use in examining the role of a physiologically related protein-transduction signal pathway toward certain endogenous disease phenotype, such as investigating the functional role of the tissue kallikrein-kinin system (KKS) in the central control of blood pressure homeostasis. Kallikrein is a proteinase enzyme that converts kininogen to vasodialative kinin peptides. To understand the role of vasodialative KKS on the pathogenesis of hypertension, the human tissue kallikrein gene *CMV-cHK,* was intracerebroventricularly injected into hypertensive rats. Cortex, cerebellum, brain stem, hippocampus, and hypothalamus identifiably expressed human tissue kallikrein protein. The expression level and its effect could lead to verify the role of the KKS system.

Similarly, the method of Direct injection of pDNA to rat fibroblast had been used to study the consequences of overexpressing dominant negative forms of the ubiquitous mitogen-activated protein kinase (MAP-kinase) toward inhibition of cell proliferation. Direct pDNA microinjection technique was also used to demonstrate the absolute requirement of the protein Cyclin A in DNA synthesis, as opposed to the popular belief that the Cyclin A was uniquely involved in the mitotic activation only. An SV40 expression vector encoding the full-length, antisense Cyclin A RNA, upon direct microinjection into synchronized mammalian cells, completely suppressed Cyclin A expression at S phase, resulting in inhibition of DNA synthesis.

2.4 Gene Transfer to Skeletal Muscle

A variety of diseases such as muscular dystrophies, chronic ischemic limb syndromes and so on, were treated by the technique of direct gene transfer to skeletal muscle. Specifically engineered pDNAs and the vector systems were developed that enabled regulated and tissue-specific transgene expression in skeletal muscle *in vivo*. Naked pDNA–based gene transfer had been used in different animal models, for example, in correcting Duchenne Muscular Dystrophy, to supply sources of therapeutic protein systemically, for genetic vaccination against pathogens and tumor cells. However, larger animals showed limited clinical utility owing to inefficient gene expression in them.

On quantifying the gene-uptake in the muscles, the IM injection showed less than 1% uptake of injected dose and was limited to cells adjacent to the needle track. Using hypertonic sucrose, or muscle revitalizers, the efficiency and reproducibility

of gene expression could be increased. Intraarterial injection of naked pDNA into the femoral arteries of rats showed 2 orders of magnitude higher transgene-expression level throughout the muscles of hind limb compared to that obtained in direct muscular injection. Myofibers were 10% more transfected through intravascular delivery than with the direct IM injection. This intraarterial injection technique was extended to the nonhuman primates also. Hypothetically, the pDNA upon intravascular injection extravasates out by the intravascular pressure following the convective flow across the endothelium, and was soon picked up by the *in situ* muscle cells with the help of membrane receptors. This was evidenced by the fact that the naked pDNA was taken up by hepatocytes *in vivo* by a receptor-mediated process. Several DNA receptors had been discovered in human leukocytes, peritoneal macrophages, and in wide variety of tissues and tumor cells. For the enhancement of IM gene expression, a fresh look is needed toward the poorly understood mechanism of molecular recognition and characterization of the cell surface receptor(s) involved in the binding and internalization of DNA. It is reported that rapid injection of pDNA in a large volume (e.g. 5 µg of DNA/20 g mouse in 1.5 to 2.0 mL of saline solution) through the tail vein left the injected DNA in the inferior vena cava. The DNA flowed back to the tissues linked to this vascular system, primarily the liver. The hydrodynamic pressure forced DNA into the liver cells before it was mixed with blood. By this process, the liver showed the highest expression of gene; internal organs such as lung, spleen, heart, and kidney were also efficiently transfected. It was also shown that briefly clamping the vena cava following tail vein injection of pDNA in a small volume efficiently transfected both liver and diaphragm. The result is potentially important because diaphragm is barely transfected by hydrodynamics-based method. The full-length dystrophin cDNA can be delivered to the diaphragm for the treatment of Duchenne Muscular Dystrophy. It is well known that patients with Duchenne Muscular Dystrophy often suffer from fatal respiratory failure due to the dystrophic diaphragm muscle collapse.

2.5 Gene Delivery for Myocardial Diseases

Myocardial gene delivery via direct injection or through coronary vasculature with naked pDNA usually showed low levels of gene transfection. However, the results so obtained had invaluable impact in characterizing the role of promoters in cardiac tissue and further helped in examining the effect on transferred foreign gene expression by the influences of naturally occurring mechanical and hormonal stimuli of the myocardium.

It was demonstrated that the tissue-specific promoter chimeras injected into the heart could respond accurately to shift in thyroid hormone levels *in vivo*. Injection of pDNA with gene constructs driven by cellular promoters resulted in detectable levels of reporter gene activities. The cellular promoter was derived from the rat α-myosin heavy chain (α-MHC) gene. The expression of this gene *in vivo* is restricted to cardiac muscle and is positively regulated by thyroid hormone. The regulatory portion of genes expressing specifically in cardiac muscles could be identified using this method. Direct DNA injection had been extended to evaluate and characterize the activation properties of a cardiac-specific promoter/enhancer of the slow/cardiac troponin C (cTnC) gene that express in cardiac striated muscles.

Myocardial direct DNA injection was also utilized to analyze the transcriptional regulation of brain creatine kinase (BCK) gene in the developing heart. pDNA constructs containing BCK promoter and *CAT* or luciferase reporter gene was delivered into the left lateral wall and apex of the ventricle on the heart. The study might provide insight into the embryonic gene expressing mechanism during cardiogenesis. Because the *BCK* gene, the major gene for cytoplasmic creatine kinase expressed in the embryonic heart, is downregulated during cardiogenesis, it is reinstated in response to stimuli such as ischemia, hypertrophy, or heart failure in the adult.

The method of direct pDNA injection was used to explore the effect of specific pathophysiological state on cardiac gene expression, such as ischemia, myocardial infarction, reperfusion injury, hypertension and so on. Ischemia is a disease state that is formed when tissues are starved of blood supply and nutrients because of deficient supply of blood through possibly narrowed or blocked arteries. Sporadic myocardial ischemia is prevalently associated with coronary arterial diseases. Ischemia related disease phenotype needs a therapeutic gene, which could be selectively upregulated by the elevated signals for ischemic activity and consequently downregulated when the activity represses. In this context, Prentice et al. introduced expression plasmids containing muscle-specific α-MHC promoters and hypoxia-responsive enhancer (HRE) elements linked to a reporter gene in cultured cells or into the rabbit myocardium, and measured the regulation of these constructs by hypoxia or experimental ischemia. It was shown that the expression of reporter gene was induced by both hypoxia *in vitro* and by a short interval of ischemia *in vivo*.

There were different reports concerning the stability of plasmid-based transgenes in both skeletal and cardiac muscles. It was shown that the rat cardiac myocytes could express *β-galactosidase* gene under the control of the Rous sarcoma virus promoter, by the injection of pDNA encoding the reporter gene directly into the left ventricular wall. β-galactosidase expressed in cardiac myocytes was detected in rat hearts for at least four weeks after injection of the *β-galactosidase* gene. In postmitotic cardiac and skeletal muscle cells, the transgene expression of the pDNA declines with time, probably due to the episomal localization of the DNA. The reason that the striated muscles showed higher capacity for uptake and expressing of pDNA following direct injection was not clear; the efficient gene transfer might be induced by cellular membrane rupturing and destabilization, followed by inflammation caused by the injection needle.

2.6 Gene Therapy for Angiogenesis

Because ischemia is formed as a result of deficient supply of blood to tissues, formation of new blood vessels is a remedy against this disease. One of the mechanisms that involves the formation of new blood vessels is angiogenesis. Angiogenesis is the process of new blood vessel development for the vascularization of various organs, for wound healing, and to allow cancer development and proliferation.

Therapeutic angiogenesis involves replenishing angiogenic growth factors by administering recombinant proteins or endothelial growth-factor gene. The recombinant proteins have severe limitation on its usage, as they are expensive and difficult to produce on a large scale.

On the other hand, gene therapy provides a systemic and long-term effect with modification in the effective dosage of the therapeutic agent. To evade potential problems of pathological angiogenesis, transient gene expression is usually preferred for this kind of treatment. Tsurumi et al. introduced naked pDNA encoding vascular endothelial growth factor (VEGF) by (IM injection into ischemic hind limb muscles of a rabbit model and observed that the vessels and blood-capillaries were increased in rabbit muscles injected with VEGF compared to controls. An enhanced vascularity-induced perfusion followed by increased blood flow in the ischemic limbs was also observed. In clinical trial, Simovic et al. introduced naked pDNA encoding human *VEGF* gene by direct IM injection to chronic ischemic limbs of patients, to treat peripheral neuropathy caused by critical limb ischemia. The patients showed decreased neuropathic disability in the treated limbs, indicating that long-term therapy might improve the integrity in tissues of ischemic limb and consequent retrieval of limb.

2.7 Gene Therapy for Autoimmune Diseases

Autoimmune disease is a pathogenic condition in which ones immune system erroneously targets and aggresses a person's own cells, tissues, and organs. The most prevalent symptom of this disease is inflammation, which is caused by the abundant presence of a large number of immune cells and molecules in the target site of the body. Autoimmune diseases or other inflammatory conditions were primarily and successfully confronted by gene therapy through the delivery of cytokines or cytokine inhibitors. Interferon γ. (IFN-γ), interleukin-1 (IL-1, α or β), IL-12, and tumor necrosis factor α (TNFα) are recurrently addressed inflammatory cytokines in illnesses related to autoimmune/inflammatory diseases. Other than these cytokines, transforming growth factor β (TGF-β) is also a key regulatory cytokine, because TGF-β inhibits T and B cell responses, irregularity of which leads to elevation of autoimmunity invoked disease conditions.

In animal models, pDNA constructs with the encoding anti-inflammatory cytokine genes for IL-10, IL-4, and TGF-β1 were injected into either tibialis anterior or rectus femoris muscles in nonobese diabetic (NOD) mouse against autoimmune diabetic disease. Although there was no marked decrease in severity of insulitis, the diabetes was reduced in NOD mice injected with IL10 as compared to untreated NOD mice. In another experiment, treatment of autoimmunity prone NOD mice with pCMV-TGF-β1 resulted in considerable elevation of TGF-β1 level in the plasma. The increased levels of TGF-β1 exerted various immunosuppressive effects such as suppression of delayed-type hypersensitivity (DTH), and prevention of insulitic and diabetic incidence in this kind of mice. TGF-β1, IL-4, and IFN-γ gene coding plasmid vectors were also injected intramuscularly into rodent models for treating experimental allergic encephalomyelitis (EAE), systemic lupus erythematosus (SLE), colitis, and Streptococcal cell wall-induced arthritis (SCW arthritis).

3 Improving Plasmid DNA-mediated Gene Transfer by Electroporation

Electroporation is a process of exposing cells to controlled electric field for the

purpose of cellular membrane permeability. The electric pulses, intensely localized to destabilize the membrane, allow molecules to enter cells. A variety of genetic materials were inserted into the cells *in vitro* by electroporation. Electrochemotherapy facilitates the cellular entry of hydrophilic anticancer agents such as bleomycin to obtain drastically improved antitumor effect in malignant melanoma.

Recently, *in vivo* electroporation has emerged as a leading technology for developing nonviral gene therapies and nucleic acid vaccines (NAV). Naked pDNA injections accompanied by electroporation showed 10 to 1000-fold increases in gene expressions as compared to the nonelectroporated direct injections. However, the duration of a gene expression following *in vivo* electroporation was dependent on target tissue and plasmid constructs. Despite this fact, a broader variety of cells showed reporter gene expressions.

The major advantage of electroporation is that a treatment-area specific *in vivo* gene expression is possible wherein specific tissue could be directed by using specifically designed electrodes. A high level of controlled expression of specific gene was obtained by using tissue-specific promoter directed against specific tissue with a different pulsing parameter.

Various disease pathologies underwent electroporation-mediated *in vivo* gene transfer. The successful utilization of this technique was done in targeting hepatic parenchyma, hepatocellular carcinoma (HCC), skin, skeletal muscle, mouse testes, melanoma, human primary myoblast, glomeruli, brain, human primary hematopoietic stem cells, human esophageal tumor, and rat skeletal muscle for correcting anemia of renal failure. Furthermore, electroporation of TGF-β1 gene to the wound models in diabetic mice resulted in higher cell proliferation, denser yet organized extracellular matrix formation, collagen synthesis, and angiogenesis in the treated wound site.

Electroporation utilizing high electric field strength induces tissue damage. This restricts its usage. Efficient and safe electrotransfer for delivering exogenous material into tissues must be developed before the clinical potential of gene therapy can be realized. Recently, a novel syringe electrode was developed. With this electrode, electric field was directly delivered to the cells in which pDNA had been injected, the injected DNA could be confined to the high field region without affecting the adjacent areas. High transfection efficiency was observed with comparatively lower field strength that caused minimal tissue damage.

A technique called *microelectroporation* was utilized locally to introduce a transgene into chick embryo and for expressing the gene in a spatial and temporal manner. By the microelectroporation technique, DNA molecules were efficiently introduced into the optic vesicle, sensory placodes, surface ectoderm, neuroepithelium of the central nervous system (CNS), and into the somites and limb mesenchyme.

4 Improving Plasmid DNA Transfer Mediated by Gene Gun

Gene gun is a physical way of administering gene *in vitro* or *in vivo*. pDNA makes electrostatic complex with gold or tungsten microparticles. The DNA-metal particle upon targeting to specific tissue is forcibly expelled by a flow of regulated, highly compressed helium gas. The delivery is highly localized to the tissue part. The delivery

to different tissue depths and areas is regulated by adjusting the speed and hence impact-pressure of the projectile. The process involves easy and speedy preparation of the delivery vehicle while keeping DNA intact. This technique sometimes allows DNA to gain direct access to nucleus bypassing the endosome/lysosome. These cellular compartments may induce possible enzymatic degradation. Because of the benefit of accessibility, this technique is especially suitable for gene transfer to skin and for superficial wounds. There are several examples in various animal models, which have shown a high level of transgene expression in the epidermis and dermis of the skin.

By the gene gun technique, mouse skin was transfected with IL-6 and hemagglutinin encoded DNA to elicit protective immune responses against equine influenza virus. Several different large animals such as rhesus monkeys, pigs, and horses were also immunized against virus by transfecting gene encoding the viral antigen.

Detectable transgene activities were also noticed in various nonsuperficial organs, such as lungs, pancreas, kidney, muscle, and cornea. Gene gun was also used to treat against tumor growth. Intradermal tumor upon *IL-12* gene delivery by gene gun gave detectable levels of the gene product at the treatment site. This eventually led to complete tumor regression within seven days. TGF-β1 encoded plasmid bombardment to rat tissue enhanced the tensile strength of the tissue by almost twofold, as compared to the control constituting nongene gun mediated direct injection. Porcine partial-thickness wounds, when transfected with a vector expressing epidermal growth factor (EGF) showed an increased rate of epithelial cell formation. This increased epithelialization shortened the wound healing time by 20%.

5
Lipid-based Vectors

5.1
Idea Behind Lipid-based Vectors: Recent and Classical Uses

The lipid-based DNA delivery system was first utilized on the premise that naked DNA upon injection *in vivo* might be degraded by endogenous DNase. The DNA would remain protected inside the lipid-based delivery vehicle during its run through the circulating blood stream. With necessary chemical modification, this vehicle would target the DNA toward specific cellular sites.

These lipids are a class of molecule that self-assemble in aqueous or organic media. Depending on its molecular architecture and in the presence or absence of cosolute, they assume structures such as micelle, emulsion, or liposome in aqueous media, and reverse micelle in organic media. However, among all the systems, liposomal systems found most biological usage, probably owing to its close resemblance with the cellular membrane. They constitute a bilayered structure, which can encapsulate water-soluble molecules in its aqueous hydrophilic core or water-insoluble molecules in its hydrophobic bilayer. Liposome-based drug delivery systems have shown promise in clinical use and several products have already been approved by the FDA. Fraley et al. had shown for the first time that encapsulating DNA in liposomal aqueous core could also deliver DNA to cellular targets. They used a composite liposomal system containing anionic and nonionic lipids. The DNA encapsulation efficiency for this system was low. Toward enhancing gene delivery and targeting ability of the liposome to specific tissue site, anionic

liposomes encapsulating DNA were coated with target-specific antibody to make pH-sensitive immunoliposomes. These liposomes upon intraperitoneal (IP) injection, showed specific transfection to tumor cells in an ascites tumor model in nude mice. Very recently, the immunoliposomes were revisited for targeting brain. An exogenous gene was targeted to brain through the blood brain barrier by intravenous (i.v.) injection of pegylated immunoliposomes conjugated with antibody to rat transferrin receptor. The whole entity was targeted to brain via the transcytosis of transferrin receptor.

Felgner et al. for the first time used cationic liposomes for gene transfection. The primary idea was to electrostatically condense DNA with more than one equivalent of cationic lipid and the negatively charged cells would take up the net positively charged entity when fed to the cell. Overall gene delivery to the cells was very high compared to any contemporary nonviral gene delivery techniques. This opened up a new vista in the field of gene therapy. Soon a plethora of literature developed, which chronicled the painstaking fine-tuning of the chemical structure of lipids by systematic structure-activity studies. These studies were done to dig out the structure of the potentially most potent cationic lipid for gene transfection.

pDNA played a significant role in this context. pDNA reconstructed with recombinant marker/reporter gene and suitable promoter is primarily used as a tool to screen the efficient transfection lipid from a library of cationic lipidic molecules. The electrostatic lipid–DNA complex that is formed by the recombination of these first generation cationic lipids with DNA is termed *lipoplex*. Cationic polymers also condense DNA and, with or without the presence of lipid, these polymers can deliver DNA to cells. This makes the basis of the second-generation gene delivery systems. Cationic polymers, cationic dendrimers, and so on condense DNA to make a complex called ''polyplex''. If liposomes, cationic or anionic are used to encapsulate the precondensed cationic polymer–DNA complex, and are used to deliver DNA to cells, then the whole entity is termed *lipopolyplex*. We will talk about these second-generation gene delivery systems later in this chapter.

5.1.1 Structures of First Generation Cationic Lipids

In the process of finding out the best cationic transfection lipid, several groups throughout the world, over the last 15 to 17 years, explored different chemistries to evolve different chemical structures, which made quite a big library of molecules. It is very interesting to know that several architectural differences in the molecular infrastructure of cationic lipids evolved, which lead to the formation of cationic lipids of varied transfection ability. Here, we will briefly yet broadly classify the categories of cationic lipids with varied degrees of chemical moieties (Fig. 2).

1. *Lipids with glycerol backbone containing aliphatic carbon chain(s)*: DOTMA, DMRIE, DORIE, DOSPA, GAP-DLRIE, DOTAP, DMDHP and so on. These lipids are linked to glycerol moiety through ether or ester bond and have either a single cationic charge with none, single, or multiple hydroxyl groups, or have multiple cationic charges by possessing spermidine derivatives.
2. *Lipids with long-chain alkylamine/alkylamide moiety*: DDAB, DOGS, LPLL, GS2888, 14DEA2, diC14amidine,

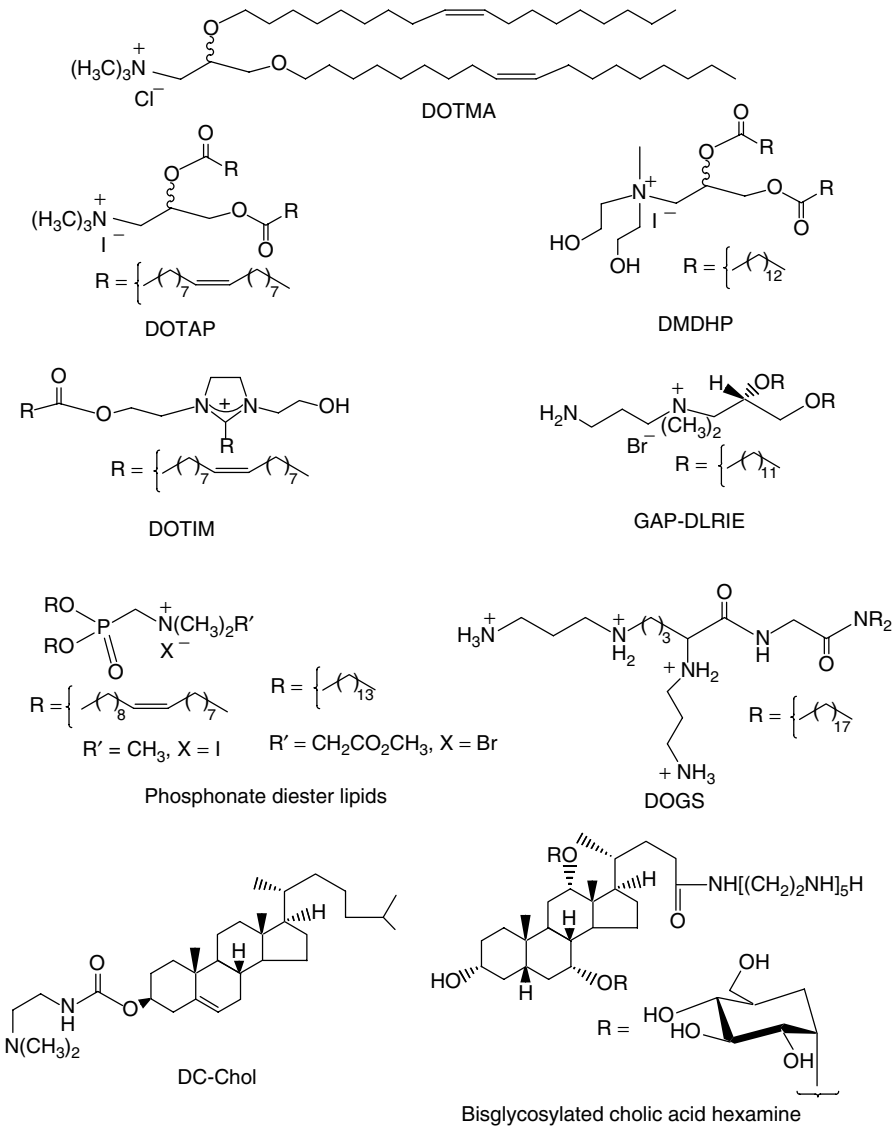

Fig. 2 Structures of some representative cationic lipids.

DHDEAB, TFX™ and so on. These are basically nonglycerol-based lipids with single or multiple charges. The charges arise because of the presence of ammonium or multiple amines or spermidines. Some of these lipids also possess multiple hydroxyl groups.

3. *Lipids with cholesterol moiety*: DC-Chol and other cholesterol derivatives, biglycosylated cholic acid derivative and cholesterol with polyamines, spermidines and so on.
4. *Lipids with L-α-phosphatidylethanolamine derivatives with spermidines*:

1,2-dipalmitoylphosphatidylethanolamidospermine (DPPES) or L-α-phosphatidylcholine with phosphonate diester.
5. *Lipids with imidazole derivative*: DOTIM or nonglycerol-based lipids with long-chain alkyl acyl carnitine ester.

There were many other lipids that were synthesized and tested for gene transfection. Only a few of these lipids had shown consistent and relatively high level of transfection in various cell lines and in animal models *in vivo*. Most of these first generation formulations were not long circulating in the blood, owing to the fact that the DNA/cationic lipid complex disintegrates in the presence of negatively charged blood proteins. Additionally, they showed no specific targeting of cells. Finally, in spite of such a big library of molecules, no consensus thumb-rule could be predicted or ascertained regarding the magic structure of lipid, which might show best transfection in all kinds of cells consistently. This is because there were so many parameters involved in the whole process of transfection. In order to develop the potentially best nonviral gene delivery system, we have to understand various barriers confronting transfection. Here, we will briefly discuss these barriers.

5.2 Cellular Barriers for Transfection

To develop an efficient gene delivery system, it seems necessary to understand the extra- and intracellular processes involved in the overall transfection mechanism. This will lead to comprehending the challenge before the task of developing efficient lipid-based nonviral vectors for gene therapy applications. For this purpose, cationic liposomes and pDNA are used widely to understand the cellular mechanism involved in the transfection (see Fig. 3).

5.2.1 Structure of Lipid/DNA Complex

Positively charged cationic liposomes electrostatically interact with negatively charged nucleic acid sequences to form fused, aggregated complexes, which are capable of entering a cell. These aggregates have a very heterogeneous size distribution with respect to particle size and net charge. The lipid-to-DNA mass and charge ratio, which defines the size and net surface charge of the complex, is an important factor to determine transfection efficiency. Hence, the structural features associated with this kind of complex need complete interpretation. Structural features revealed by electron microscopy include lipid-coated DNA strands, aggregates of liposome intercalating DNA, DNA entrapped between the lamellae of aggregated multilamellar structure, and tubular structure consisting of fused liposome around DNA. Polycations such as polylysine or multivalent cationic lipid condense DNA into small compact particles. Cells can take these compacted DNA much more efficiently than the lipid/DNA condensed particles obtained by the interaction of DNA by monovalent cationic lipids.

5.2.2 Entry of DNA into Cells

The presence of glycophospholipids and negatively charged proteins such as proteoglycans, glycosaminoglycans and so on imparts negative charges on the cell surfaces. It was hypothesized that membrane fusion between cationic liposome and negatively charged cell membrane is the primary means of cell entry. The hypothesis was based on the supposition that cationic and anionic liposomes readily

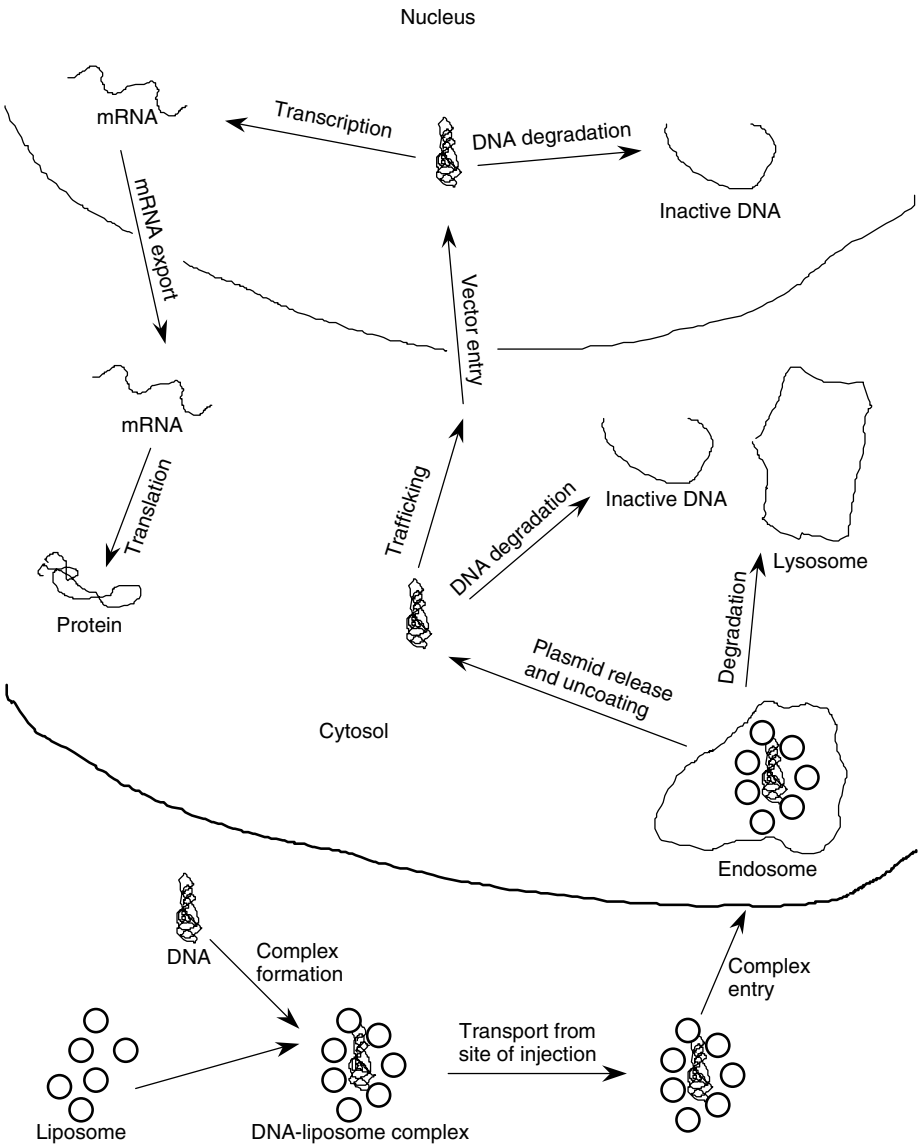

Fig. 3 Schematic illustration of the processes involved in gene delivery and expression.

fuse. It was conceptualized that the interaction of the cationic complex with the cell is primarily electrostatic, and does not involve any specific receptor for the cationic moiety. Other experiments also suggested that the mechanism of DNA transfer to animal cells from cationic liposomes might not entail a simple fusion of liposomal and cellular membrane. However, it was shown that heparin sulfates, the highly anionic polysaccharides, serve as an important cell surface receptor for cationic

lipid–DNA complexes. The nondifferentiated edged airway epithelial cells endocytose liposome–DNA complexes consequent to their relatively high negative charge and phagocytic activity compared to relatively more differentiated cells. Evidences now strongly suggest that slow endocytosis of intact lipid/DNA complex could be the primary method for cellular entry.

5.2.3 Fate of Complex Inside the Cell: Escape into Cytosol

After cellular entry, the lipoplex is engulfed into the lower pH compartment called *early endosomes* in the perimembranous region. The intracellular trafficking was ascertained by an experiment wherein a liposome composed of lipopolylysine (LPLL) and DOPE (1,2-dioleoyl-sn-glycero-3-phosphatidylethylamine) was first used to condense DNA to form electron-dense particles recognized by thin-section transmission EM and upon treatment to the cells a majority of them were found to reside in vesicular compartments. The endosomal contents usually pass into lysosome, the cell organelle in the perinuclear region that houses a host of degredative enzymes. The hydrolytic enzymes degrade most if not all of the lysosomal contents. So, it becomes necessary that the endosomal content must free itself at the early endosome stage to keep the DNA intact. Disruption of endosomal vesicle is visualized in the liposomal system containing DOPE as a helper colipid. DOPE, with its tendency to promote significant polymorphic changes in the lipid phase, stimulates membrane fusion or destabilization. This is followed by leakage of endosomal content into the cytoplasm. DOPE, in aqueous media, assumes inverted hexagonal phase II structure, which is frequently obtained in regions of membrane where it fuses with another membrane. Thus, one may assume that DOPE, or liposome formulation containing DOPE, might fuse with endosomal membrane and destabilize it to leak out the content from the endosome.

If the early endosomal release is not possible, then another way to keep DNA intact in lysosome is to protect the DNA from lysosomal degradation. Cationic liposomes formulated with cholesterol are believed to offer a useful role in keeping DNA intact. It was demonstrated that the lysosomal enzymes work at lower pH, that is, $pH < 6$. It was also shown that cholesterol-containing liposomes, which possess greater stability and lower ion-permeability compared to DOPE-containing liposomes, provide an improved stability to the lipid–DNA complex in the cytosol. It is easily conceivable that if the endosomal content passes onto lysosome before being released from endosomes, the lipoplex could remain secured in the lysosome.

Cationic lipids can destabilize a cellular membrane because of its intrinsic detergent property. Therefore, destabilization of endosomal and/or lysosomal membrane may be a contribution from the cationic lipids itself. In the same context, it was shown that the cationic lipid/DOPE or cationic lipid/cholesterol liposome formulation, exhibit surface anisotropies in terms of increased liposomal surface pH. The surface pH of the liposomal formulations exhibits at least two pH units higher than the pH of the solution at which they are made. Therefore, a liposomal solution made at physiological pH may in reality exhibit a surface $pH > 9$, which is detrimental for both the stability of endosome and activity of lysosomal enzymes. Endosomal disruptions were also done with fusogenic peptides, which promote pH-dependent fusion of small liposomes when

associated with lipid bilayer. When these peptides were codelivered with lipid/DNA complex, they imparted formidable endosomal disruption by changing its usual random coil conformation into amphipathic α-helix conformation at lower pH, resulting in consequent cytoplasmic delivery of DNA.

5.2.4 Entry of DNA in Nucleus

The success of lipid-mediated gene transfer is severely limited by the inefficient transport of transfected DNA from the cytoplasm into the nucleus. In general, macromolecules enter the nucleus through nuclear pores. Molecular aggregates with size more than 55 Å in diameter or molecular weight greater than 40 KD utilize the nuclear pore complex (NPC) to access the nucleus. NPC bind with molecular aggregates associated with nuclear localization signal (NLS) peptide and help it to translocate across the nuclear membrane. One of the typical signals is the NLS from SV40 large T antigen (PKRRRKV), which had been conjugated to many different molecules to gain nuclear access. NLS peptide-conjugated pDNA was delivered efficiently inside the nucleus with an enhanced gene expression. Similarly, SV40 T antigen NLS codelivered with DOTAP cationic liposome mediated efficient gene transfer and expression in the cell. The genes delivered inside the nucleus require uncoating from the lipidic shell before the transcription starts. It is generally assumed that pDNA is displaced from the complex by anionic macromolecules in the nucleus. In this regard, an alternative hypothesis for cytosolic release of DNA from lipid/DNA complex had been proposed. Demonstration through model studies showed that the pDNA was released from cationic liposome/DNA complexes by anionic liposomes exhibiting compositions mimicking the cytoplasmic face of the lipid monolayer of the cellular membrane. Membrane destabilization followed by flip-flop of the liposome/DNA complex by the anionic lipids by electrostatic interaction resulted in charge neutralized lipidic ion pairs followed by release of pDNA.

To evade the nuclear transport, an alternative approach was developed, which utilizes T7-based cytoplasmic expression vectors. Here, the inefficiently nuclear-transported DNA could be expressed in the cytoplasm itself.

6 Second Generation of Lipidic Delivery System (Lipopolyplex)

6.1 Polycation-condensed DNA Entrapped in Cationic Liposome: LPD-I Formulation

One of the prerequisites for a bioentity entering the cell and the nucleus is to possess a small size. The delivery of DNA was efficient through cationic lipidic formulation mediated gene delivery, but the nuclear transport from cytoplasm was quite an inefficient process. Generally, lipoplexes formed by multiple charged cationic lipids made small (~20 nm), highly condensed DNA/lipidic complex. These complexes were found to be more transfecting than the lipoplex formed by monocationic lipids and DNA. Synthetic cationic polymers like poly-L-lysine (PLL) could also condense DNA into very small compacted particles. This compact complex was allowed to freely mix with cationic liposomal solution. The overall complex so formed was termed lipid-protamine-DNA (LPD-I). A sucrose gradient ultracentrifugation of the heterogeneous mixture showed the existence of various populations associated

with varied amounts of lipid. Negative-stain EM studies of purified complexes showed electron-dense structures ranging from elongated rod-shaped to ball-shaped particles. The purified fractions were several fold more transfection efficient than unpurified ones. The fractions that contained more lipids were more efficient in gene transfection than those containing fewer lipids. The transfection efficiency of LPD-I was many folds higher than the corresponding cationic liposome–DNA complex. It is hypothesized that (1) the small compacted structure of DNA resulted in high cellular and nuclear uptake, (2) the DNA is protected efficiently against enzymatic degradation, and (3) PLL may have mimicked the NLS for nuclear delivery of DNA. An alternative cationic polymer, protamine sulfate, from salmon sperm was used as a substitution for PLL. Protamine sulfate is a small (MW ~4000 vs ~18 500 for PLL), highly positively charged peptide and very basic due to the presence of 21 arginine residues, which contains an NLS. It is naturally occurring (whereas PLL is synthetic), a USP grade compound, FDA approved and finds use as an antidote to heparin-induced anticoagulation. With a routine history of human administration, the issues of toxicity and immunogenicity were minimal for protamine sulfate.

Both protamine sulfate and PLL were compared for their transfection efficiencies. With the same amount of DNA and cationic lipid, PLL reached its efficiency plateau at an amount that was half the amount of protamine sulfate, but the overall efficiency of protamine sulfate was 2 to 7-fold higher than PLL in different cell lines. The extent of transfection efficiency for LPD-I was 7 to 45-fold higher than the levels shown by DNA/cationic lipid complex. Phosphate and free-base forms of protamine showed lower levels of transfection and the activity was comparable to lipoplex. It is noteworthy that arginine, which exists as a salt of sulfate, and the lysine, which exists as a free base or as a phosphated salt, showed a variance in the relative transfection efficiencies even though the percentage of basic (arginine + lysine) residues remained relatively constant.

Upon i.v. injection, LPD-I made with DOTAP had shown very high gene expression in heart, lung, liver, spleen, and kidney, with the highest expression found in the lung. The *in vivo* gene expression had steadily increased with increase in cationic lipid and/or protamine, but the protamine–DNA charge ratio was kept below 2 : 1 to avoid the formation of large aggregates. After LPD injection, transgene expression was detected as early as 1 h, peaked at 6 h, and declined thereafter. Lung had consistently shown the highest gene expression, which lasted for 2 days. Even after 4 days of LPD injection, gene expression could still be detected in lung, spleen, and liver.

In a biodistribution study with labeled DNA and liposome, it was revealed that DNA was rapidly removed from circulation by the liver after injection of protamine–DNA complexes, and uptake by the lung was always less than 10% of injected dose at all time points. But DNA when formulated in LPD was trapped in lung to an extent of 40% within 5 min of LPD injection. In Southern blot analysis, it was revealed that the pDNA injected with LPD was detectable in the lung in a much higher quantity than the control, even after 6 h of i.v. injection. Intraportal injection gave significantly lower gene expression than with i.v. injection.

6.2 Polycation-condensed DNA in Anionic Liposomes: LPD-II Formulation

Some disadvantages always accompany the cationic lipid-mediated gene transfection. Cytotoxic effect in cells/tissues is the primary concern that requires early attention. The cationic lipids exhibit relatively large sizes, while complexation with DNA provide suboptimal DNA condensation and have limited efficiency and lack of tissue specificity, whereas anionic liposomes used in gene therapy have shown poor encapsulation efficiencies due to the large size and excessive negative charge of uncondensed pDNA. The utilization of anionic liposome was revisited during a recent approach, which also utilized the concept of condensing DNA by cationic polymers. A delivery vector was developed wherein polylysine-condensed pDNA was entrapped into folate-targeted anionic liposomes via charge interaction. It had structural similarity as LPD-I and it was named *LPD-II*. It differed from LPD-I in that anionic lipids instead of cationic lipids were used. This novel vector was more efficient and less cytotoxic compared to conventional cationic liposomal vectors.

Folate-targeted LPD-II particles were generated by mixing anionic liposomes composed of DOPE/CHEMS/folate-PEG-DOPE and the cationic DNA–polylysine (1 : 0.75, w/w) complexes. Structural analysis of LPD-II by negative-stain EM showed that the DNA–polylysine (which appears as rod shaped individually) and lipid complex appeared as a highly electron dense, spherical core with a low-density coating. The mean diameter of these particles was 74 ± 14 nm, that is, smaller than the empty liposomes.

KB cells expressing folate receptors were transfected with LPD-II particles containing luciferase reporter gene and high transfection efficiency was observed. The activity could be inhibited by the presence of excess free folate. Control LPD-II particles generated with nontargeted liposomes was only active at low lipid/DNA ratios, suggesting that the transfection by LPD-II particles was only receptor dependent when the overall charge was negative. Compared with DC-Chol/DOPE/DNA-liposome complexes, LPD-II showed ~20 to 30-fold more transfection activity. On replacing DOPE with DOPC in the original formulation, the transfection was severely reduced. This indicated that the fusogenic activity of DOPE was essential for the transfection activity of LPD-II particles.

Their low physiological stability, inefficient cellular uptake, and the lack of tissue specificity currently limit the therapeutic applications of antisense oligonucleotides (ODN). The use of various vectors renders phosphodiester (PO) ODN resistant to enzymatic digestion. KB cells, which overexpress folate binding protein, were also transfected with LPD-II containing targeting ligand folate to deliver ODN against epidermal growth-factor receptor (EGFR). This resulted in downregulation of EGFR and growth inhibition of KB cells. The modified backbone-ODN, namely, phosphorothioate (PS) and monomethylphosphonate (MP) are more stable to enzymatic degradation compared to PO ODN, but they suffer from increased toxicity and decreased specificity. In a study, PO ODN against EGFR had shown growth inhibitory effect to KB cells compared to that of PS/PO ODN when delivered with LPD-II, indicating that LPD-II could also protect PO ODN from attack by enzymes inside cells.

7
Emulsion-mediated Gene Transfer

7.1
General Development

Emulsions are one of the most widely studied colloidal dispersion systems for the delivery of drugs. The oil-in-water emulsion is made of oil dispersed in an aqueous phase with a suitable emulsifier such as phospholipids, nonionic or ionic surfactants. Castor oil or soybean oil is predominantly used as the core oil phase. Nonionic surfactants such as Tween, Span, Brij, and pluronic copolymers are used as coemulsifiers. The ionic coemulsifiers are phospholipids or cationic lipids. A number of structure/activity studies had been done with different emulsion formulations, which were subsequently used for gene delivery *in vitro* and *in vivo*. The nonionic surfactants such as Tween, Span, Brij, and pluronic copolymers were found to be excellent coemulsifiers when used along with castor oil, DC-Chol, and DOPE. The *in vitro* transfection study on BL-6 cells showed that the Tween surfactant containing formulations had more serum resistivity and exhibited higher transfection in serum-containing media than in the absence of serum. One of the Brij containing formulations, that is, one with 2-oxyethylene chains, showed the highest transfection efficiency in the presence of serum. The toxicity of each formulation is minimal. In a DOTAP, soybean oil, and pDNA emulsion complex, it was observed that in spite of the change of zeta potential with varying amounts of DNA, the structure and the size of the emulsion complex remained mostly unchanged. The stability of this emulsion complex was shown to be high, and inhibited DNase-I digestion of pDNA. In serum-containing media, the emulsion showed much higher transfection efficiency compared to lipofectamine/DNA transfection complex. On inclusion of polyethyleneglycol-PE in the emulsion complex, a high level transfection was observed even in the media containing 90% of serum. This result suggested that *in vivo* transfection could be done with this emulsion complex. Another soybean oil-DOTAP emulsion was used to transfer genes to the epithelial cells of the mouse nasal cavity via intranasal instillation. The emulsion showed enhanced stability against heparin exchange and exhibited higher level of transfection compared to commercially available liposome/DNA complex in nasal cavity mucosa.

7.2
Reconstituted Chylomicron Remnants for Gene Transfer

Chylomicrons are triglyceride rich lipoproteins that are slowly modified during circulation in blood. The core glyceride structure is hydrolyzed by the lipoprotein lipase. It is by the apolipoprotein-specific receptors that the hepatocytes in the liver consume these remnants. It had been shown that even reconstituted chylomicron remnants (RCR) formed by purified lipids could also be taken up by the hepatocytes following i.v. injections. In our lab, we modified the system and used it for delivery of DNA into liver cells. DNA being predominantly hydrophilic in nature cannot be included in the hydrophobic interior of the RCR. TC-Chol, a quaternary ammonium analog of DC-Chol, was used in various amounts to make complexes with DNA. The resultant hydrophobic complexes upon extraction from aqueous solution were emulsified with commercially available

lipids (olive oil: L-α-phosphatidyl choline: L-α-lysophosphatidyl choline: cholesteryl oleate) by homogenization. DNA/TC-Chol complex was incorporated into the internal oil space of RCR and remained protected against Dnase-I digestion. The RCR containing DNA/TC-Chol complex, injected intraportally, gave the transgene luciferase expression in the liver 100-fold higher than with naked DNA injection. The expression was also obtained in the spleen, lung, and heart, but was 25 to 800-fold lower than that in the liver. The gene expressions obtained through tail vein injection was 100-fold lower than that of the mice injected intraportally. This was likely because the RCR did not contain any apolipoproteins on its surface, which could have otherwise facilitated the receptor-mediated uptake. Moreover, the colloidal stability might not have been as good as the ones containing apolipoproteins. RCR did not employ any protein or peptide that acts as an antigen. So, it could be injected repetitively by using a catheter method that had been established for multiple portal vein infusion. We have recently improved the formulation by adding pegylated lipid to the surface of RCR and showed that the circulation time of the particle was prolonged significantly.

8 Use of Cationic Liposome/DNA Complex (Lipoplex)

Lipoplexes are widely used for transferring genes to various *in vivo* targets with comparative ease and least toxic effect to the host. Use of lipoplexes in gene therapy clinical trials comprises almost one-fourth of the total gene therapy clinical trials. pDNA containing various therapeutic genes were used to treat a variety of disease pathologies. A vast amount of literature is available on the *in vitro*, preclinical, and clinical evaluations. Lipoplexes enjoy the property of easy administration in body without eliciting any extradiscomfort to the patient or the animal. Intravenous, intradermal, intraperitoneal, and direct injections are the common ways through which lipoplexes are injected in to the body. In the targeting front, several ligand associated cationic liposomes were developed to target genes to specific cell targets such as cancer. Recently, a cationic liposomal stealth gene delivery system was developed utilizing a sigma ligand associated polyethylene glycol–based lipid. The system could target and deliver genes specifically to sigma receptor overexpressing breast adenocarcinoma cells without showing any targeting ability to sigma receptor non-overexpressing cancer cells. Additionally, the stealth lipoplex was serum stable. The PEG lipid was chemically modified with a neuroleptic drug, haloperidol (used for over three decades to treat psychotic patients), to target cancer cells that overexpress sigma receptors. No conclusive links were ascertained between cancer pathogenicity and overexpressing sigma receptors in certain cancer cells. But, this versatile sigma receptor targeting stealth cationic liposomal system could be potentially used to target therapeutic anticancer genes to breast cancer or other cancer models that were implicated with overexpressing sigma receptors.

8.1 *In Vivo* Biodistribution Through Intravenous Injection: Therapeutic Implications

Intravenous injection is a widely used mode of gene delivery in animals. On i.v. lipoplex injection *in vivo*, the residence

of DNA primarily in heart and lungs even after nine days with minimal toxicity was observed. Intravenous injected lipoplex expressed transgene in almost all organs including lung, kidney, heart, spleen, liver, brain and so on, and the expression stayed for nine weeks with apparently no treatment related toxicity. Toxicity and antitumor response was evaluated on mice and pigs with high doses of lipoplex containing *MHC* gene incorporated pDNA.

Recently, more work has been done to increase the overall transfection efficiency with much higher targeting capability and reproducibility of the liposomal delivery system. Intravenously administered lipoplex avidly reacts with blood components. So, it is necessary to keep the complex intact in the blood till it reaches the organ of interest. It was shown that in the presence of erythrocytes, cationic lipid/cholesterol formulation did not induce fusion between erythrocytes, whereas the cationic lipid/DOPE formulation possessing high fluidity in its structure induced fusion between the erythrocytes after a short incubation period. This offered an explanation as to why cholesterol makes a superior formulation with cationic lipids for *in vivo* purpose.

A repeated systemic i.v. injection of cytokine gene (*IFNβ1*) by lipoplexes gave a systemic expression of human interferon-β in mice, thereby increasing the possibility of cytokines used for therapeutic purposes in a systemic manner. An enhanced and highly selective liver targeting by i.v. injection of cationic lipoplex containing β-sitosterol beta-D-glucoside (*Sit-G*) gene was also observed. Intravenous injections showed gene expression in all major organs including heart, lung, liver, spleen, and kidney, with lung being most efficiently transfected. For efficient targeting and gene expression in the lung, i.v. injection was favored over intratracheal instillation. Uyechi et al. had shown by injecting fluorescently tagged lipoplexes through the vein that the entire lung lobe was homogeneously fluorescent, whereas intratracheal administration resulted in regional distribution of lipoplex, concentrated around bronchioles and distal airways.

LPD-I lipopolyplex particles upon i.v. injection were also distributed to spleen along with the major organs, where they were endocytosed and released to the cytoplasm. Administrations of these particles containing unmethylated CpG motif in pDNA elicit immunostimulation that subsequently showed tumorostatic effect. The effect of CpG will be discussed in detail in the later part of this chapter. However, the spleen delivery idea was utilized to deliver antigenic peptides entrapped in LPD particles to the cytoplasm of splenic antigen presenting cells. It is known that *E6* and *E7* are two oncogenes responsible for the maintenance of the malignant state of HPV-positive tumors. Therefore, an arginine containing small peptide epitope derived from tumor antigen, HPV-E7 protein was electrostatically attached to pDNA. The preattached peptide-DNA was condensed by protamine and finally the whole entity was enclosed in LPD using cationic lipid. The particle upon i.v. injection was delivered to the splenic APCs and thereby induced E7 mediated immune response against syngeneic HPV-induced tumor in mice.

8.2 Directly Injected Lipoplexes Used Against Cancer and Other Diseases

Direct injection to tissue is a common approach for cationic lipid-mediated gene

therapy. Intratumoral injection of DNA-liposome complexes containing either E6 or E7 antisense plasmid resulted in significant growth inhibition of C3 tumors grown in a syngeneic mouse model. A direct injection of recombinant pDNA containing murine class I major histocompatibility complex (*MHC*) gene into localized arterial segment of various major organs showed that the direct gene transfer by liposomal transfection did not lead to treatment related toxicity, autoimmunity, or gonadal localization of the transgene in mice. The toxicity of gene delivery by DNA liposomes was also analyzed in pigs and rabbits *in vivo*. There were no clinically significant immunopathology in major organs such as, brain, heart, lung, liver, kidney, spleen, and skeletal muscles. To stimulate local tumor immunity in patients with stage IV melanoma, Nabel et al. injected pDNA encoding MHC class I protein complexed with cationic lipid directly into the cutaneous tumor nodules. Treated lesions exhibited the presence of T cell, followed by an enhanced reactivity of tumor infiltrating lymphocytes. As a result, local inhibition of tumor followed by complete diminution of tumor was observed in some of the treated patients. Mohr et al. had shown that direct lipolex injection to intrahepatic hepatocellular carcinoma produced by human HCC cells appeared far superior to systemic administration for gene therapy for localized intrahepatic tumors, because the direct administration to tumors left the surrounding normal hepatic cells untouched. In another typical example, *in vivo* direct intratumor injection of plasmid containing the coding sequence for the human *IL-2* gene complexed with cationic lipid formulation resulted in retention of intact pDNA in the tumor tissue and IL-2 secretion by cell cultures derived from the injected tumors. Formulation of this lipid with the cationic lipid inhibited DNA degradation and enhanced *in vivo* transfection efficiency over pDNA alone.

Airway administration of liposome complexes was used for the treatment of pulmonary diseases including cystic fibrosis (CF). Cationic liposome/DNA complex showed no adverse effect toward airway epithelial integrity; hence, the cationic lipid-based delivery system proved to be appropriate for use in human trials for CF. A series of preclinical trials were done in CF patients with intranasal instillation to evaluate the risk factors associated with the treatment. Since there was no apparent toxicity associated with lipoplexes as was seen from these trials, progress has been made in delivering the complexes to the entire lung by aerosol in CF patients. By nebulization, lipoplex was delivered into the airways of mutant mice to obtain human cystic fibrosis transmembrane conductance regulator (CFTR) cDNA expression in the respiratory tract. A study conducted on CF patients revealed that pCMV-CFTR/cationic liposome complex on administration to the nasal epithelium gave no evidence of excess nasal inflammation, or any adverse events related to active treatment. Gene transfer and expression assayed by PCR revealed the presence of transgene DNA in seven of the eight treated patients up to 28 days after treatment. Intranasal instillation technique was also used in the mouse model, to incorporate cationic lipid/DNA complexes. The CFTR dysfunctional gene gives rise to several multiple defects in airway epithelia, one of them being altered Cl−and Na+ permeability. Zhang et al. had shown that the goblet cells were more efficiently targeted with lipoplexes than any other cells in the entire spectrum of lung airway epithelia. This was ascertained by

the fact that an efficiently reduced mucous sulfation to levels seen in non-CF airways was observed with lipoplex/DNA in spite of low levels of *CFTR* gene expression in lung epithelial cells in human bronchial xenograft model of mice as compared to non-CF airways of control mice. These kinds of apparent complexities in CFTR function presented challenges in the design of different lipoplex formulations that were capable of generating the endogenous patterns of *CFTR* gene expression in specific lung epithelial cells.

8.3 Intraperitoneal Injection of Lipoplex for Treating Cancer

IP injection of lipoplex was done to transfect cells in the peritoneum region. Nude mice bearing disseminated human ovarian tumors derived from the p185-overexpressing SKOV-3 ovarian cancer cells were injected with *E1A* gene/lipoplex intraperitoneally. These tumors resemble stage III of human ovarian cancer. The expression of E1A protein decreased the expression of p185 oncoprotein, and hence increased the survival rate of mice. Seventy percent of the treated group survived for 1.5 years from the last injection, but the untreated group barely survived more than 16 weeks. The treatment of complex containing 1/13 of the original lipid dose also worked as efficiently as the normal dose. There was no apparent toxicity or major organ pathologic change. There was no trace of E1A DNA in the liver, lung, heart, spleen, brain, uterus, and ovaries of the treated mice even after $1\frac{1}{2}$ years.

9 Gene Delivery by Polymeric Systems (Polyplex)

9.1 General Development and Uses

An alternative nonviral gene delivery system has been developed, which utilizes polymers, cationic or neutral. Cationic polymers are predominantly used since they efficiently condense DNA to very small particles. These complexes are called *polyplexes*. Wu et al. for the first time utilized polylysine-asialo-orosomucoid conjugate to condense pDNA and targeted the pDNA to liver. pDNA condensed with protamine/polylysine conjugate of iron transport protein, transferrin, was efficiently delivered to eukaryotic cells. pDNA was delivered to primary peripheral blood lymphocytes utilizing CD3 T-cell receptors. pDNA condensed by CD3 antibody–polylysine conjugate showed receptor-mediated endocytosis to efficiently internalize pDNA into T lymphocytes. Depending on the cell-binding ligand, specific targeting was obtained in different cell lines.

Several of the most effective polymeric delivery systems were polyamidoamine (PAMAM) dendrimers and polyethyleneimines (PEI). Being nonbiodegradable, these synthetic polymers posed a potential toxicity to cell, and hence biodegradable polypeptides like PLL and protamine were used for condensation and delivery of gene but with limited efficacy in transfection. They were usually used with cationic lipids to obtain enhanced transfection activity. Among the biodegradable polymers, chitosan and β-cyclodextrin–based polymers were also used for gene transfection.

Although the cationic polymers shared the same mechanism of DNA condensation, the transfection efficiency greatly

varied between polymers. Even different molecular weight and isomeric forms of the same polymer showed different physicochemical characteristics, transfection efficiency, and toxicity.

Ligand conjugated polymers were used for *in vivo* targeting and expression of gene. Kircheis et al. reported an enhanced level of transfection in subcutaneous Neuro2a tumors on intratumoral injection of transferrin-PEI/pDNA compared with naked pDNA injection. On pegylation, Tf-PEI/pDNA complex became serum resistant without losing its targetability, and the complex could be efficiently targeted to neuro2a tumors in mouse tumor model after i.v. injection. Neurotensin cross-linked PLL polyplexed with pDNA upon injection into the substantia nigra of rat, showed a high level of transfection in nigrostriatal dopamine neurons that was detectable up to 15 days.

EBV-based plasmid vector containing thymidine kinase (*TK*) gene coupled with PAMAM dendrimer (EBV/polyplex) was used in suicide gene therapy of cancer. Intratumoral injection of *TK* gene containing EBV/dendrimer polyplex into Huh7 HCC tumors in severly compromised immuno-deficient (SCID) mice showed remarkable suppression of tumor growth leading to prolongation of survival time. Gene transfer to the lung was obtained by i.v. injection of G9 PAMAM dendrimer-complexed pDNA into mice. This resulted in high levels of transgene expression in the alveoli at 12 and 24 h, followed by a second peak of expression three to five days after administration. But bronchial epithelium was primarily targeted with the direct endobronchial administration of this polyplex. Topical *in vivo* delivery of pDNA to the hairless mice skin was done with PAMAM dendrimer polyplex. The polyplex was incorporated in or coated on the surface of poly (DL-lactide-co-glycolide) (PLGA) or collagen-based biodegradable membranes.

In an effort to transfer gene to rabbit carotid artery, Turunen et al. used DNA/fractured dendrimer (generation 6) polyplex to obtain a high level of gene transfer (4.4%) compared with what was obtained by lipoplex. The arterial gene transfer was particularly useful because it could be used as a tool for treating various vascular diseases. *In vivo* gene transfer method, in this study, employed a gene delivery reservoir (collar) around the carotid artery, which served as a reservoir for the gene delivery solution. This type of local gene transfer with cationic polyplex provided a technically efficient way of treating arterial diseases during vascular surgeries, such as by-pass and other surgeries. These dendrimer-based polyplexes showed a clear advantage over polylysine in that polyplexes largely buffer the drop of endosomal pH inside the endosome leading to increase in *in vitro* transfection efficiencies.

Qin et al. used starburst PAMAM dendrimers to transfer genes into a murine cardiac transplantation model. These starburst dendrimers are a special class of its kind, which are highly branched spherical polymers with large numbers of amino groups on the surface. At the time of transplantation of whole heart in the recipient mice, the dendrimer/β-gal pDNA was directly injected into the graft tissue. X-gal staining revealed a highly efficient and widespread transgene expression in both myocytes and the graft infiltrating cells with the peak lasting up to 14 days. For organ transplantation, severe tissue-rejection is a common immune response. Viral IL-10, a cytokine synthesis inhibitory factor is able to regulate a variety of negative immune responses by suppressing the

synthesis of IFN-γ, or inhibiting IL-1, IL-6, IL-8, IL-12, and TNF-α. Direct injection of this dendrimer/viral *IL-10* gene with α-MHC promoter polyplex to the cardiac tissue showed an increased survival of the cardiac allograft. As little as 0.31 μg of the injected pDNA led to an increased mean survival from 13.9 to 38.6 days.

9.2 Targeted Gene Delivery by Antibodies Conjugated with Polycations

Polyamines had shown efficient transfection to lung endothelium. An efficient targeted transfection vector to lungs could be achieved by conjugating a targeting ligand against platelet endothelial cell adhesion molecule-1 (PECAM-1) to polyamines. This ligand–polyamine complex was targeted efficiently to the pulmonary endothelial cells. A chemical vector was synthesized by covalent conjugation of polyethylenimine and anti-PECAM antibody (Ab). The cationic complex was shown to deliver DNA specifically to mouse lung endothelial cells. The highest gene expression was obtained at relatively low plus-to-minus charge ratios. The PEI, conjugated with a control IgG, did not enhance transfection of mouse lung endothelial cells. Intravenous injection of this anti-PECAM Ab-PEI /DNA showed an increased lung expression in mice compared to other modes of injection.

Immunostimulatory cytokine, TNF-α in blood was found to be about fivefold less in the mice injected with PEI-anti-PECAM Ab/DNA than in the mice injected with PEI/DNA. The decrease in TNF-α was partially reversible by pretreating mice with Ab to PECAM. Immunosuppressant dexamethasone, when injected along with anti-PECAM Ab/DNA, not only improved the persistence and level of gene expression in the lung but also shortened the refractory period for repeated dosing. This supported a potential therapeutic role of dexamethasone in lung gene transfer with Ab-polymer conjugates.

Similarly, Ferkol et al. targeted the polymeric immunoglobulin receptor (pIgR), which are expressed in lung and liver tissues and transferred pDNA to these tissues. The targeting ligand, anti-secretory component (SC) Fab antibody was covalently linked to PLL. The polycation upon condensing pDNA was delivered successfully to airway epithelium *in vivo*. Tissues that do not express the pIgR, spleen, and heart, were not transfected. In addition, conjugate prepared with irrelevant Fab fragments did not produce detectable transgene activity. This complex specifically targeted pIgR-bearing tissues, but after repeated dosing increased humoral immune response against anti-SC Fab antibody was observed.

10 Nonviral Vector Related Cytotoxicity

It is known from the 1980s that the bacterial DNA stimulates the formation of cytotoxic IFN-α, β, and IL-12 when the DNA is taken up by macrophages. It in turn leads to NK cell activation and production of proinflammatory cytokine IFN-γ. This is accompanied by the proliferation of B cell and hence reduction of apoptosis and release of IL-6 and IL-12. These proinflammatory effects were found to be due to some immunostimulatory sequences in prokaryotic DNA that contained unmethylated CpG dinucleotide motif flanked by two 5′ purines and two 3′ pyrimidines. pDNA, which is derived from bacterial DNA, induces these immune

responses. The unmethylated CpG motif–containing sequence occurs four times more frequently in prokaryote DNA than in eukaryotic DNA. Moreover, the CpG motifs are usually 75% more methylated in mammalian DNA than in prokaryotic DNA. On methylation of the cytosine bases in plasmid, the immunostimulatory effect is decreased considerably. Immature dendritic cells tend to produce proinflammatory IFN-α, β, IL-6, IL-12, and TNF-α on exposure to CpG containing oligonucleotide or bacterial plasmid.

These immune-stimulatory effects leading to inflammatory cytokine productions had negative impact on the systemic gene delivery of cationic lipid/DNA complexes. On recognition of pDNA by splenic macrophages during circulation, there was every chance that the pDNA would elicit an immune response, which might lead to phagocytosis of the complex and hence to decreased transgene expression. A high level of proinflammatory cytokine also led to inactivation of several promoters, resulting in a decrease in transgene expression. The death of animals by high dose lipoplex injection for obtaining high transgene expression could be attributed both to the high concentration of lipid and to pDNA mediated toxicity. In the case of local lipoplex administration in animals, minimal toxicity was observed. However, on i.v. injection or intratracheal instillation, high levels of IFN-γ and TNF-α were observed. Pretreating cytokine-neutralizing antibodies during i.v. injection of lipoplex, CpG triggered inflammation and immune responses were minimized and prolonged gene expression was obtained. Repeated dosing without any antibody treatment led to silenced transgene expression after one or two weeks.

It is not clear though how cytokine production decreases the transgene expression, but various ongoing efforts to minimize CpG related immune responses and toxicity, and to enhance transgene expression is worth mentioning. Hofmann et al. had used PCR-amplified fragments containing encoded therapeutic gene and regulatory elements for preparing LPD. On delivering, a similar level of gene expression comparable to pDNA lipoplex was obtained. However, a much lower level of cytokine response was observed, which sustained the gene expression for a longer period than pDNA. PCR fragment contains fewer CpG motifs than the full-length pDNA, which led to reduced CpG triggered adverse effects. Yew et al. had shown that on mutating CpG or its flanking motifs in the plasmid, a decreased level of cytokine and increased transgene expression could be obtained. A limited interaction of plasmid with immune cells could also lead to decreased cytokine response. It could be achieved by sequentially injecting cationic liposomes and free pDNA. Song et al. used this process for the purpose of efficiently transfecting the lung by prolonging the residency time and interaction of DNA with pulmonary endothelium. Tan et al. used the same concept to show that sequential injection led to the formation of a lower level of cytokines as compared to lipoplex injection. It is evident from the above efforts that understanding the detailed mechanism of CpG induced immune response is required for increasing the efficacy of pDNA mediated gene delivery.

11 Conclusion

Since the first attempt of utilizing pDNA for gene delivery to cells, the two decades have seen many attempts to enhance the

efficacy of genetic vectors, to test various therapeutically important genes, to understand the mechanism of gene delivery, associated toxicity, and factors inhibiting gene expression. A number of gene therapy clinical trials were also performed. Although no single vector is superior to other vectors, each *in vivo* gene transfer application will find its vector system for optimal performance. Understanding cellular barriers and possible means to overcome them will undoubtedly further improve the performance of a nonviral vector.

Acknowledgment

The original work from Leaf Huang's lab described in this review has been supported by NIH grants CA 74918, AR 45925, DK 44935, AI 48851. ''Fast Track Research Grant for Young Scientists'' from Department of Science & Technology, Govt. of India supported the work done in Rajkumar Banerjee's lab as described in this chapter.

Keywords

Fiber (of Viruses)
Extracellular structure protruding from each vertex of the virus capsid, which plays an important role in virus infection by binding to its primary receptor.

Promoter
A DNA sequence recognized by RNA polymerase, which initiates transcription and contributes to specific transgene expression by regulation of viral DNA transcription process.

Transcription
The process of copying DNA to RNA by RNA polymerase, in which protein expression level can be controlled for specificity.

Transcriptional Targeting
To achieve selective transgene expression by placing the therapeutic gene under the control of specific promoters that are activated in target cells but not in untarget cells.

Transductional Targeting
To achieve selective transgene expression by redirecting binding of the fiber capsid protein away from a native receptor to an alternative cell-selective receptor.

Tropism
Movement in an organism in response to some environmental stimulus, which is utilized as affinity of adenovirus vectors to the cells representing infectivity in vector targeting.

In gene therapy, current vector systems demonstrate insufficient expression and lack of specificity, resulting in poor curative effects in target cells and/or high toxicity to nontarget cells. Thus, vector optimization is critical for the derivation of efficient clinical gene therapeutics. Recently, adenoviral vectors have been targeted at the level of transduction and transcription to overcome these issues. Using genetic capsid modification techniques, adapter molecules with tissue-specific antibodies and tissue-specific promoters (TSPs), these vectors can be efficiently targeted. These strategies are applicable for many types of target cells and are compatible with a variety of targeting molecules. These combinations are aimed at improving therapeutic index of diseases such as cancers, as well as nonmalignant diseases such as pulmonary hypertension.

1 Introduction

Genetic-based therapies, such as gene therapy, represent a novel approach under investigation for the diagnosis and treatment of a wide variety of diseases. As with most conventional therapies, the balance between target cell and nontarget cell toxicity determines the therapeutic index of gene therapy. All gene therapy strategies are fundamentally based on the expression of transgenes and require efficient delivery of the therapeutic gene. However, correlative laboratory studies have demonstrated the limited ability of current generation vector systems to efficiently transduce targeted cells. In addition, limitations in vector specificity can lead to transduction of normal cells and untoward toxicity even in the setting of compartmental dosing. Thus, vector optimization is critical for the derivation of efficient clinical gene therapeutics. In this regard, adenovirus (Ad) serotype 5 (Ad5) is the predominant adenovirus vector for gene therapy, since it can transduce both dividing and nondividing cells and infect a wide variety of cell types. However, an increasing number of tumor types have been reported to be relatively refractory to Ad5 infection due to the paucity of the native Ad5 receptor, coxsackievirus-adenovirus receptor (CAR). On the other hand, its wide tropism, which is mediated by Ad5 fiber protein and CAR, allows infection of many types of cells expressing CAR in normal human tissues such as hepatocytes, precluding *in vivo* targeting and provoking immune responses that can prevent repeated administration and even shorten the duration of therapeutic gene expression.

In the last two decades, Ad5 has been well characterized in its life cycle, capsid proteins function and, more importantly, the biology of infection in cells. Thus, there is much data on which to base Ad vector targeting strategies. Briefly, three distinct sequential steps are required for Ad infection and transgene expression: (1) binding of the Ad to specific receptors on the surface of the target cell; (2) internalization of the virus; and (3) transfer of the viral genome to the nucleus in which the transgene is expressed through transcription and translation (Fig. 1). On the basis of these steps, three opportunities for targeting intervention are implied: (1) Ad delivery to targeted organs/sites; (2) Ad binding

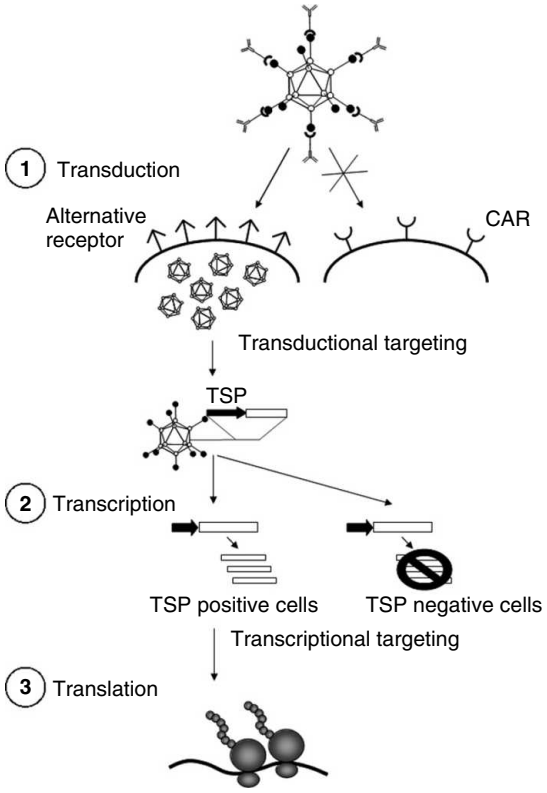

Fig. 1 Strategies for retargeting of Ad vectors.

and entry in targeted cells through primary and/or secondary Ad receptor; (3) protein expression of the transgene in the targeted cells through transcription and translation. This review outlines a series of Ad vectors that have addressed the issue of the vector targeting of gene therapy.

2 Transcriptional Targeting

To date, vectors employed for cancer gene therapy have included constitutively active promoters such as the cytomegalovirus (CMV) promoter, simian virus 40 (SV40) promoter and cytomegalovirus immediate-early enhancer, chicken β-actin promoter and the rabbit β-globin polyadenylation signal (CAG) promoter. The CMV promoter is a strongly positive regulator but lacks expression specificity. Owing to this and other reasons, mammalian cellular promoters are being explored for cancer gene therapy; the goal is specific and it is the persistent expression of therapeutic genes in tumors or target tissues.

One goal of targeting is to minimize the ectopic transgene expression in order to prevent toxicity when the therapeutic gene is cytocidal or an enzyme that activates a prodrug. Adverse effects due to gene expression in nontarget cells, most abundantly liver toxicity and toxicity to the bone marrow, have been reported in preclinical studies. Furthermore, ectopic gene expression in immune cells may be responsible for an immune response to the

transgene, thus limiting therapeutic efficacy. Target cell–specific gene expression may be accomplished through restriction of gene expression by using tissue-specific promoters (TSPs). To achieve this, efficient gene therapy regimens require transgene expression in the tumor, which has been denoted as the ''on'' status, and absence of expression in the relevant normal tissues, particularly in liver, which has been denoted as the ''off'' status.

Most TSPs reflect the natural property of the normal cells in target tissue/organs. Pathological changes in target tissues/organs, such as degeneration or malignant transformation, can alter expression of TSPs (i.e. activation of TSPs may be caused by these pathological changes). Thus, utilizing TSPs can enable a successful transcriptional targeting by maintaining higher transductional activity and specificity. To identify the best TSP for targeting cancer, one approach is to use ''organ specific'' promoters. Some of the targeted organs such as thyroid, breast, and pancreas secrete organ-specific proteins, such as thyroglobulin (TG), lactalbumin, and insulin. Promoters of these proteins are candidates of TSP and promoter activities can be predicted via monitoring these proteins. On the other hand, ectopic expression of these TSPs in normal cells in the organ must also be considered, except in particular cancers in which the function of the organ does not require preservation, such as uterus and prostate. However, TSPs often become overexpressed during transformation and may have a high therapeutic index without damaging normal cells/tissues. Another approach is to use ''cancer specific'' promoters, the genes of which are linked to malignant transformation and are expressed in a variety of cancers. In this case, promoter activity should also be analyzed in normal cells, such as stem cells and germ cells.

2.1 Gastrointestinal Cancers

Advanced gastrointestinal cancers, especially those associated with distant metastatic disease, are excellent candidates for gene therapy. A number of colon cancer targeting strategies have been reported. Carcinoembryonic antigen (CEA) promoter is the most frequently used TSP for colon cancer targeting. CEA is an oncofetal protein and is often detected at high levels in the serum of patients with colon cancers. Cytosine deaminase (CD), herpes simplex virus-thymidine kinase (HSV-tk), and diphtheria toxin are common therapeutic genes, and suicide gene therapy strategies using Ad vector constructed with *HSV-tk* or *CD* gene driven by the CEA promoter have been reported. One approach utilized the Cre/*loxP* recombination system, consisting of a Cre-producing Ad driven by the CEA promoter (Ad.CEA-Cre) and another Ad designed for inducible expression of the *HSV-TK* gene by Cre (Ad.lox-TK), to overcome the low activity of CEA promoter.

Human telomerase reverse transcriptase (hTERT) promoter, which is the catalytic subunit of the telomerase, is another promoter widely used for colon cancer and other cancers. It is expressed in most cancer cells but is quiescent in normal cells. Ad vectors with hTERT promoter driving expression of *CD* or *Bax* gene have been currently used in colon cancer models. Cyclooxygenase-2 (cox-2), an inducible isoform of the cyclooxygenase family, is closely linked to carcinogenesis and progression of colon cancers and about half of benign colon polyps. An Ad vector constructed with a cox-2 driven

HSV-tk gene demonstrated specific tumor cell killing with reduced liver toxicity using *in vitro* and *in vivo* models. Other colon cancer–specific promoters such as, the CTP1 promoter (beta-catenin-dependent promoter), the EGP-2 promoter (human epithelial glycoprotein-2 promoter), and the p21/WAF-1 promoter can also drive CD, HSV-tk or iNOS; these are useful promoters for carcinoma directed treatment modalities. For example, the EGP-2 promoter is epithelium specific, but there is highly abundant expression in the human epithelium, while the p21/WAF-1 promoter is an X-ray inducible promoter.

Gastric cancer is one of the leading causes of cancer-related death, and it remains endemic, especially in Asia, Africa, and parts of Europe. Targeted gene therapy could be one of the candidates for an innovative therapeutic approach in the treatment of advanced gastric cancer. The majority of gastric as well as colon cancers have been reported to show increased expression of cox-2 and CEA. Ad vectors with cox-2 or CEA-driven *HSV-tk* or *CD* genes showed specific cell killing for the treatment of gastric cancer. Nakaya et al. reported that suicide gene therapy with α-fetoprotein (AFP) promoter-driven HSV-tk was useful for the treatment of AFP-producing gastric cancer.

2.2 Hepatocellular Carcinoma

Hepatocellular carcinoma (HCC) is one of the most common malignancies worldwide. Since most conventional therapies have shown no survival benefit, gene therapy may provide an alternative therapeutic approach for the treatment of HCC. Many trials for targeting HCC have been reported and most of these were targeted using the AFP promoter. AFP is a glycoprotein that is similar to albumin and is produced by the fetal liver. The AFP gene is normally expressed in fetal liver and is transcriptionally silent in adult liver but is overexpressed in HCC. The level of AFP elevation in HCC has been shown to correlate with poor tumor differentiation, increased tumor burden, early recurrence following tumor resection, and unfavorable prognosis. A number of strategies using AFP promoter driving the suicide genes, CD or HSV-tk, have been reported, some of which were constructed in combination with the Cre/*loxP* system or with the phosphoglycerate kinase (PKG) promoter to overcome the low transcriptional activity of the AFP promoter. Other TSPs for HCC have not been reported yet in the context of Ad-based gene therapy. However, Onishi et al. demonstrated hTERT transcripts in surgically resected HCC by *in situ* hybridization and suggested that the hTERT promoter is a good candidate as a target for HCC.

2.3 Pancreas/Pancreatic Carcinoma

The pancreas is both an exocrine and an endocrine organ. Amylase and insulin are representative proteins that are secreted from this organ. Therefore, targeting pancreatic carcinoma using these promoters is a rational strategy. The homeodomain transcription factor activating the insulin promoter, the pancreatic duodenal homeobox-1 (PDX-1), is an essential regulator of pancreatic endocrine cell development and adult islet β-cell function. Recently, expression of PDX-1 was found in several human pancreatic cancer cell lines. Wang et al. showed that the rat insulin promoter (RIP), used to drive the

HSV-tk and *CD* genes, resulted in cytotoxicity of PDX-1–positive insulinoma cells. The murine pancreatic amylase promoter was also tested for LacZ reporter gene expression in the pancreas for the treatment of metabolic disease therapy. In approximately one-third of pancreatic cancers, the proto-oncogene, *erbB2*, is overexpressed due to transcriptional upregulation of the *erbB2* gene with or without amplification. Harris et al. constructed an Ad vector with the *CD* gene driven by the erbB2 promoter, which demonstrated pancreatic cell–specific killing. Several other cancer-specific promoters such as the midkine, cox-2, and hTERT promoters, driving either reporter or suicide genes have shown specific transduction and therapeutic effect in pancreatic carcinoma.

2.4 Lung Cancers/Mesothelioma

Lung cancer has the highest mortality rate of all malignancies in developed countries; thus, novel therapeutic approaches such as gene therapy is required in this field. Small-cell lung cancer (SCLC), which comprises about 25% of lung cancers, characteristically secretes a variety of neuropeptides, such as adrenocorticotrophin hormone (ACTH), gastrin-releasing peptide (GRP), gastrin, neuron-specific enolase (NSE), cholecystokinin, and arginine vasopressin promoter (AVP). Many of these peptides can act as autocrine growth factors to the tumor. Yoshizawa et al. constructed vectors with HSV-tk driven by the NSE or GRP promoter and demonstrated a therapeutic effect in SCLC in an *in vitro* or *in vivo* model. Coulson et al. showed specific reporter gene transduction in SCLC cells using an AVP driven vector, indicating that AVP is also a candidate TSP for SCLC targeting.

Carcinogenesis related promoters, which are also candidate TSPs for other cancers, demonstrate lung cancer–specific transduction. For example, vascular endothelial growth factor (VEGF), which is one of the most effective mitogens specific for endothelial cells (EC), has been implicated in the neovascularization of a variety of tumors including lung cancers, especially in hypoxic conditions such as that found inside solid tumors. The mouse lung cancer cell line, A11, which was transfected with a vector harboring the VEGF promoter fused to the *HSV-tk* gene were demonstrated to give specific sensitivity to ganciclovir (GCV). This effect was enhanced by exposure to hypoxia followed by reoxygenation. The cytotoxic effect of the proapoptotic gene, *Bax*, was evaluated using an Ad vector expressing the human *Bax* gene under the control of the human VEGF promoter, suggesting a possible therapeutic application using this cancer-specific proapoptotic gene. Hexokinase type II (HKII), one of the hexokinases (HKs; ATP: D-hexose-6-phosphotransferase) that catalyzes the first committed step of glycolysis, is found in insulin-responsive tissues such as skeletal muscle, adipose tissue, and heart. In addition, tumors at various stages of malignancies show an increase in HK II activity compared with normal tissues. Katabi et al. reported that HKII promoter is another candidate TSP for non–small cell lung cancer by showing specific reporter gene expression and therapeutic effect of suicide gene therapy in an *in vivo* model.

Other TSPs, such as EGP-2/Ep-CAM and hTERT, which were previously utilized in gastrointestinal cancers and HCCs, were also successful for targeting lung cancer. Ad vectors with HSV-tk, CD and Bax, driven by these promoters demonstrated

specific gene transfer and therapeutic effects using both *in vitro* and *in vivo* models. Fukazawa et al. reported that a dual promoter system using the human surfactant protein A1 (hSPA1) promoter and the hTERT promoter were useful for targeting lung cancer as demonstrated by reporter gene analysis.

2.5 Breast Cancer

Breast cancer remains one of the most common malignancies in women today and many gene therapy strategies are studied in this field. In some women, breast cancer is a local disease without distant spread. However, most women with primary breast cancer have subclinical metastases. Therefore, systemic administration of targeted Ad vector is a reasonable approach in the treatment of breast cancer patients with metastasis.

Human α-lactalbumin (ALA) is an enzyme involved in lactose production and the breast cancer antigen ALA, which is normally expressed in the fully differentiated lactating mammary gland at the onset of parturition. ALA was shown to be expressed in more than 60% of breast cancer tissues in the clinical cases tested. The ovine β-lactoglobulin (BLG) protein is the most abundant whey protein in the milk of ruminants and it is regulated in a hormone-dependent manner similar to ALA, although it is not normally expressed in mice or humans. Leonard et al. constructed a series of Ad vectors that express *CD* gene under the transcriptional control of either the ALA or the BLG promoter, and demonstrated a therapeutic effect in a breast cancer xenograft model. CEA, previously mentioned as a TSP for GI cancers, is also a tumor marker of breast cancers, and increased CEA level in the serum has been observed in approximately 10% of the total breast cancer patients and 40 to 70% of recurrent ones. Qiao et al. reported that an Ad vector with *HSV-tk* gene driven by the CEA promoter demonstrated CEA-specific breast cancer cell killing using both *in vitro* and *in vivo* models.

Highly malignant cancers, such as breast cancer, are usually thermoresistant because they produce heat shock protein 70 (hsp70). Braiden et al. examined the effects of hsp promoter-mediated suicide gene therapy using the HSV-tk/GCV system for breast cancer in combination with hyperthermia. This report demonstrated that combination strategies were synergistically effective in mediating Fas-dependent apoptosis for breast cancer–specific gene therapy. Another stress-inducible chaperone protein with antiapoptotic properties is GRP78. GRP78 is overexpressed in transformed cells and during glucose starvation, acidosis, and hypoxic conditions, characteristic of poorly vascularized tumors. Dong et al. demonstrated that the GRP78 promoter is able to eradicate tumors using murine cells in immunocompetent models by driving expression of the *HSV-tk* suicide gene. Further, this system offers the advantage of positron-emission tomography (PET) imaging in combination with the suicide gene therapy in a breast cancer model.

Breast cancers usually arise from epithelial cells, and epithelial-based cancers have a variety of target specific TSPs. L-plastin (*LP*), which gene codes for an actin-binding protein, has been shown to be expressed at high levels in human epithelial cancer cells, but not in normal cells. Thus, LP is also a candidate TSP for targeting breast cancer. An Ad vector with an LP-driven *CD* or *E1* gene demonstrated a therapeutic effect in breast

cancer xenograft model. Additionally, the chemokine receptor, CXCR4, was recently reported to be markedly upregulated in breast cancer cells, but undetectable in normal mammary epithelial cells. An Ad vector with a CXCR4 promoter-driven reporter gene showed breast cancer–specific transduction, indicating that it is also a candidate TSP for targeting breast cancer. In breast cancer, overexpression of *erb*B-2 has been observed in approximately 20% and has been associated with reduced relapse-free patients and overall poor patient survival. Pandha et al. have shown that the tumor-specific *erb*B-2 promoter driving the *CD* gene resulted in levels of CD expression in a phase I clinical trial of breast cancer patients. Finally, two promoters of note are the hTERT and hexokinase promoters. The analysis of reporter gene expression driven by hTERT promoter or hexokinase promoter has demonstrated breast cancer–specific transduction, indicating that they are candidate TSPs for targeting breast cancer.

2.6 Urological Cancers

Gene therapy studies in urological diseases have been performed in prostate, bladder, and renal cell cancers. A variety of clinical gene therapy trials for prostate cancer have been reported, because of the large numbers of patients that are available and regional localization allowing a variety of direct intratumoral approaches. Prostate-specific antigen (PSA), a 34-kDa chymotrypsin-like serine protease and its promoter are known to be highly specific to prostate tissue and multiple PSA-targeted gene therapy strategies have been utilized for prostate cancer using reporter genes and suicide genes. However, due to low activity, some PSA promoter approaches have used a Cre/*loxP* system to enhance promoter activity. Prostate-specific membrane antigen (PSMA) is a type-2 membrane protein expressed in the prostate, and it is highly expressed in metastatic or poorly differentiated adenocarcinomas. Ad vectors with *HSV-tk* or *CD* gene driven by PSMA promoter, demonstrated a therapeutic effect using *in vitro* and *in vivo* models. These results illustrate that PSMA is also a candidate TSP for targeting prostate cancer.

Dihydrotestosterone (DHT)-inducible third-generation probasin-derived promoter, ARR(2)PB, which has been modified to contain two androgen response elements, has also been one of the prostate cancer–specific promoters used. Therapeutic viruses constructed with the Bax or Bad apoptotic protein gene driven by ARR(2)PB induced specific overexpression of these gene and apoptosis in prostate cancer cells. The T-cell receptor γ-chain alternate reading frame protein (TARP), is a protein that is uniquely expressed in prostate epithelial cells and prostate cancer cells. Cheng et al. showed that the transcriptional activity of an Ad vector with a chimeric sequence comprising of the TARP promoter and the PSA enhancer is highly active in testosterone-deprived prostate cancer cells. Caveolin-1 (a structural component of caveolae), human glandular kallikrein 2 (hK2) and osteocalcin (a major noncollagenous bone matrix protein) are upregulated in higher-grade stage, androgen resistant or metastatic prostate cancer. Ad vectors with these promoters have been demonstrated to possess prostate cancer cell–specific transduction or killing with reporter gene expression or suicide gene therapy.

Compared to prostate cancer, very few gene therapy strategies have been studied in bladder cancer or renal cell carcinoma

(RCC). In bladder cancer gene therapy, Ad vectors with either an *LacZ* or a *CD* gene driven by the L-plastin promoter demonstrated specific reporter gene expression and therapeutic effect, respectively. An Ad vector with the luciferase reporter gene driven by CXCR4 (one of the chemokine receptors), showed specific transduction of RCC cells with liver off status *in vivo*, indicating that the CXCR4 promoter is a novel candidate for transcriptional targeting of RCC.

2.7 Gynecological Cancers

In the gynecological field, ovarian and cervical cancers are good candidates for gene therapy. A number of targeting strategies for ovarian cancer have been reported, with targeting using hTERT promoter being utilized most frequently. Ad vectors in combination with luciferase, *HSV-tk* and *Bax* gene demonstrated ovarian cancer–specific transduction and cell killing. KDR/flk-1 and flt-1 are receptors of VEGF and are known to display dysregulated expression in both tumor vasculature and their progressions. These promoters were used for Ad construction with reporter and *CD* genes, showing usefulness for targeting certain ovarian cancers, such as nonendothelial originated ovarian cancer and teratocarcinomas.

The whey-acidic protein human epididymis protein 4 (HE4) is frequently overexpressed in ovarian cancer, suggesting that the HE4 promoter is highly transcriptionally active in this disease. Luciferase expression Ad vector driven by the HE4 promoter exhibited significant expression in ovarian cancer cells, but not in normal cells. Secretory leukoprotease inhibitor (SLPI) is a 12-kDa serine protease inhibitor expressed in some human carcinomas, including breast, lung, endometrium, and ovary. Selective Ad-mediated transgene expression could be achieved through the use of the SLPI promoter in the context of ovarian cancer. Mesothelin (MSLN), a cell surface glycoprotein, is overexpressed in ovarian cancer, but not in normal tissues with the exception of mesothelial cells. MSLN-driven luciferase expression Ad vector achieved transcriptional targeting in the context of ovarian cancer cells. Cox-2, midkine, hK2 and LP promoters have also been used for targeting ovarian cancer cells in the context of Ad vectors with reporter genes and suicide genes, demonstrating their utility as candidate TSPs for ovarian cancer.

For targeting cervical cancer cells, several TSPs, such as SLPI, cox-2, midkine, flt-1, VEGF, Survivin, and CXCR4 promoters have recently been screened using luciferase reporters in Ad vectors, with results demonstrating that VEGF and midkine are the most promising TSPs. Ad vectors with hTERT promoter-driven Bax and monocyte chemoattractant protein-1 (*MCP-1*) gene have also demonstrated tumor-specific cell killing in cervical cancer cells.

2.8 Brain Tumors

Brain tumors are some of the most fatal malignancies, and do not respond to conventional therapies, such as chemotherapy and radiotherapy. A number of gene therapy strategies, such as suicide gene therapy, have been performed with respect to these types of cancers. However, few systemic transcriptional targeting strategies have been studied in this field, because brain tumors exist in a compartment protected by a blood-brain barrier. This fact

also means that little amounts of virus flowing out from the compartment would occur in the context of local administration of therapeutic Ad vectors. Glial fibrillary acidic protein, GFA2, is an intermediate filament protein expressed primarily in astrocytes. Vandier et al. constructed a recombinant Ad vector, Adgfa2TK, in which the HSV-tk was gene driven by GFA2 promoter, demonstrating inhibition of glioma cells growing *in vitro* and *in vivo*. Ad vectors with the hTERT promoter driving the caspase-8 or the Fas associated protein with death domain (*FADD*) genes showed specific cell killing, which indicated that hTERT is also a candidate TSP for targeting gliomas. Human glandular kallikrein 2 has also been reported to be useful for gliomas as well as cervical cancer mentioned earlier.

Pituitary tumors producing prolactin (PRL) were successfully treated using Ad vectors containing the *HSV-tk* gene driven by the PRL promoter both *in vitro* and *in vivo*. Proopiomelanocortin (*POMC*) gene encodes ACTH, which causes Cusing's syndrome, when overexpressed. The POMC promoter provided useful treatment of ACTH-producing pituitary tumors via Ad transduction.

2.9 Thyroid Tumors

The thyroid gland is a relatively common site of malignant neoplasms, giving rise to 90% of all endocrine cancers, and targeted therapy is especially important for this disease in regard to preserving normal thyroid function. Thyroid carcinomas are pathologically classified into papillary, follicular, anaplastic, and medullary cancers. The two most frequent entities, papillary and follicular thyroid cancers, are usually referred to as *differentiated thyroid carcinoma* and are always positive for TG immunohistochemical staining. The Ad vectors with *HSV-tk* gene driven by the TG promoter–mediated thyroid cancer–specific cell-killing ability, with less toxicity to normal cells. On the other hand, some poorly differentiated, metastatic or most anaplastic thyroid carcinomas show diminished TG expression, accompanied by loss of some thyroid-specific transcription factors. The promoter from the calcitonin/calcitonin gene-related peptide (*CT/CGRP*) gene was tested for targeting medullary thyroid carcinoma, and showed higher, specific transduction by reporter gene analysis. Undifferentiated thyroid carcinoma was successfully targeted using an hTERT promoter-driven luciferase Ad vector, and an hTERT-targeted HSV-tk Ad vectors demonstrated specific cell killing.

2.10 Malignant Melanoma

Melanoma is a relatively rare disease, but its biological characteristics are well investigated because of its accessibility. Melanoma inhibitory activity (MIA) protein, which is highly expressed in melanoma, plays an important role in melanoma metastasis and invasion, and MIA has been identified as a highly specific and sensitive marker for malignant melanoma. Tyrosinase, the enzyme catalyzing the rate-limiting step in melanin production, is exclusively expressed in melanocytes, pigment cells of the retina and melanoma cells. Rothfels et al. reported that MIA and tyrosinase promoters mediated suicide gene therapy of malignant melanoma, resulting in melanoma-specific cell killing. Survivin, a novel member of the inhibitor of apoptosis

(IAP) protein family, is expressed in human cancers, but is quiescent in normal differentiated tissues. A survivin-driven luciferase expression Ad vector showed high activity in melanoma cells with liver off status. Cox-2 is also reported to be expressed in melanoma cells and an Ad vector containing cox-2 promoter driving the luciferase gene, demonstrating activity of the cox-2 promoter in melanoma cell lines as well as in primary melanoma cells but not in normal cells.

2.11 Other Cancers

Several transcriptional targeting strategies have been reported in squamous cell cancer and pediatric tumors. Two inducible promoters, early growth response (Egr-1), which is radiation sensitive, and Hsp70 were demonstrated to induce squamous cell cancer–specific transduction. In pediatric tumors, tyrosine hydroxylase promoter and midkine promoter were tested using neuroblastoma and Wilms' tumor cells, demonstrating their usefulness for targeting these cancers. Osteocalcin (OS) is a major noncollagenous protein of bone regulated by 1,25dihydroxyvitamin DJ [1,25-(OH)pDa] and it is believed to be expressed only by differentiated osteoblasts. The OS promoter for osteosarcoma and the hTERT promoter for fibrosarcoma were reported as useful TSPs for specific cell killing or therapeutic effects.

2.12 Normal Tissue/Organs

Fewer numbers of gene therapy strategies have been studied for nonmalignant diseases for the following reasons. First, nonmalignant targeted cells, such as endothelial cells, muscle cells, neurons and hematopoietic cells, are relatively resistant to Ad infection. Further reduction of transgene expression through transcriptional targeting would result in insufficient therapeutic effects, since most transcriptional targeting involves the loss of transgene activity in exchange for specificity. Second, most therapeutic genes for nonmalignant diseases are nontoxic ones, such as enzymes, hormones, and other important factors of cell function, which do not cause nontargeting cell death that would have resulted in severe side effects. Some gene therapy strategies for nonmalignant diseases, which would be inappropriate for targeting by constitutively active promoters, utilize targeting by TSPs (see Table 1).

2.13 Transcriptional Targeting of Replication-competent Ad

Conditionally replicative adenovirus (CRAd) agents have recently been applied for a variety of neoplastic diseases as a novel cancer gene therapy (see Fig. 2). In this approach, the virus replicates conditionally in transduced tumor cells, which lead to infection of neighboring cancer cells with progeny virus, resulting in virus-mediated oncolysis. Therefore, it is important to target CRAd agents more strictly than replication-incompetent Ad since even marginal levels of expression of TSP in untargeted normal cells could result in severe toxicity. Some TSPs that have been proved to be useful for targeting in the context of replication deficient Ad vectors have been studied in replication-competent CRAds agents (Table 2).

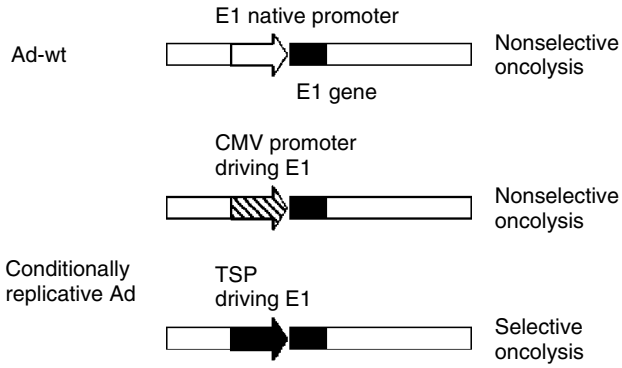

Fig. 2 Schematic representation of types of CRAd agents.

2.14 Summary

A number of promoters have already been and will be reported as TSPs for transcriptional targeting, allowing us to choose a variety of targeting strategies that would be the best for the patients or diseases. In addition, transcriptional targeting is more advantageous compared to transductional targeting in respect to a ''liver off'' phenotype. However, the use of many TSPs results in reduced transgene expression in exchange for excellent specificity, which often causes insufficient therapeutic effect. Transductional augmentation, such

as high dosage of the vector in combination with transductional targeting may result in a good therapeutic index.

3 Transductional Targeting

The extensively characterized capsid structure, genome, and replication cycle of Ad, particularly of the most commonly employed serotype 5, have allowed the molecular modifications required for their utilization of Ads as gene transfer vectors. Adenoviral infection is initiated by the recognition of the primary cellular receptor the CAR on target cells by the C-terminal portion of the fiber protein, termed the *knob*. After binding of the fiber knob domain, entry of the virus into the cell occurs via interaction of the Arg-Gly-Asp (RGD) sequence located in the viral penton base protein with cellular integrins (see Fig. 3). The development of genetically modified adenovirus (Ad) vectors with specificity for a single-cell type will require both the introduction of novel tropism determinants and the ablation of endogenous tropism. Consequently, it will not be possible to exploit the native cellular entry pathway in the propagation of these targeted Ad vectors. On this basis, Ad vector can be targeted at the level of transduction through CAR-independent infection pathways by both ablation of its wide native tropism and introduction of novel infectivity preference for target cells, a concept that is otherwise known as *retargeting*.

As most transductional targeting strategies have shown, the advantage of transductional targeting is that the retargeted Ad vector would function not only with respect to enhanced specificity but also with respect to enhanced activity of transgene expression due to improved infectivity via the receptor of interest that would typically be sacrificed in exchange for specificity in most cases of transcriptional targeting. Retargeting of Ad vectors was originally initiated with two different approaches, genetic Ad capsid modification and adaptor targeting molecules, both of which are designed to attain CAR-independent transduction pathway while forgoing the native CAR pathway. Recently, the combination

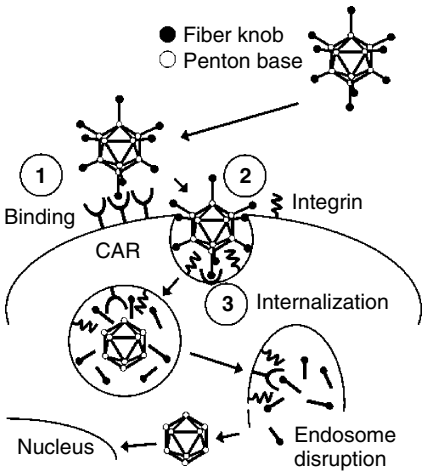

Fig. 3 The pathway of Ad entry.

of these two distinct methods was successfully achieved in an Ad vector by using the phage T4 fibritin motif.

3.1 Genetic Capsid Modification

3.1.1 Chimeric Ad Vector with Different Serotype or Species Fiber

The adenovirus fiber protein is responsible for attachment of the virion to cell surface receptors. The identity of the cellular receptor with which subgroup C adenoviruses, including Ad5 and Ad2, interact is CAR. Other subgroups including A–F except B also share this common CAR receptor for primary attachment. There is also evidence that suggests that Ad5 can also associate with other receptors including MHC class I proteins, heparin sulfate. Subgroup B adenoviruses, such as Ad3, Ad7, Ad11, Ad16, and Ad35 do not utilize CAR for cell entry. Several putative receptors for these viruses have been identified including CD46 for Ad35 and CD80/86 for Ad3. Stevenson et al. carried out a series of competition binding experiments using recombinant native fiber polypeptides from Ad5 and Ad3 and chimeric fiber proteins in which the head domains of Ad5 and Ad3 were exchanged. The results demonstrated that the determinants of Ad receptor binding are located in the knob (head) domain of the fiber, suggesting the possibility of altering the receptor specificity of the fiber protein by manipulation of sequences contained in the head domain. This very concept was initially tested by Krasnykh et al. and Stevenson et al., whereby an Ad vector containing chimeric fibers composed of the Ad3 fiber knob domain fused to the Ad5 fiber tail and shaft (Ad5/3). Ad5/3, which targets the Ad3 receptor, displayed high efficiency in circumventing CAR deficiency and enhancing gene delivery into neuroblastoma, B-lymphocytes, ovarian cancer, RCC, squamous cell carcinoma of the head and neck and melanoma cells.

Shayakhmetov et al. screened different Ad serotypes, namely, Ad3, Ad4, Ad5, Ad9, Ad35, and Ad41, for interaction with noncycling human CD34(+) cells and K562 cells at the level of virus attachment, internalization, and replication. Ad serotype 35 emerged as the variant with the highest tropism for CD34(+) cells, resulting in the completion of the chimeric Ad vector Ad5/F35, the fiber of which consists of the tail and shaft domains of Ad5 and the knob domain of Ad35. Ad5/F35 demonstrated enhanced transduction in many nonmalignant cells, such as hematopoietic cells, bone marrow cells, endothelial cells, fibroblasts, DCs, and retinal cells as well as glioma, leukemia, osteosarcoma, melanoma, colon cancer, and cervical cancer cells.

Various other chimeric Ad vectors have been reported, including Ad2 with Ad17 fiber (Ad2(17f)), Ad5 with Ad16 fiber (Ad5.Fib16) and Ad5 with Ad11 fiber (Ad5/11), demonstrating efficient transduction in airway epithelia, cardiovascular tissue, and hematopoietic cells, respectively. Interestingly, Schoggins et al. demonstrated that a chimeric Ad5 vector with the Ad41 fiber decreases transduction to hepatocytes and is useful for liver nontargeting. The Toronto strain of canine adenovirus type 2 (CAV2) exhibits native tropism and it has been evaluated as a gene therapy vector. An Ad5 vector containing the nonhuman CAV2 knob can efficiently bind to and enter CAR-deficient cells, with up to 30-fold augmentation in gene delivery in comparison to the Ad5 control vector.

3.1.2 Ad Vector with Modified Fiber Proteins

Retargeting approaches based on genetic alternation of the virion capsid via fiber knob modification with small peptides have achieved cell-specific gene delivery. Certain targeting motifs may be incorporated in this manner to route the virus toward nonnative cellular entry pathways. Wickham et al. constructed two Ad vectors that contained insertions in the Ad fiber coat protein to redirect virus binding to either α(v) integrin or heparan sulfate cellular receptors by inserting Arg-Gly-Asp (RGD) or polylysin (pK7) at the C terminus of the fiber knob region respectively. These vectors demonstrated increased transduction 5- to 500-fold in numerous cell types lacking sufficient levels of the primary Ad receptor including macrophage, endothelial, smooth muscle, fibroblast, and T cells. Krasnykh and Dmitriev et al. have shown that peptides incorporated into the HI loop of the fiber knob remains available for binding in the context of mature virions containing modified fibers, suggesting that heterologous ligands, such as RGD, could be incorporated into the HI loop of the fiber knob and that this locale possesses properties consistent with its employment in adenovirus retargeting strategies. These integrin- and/or heparan sulfate-targeting Ad vector demonstrated enhanced transgene expression in dendritic, leukemic, myeloma, head and neck cancer, ovarian cancer, and renal cell cancer cells.

Douglas et al. demonstrated retargeting of an Ad vector via nonadenoviral, artificial receptor with six histidine (6His) incorporated Ad in the knob and anti-6His single-chain antibody (scFv) expressing cells. Nicklin et al. generated genetically modified Ad fiber proteins with selective tropism to EC by engineering human endothelial cell-binding peptides SIGYPLP into the HI loop of the Ad fiber, demonstrating efficient and selective tropism for EC compared with control Ad vectors.

In summary, genetic capsid modification allows progeny virions to maintain the same physical and genome structure as their parent viruses. This property is essential when applying targeting methods to replication. Genetic capsid modification has proven to be a useful method for enhancing the infectivity of CRAds as described below. Despite the gains that have been achieved with transductional targeting via genetic methods, challenges still remain. In designing serotype or xenotype chimeras, it is difficult to predict the targeting effect in advance since cellular receptors and therefore the viral tropism of Ads other than those conventionally applied as vectors are unknown. Genetic fiber modification is complicated by the limited size restriction of peptides that can be incorporated due to the structural incompatibility between the fiber and the targeting ligand. Moreover, RGD and pK7, which are recognized by integrins and heparan sulfate that are broadly expressed in many types of cells, may contribute to enhance transductional activity but not its specificity. Combination with the other control mechanisms, such as transcriptional targeting, may be recommended to achieve more selective results.

3.2 Adaptor Molecules

Several retargeting strategies to abrogate native tropism and redirect Ad uptake through defined receptors have been attempted using bifunctional adaptor molecules. In this strategy, one element of the bispecific adaptor binds to the

Ad knob, blocking its interaction with CAR and hence its native tropism. Such attachment may be accomplished with anti-adenovirus knob Fab, single-chain Fv fragments (scFv), and the extracellular domain of CAR. The second component of the bispecific adaptor is chemically or genetically conjugated to the knob-binding portion, introducing specificity for the target cells. Some of these molecules have been antibodies (Fab, scFv) or ligands that bind to specific receptors expressed on target cells.

Particularly, these candidate molecules have included fibroblast growth factor (FGF) for Kaposi'e sarcoma, melanoma, and ovarian cancer cells; epidermal growth factor (EGF) for glioma, head and neck, skin, ovarian, and lung cancer cells; CD40 ligand for DC and ovarian cancer cells; epithelial cell adhesion molecule (Ep-CAM) for head and neck, ovarian, hepatocellular, and prostate cancer cells; angiotensin converting enzyme (ACE) for pulmonary ECs; CEA for breast cancer cells; PSMA for prostate cancer cells; MSLN for ovarian cancer cells; and high molecular weight melanoma-associated antigen (HMWMAA) for melanoma cells and the pancarcinoma antigen tumor-associated glycoprotein 72 (TAG-72), for ovarian cancer. (Table 3)

Transductional targeting with adaptor molecules was originally developed using a chemical conjugate comprising the Fab fragment of a monoclonal antibody directed against the Ad5 fiber and a full monoclonal antibody against the target molecules. However, chemical conjugates consisting of two individual portions may be difficult to manufacture as they have homogeneity property, which is undesirable in a product intended for clinical use. Recombinant fusion proteins offer a number of technological advantages including simplified production and purification when compared with chemical conjugates. Therefore, using bispecific adaptor-based Ad targeting with a recombinant fusion protein consisting of an extracellular portion of the Ad receptor CAR linked to an scFv or ligand to the targeting molecule may be a more rational approach (Table 3).

The use of bifunctional adaptors allows a myriad of molecules to be considered as candidates for rational vector targeting design. This method may be accomplished without concerns regarding size restrictions or perturbation of virus function that are commonly encountered in genetic modification techniques. With specific, defined targets incorporated into the design, cell receptor levels may be examined beforehand with flow cytometry or PCR analyses. Also, a great advantage is the fact that bispecific conjugates may be applied to the multitude of available Ad5-based vectors that have already been constructed for specific disease contexts. These vectors contain the unmodified Ad5 knob with which the conjugates can interact. On the other hand, retargeting in this case is successful only during the initial transduction, but not in replication-dependent situations involving subsequent infection by progeny virions, unless the adaptor molecules are continuously and appropriately provided *in situ*. Therefore, it is unclear how feasible this method would be in the context of replication-competent Ad vectors.

3.3 Genetic Capsid Modification Combined with Adaptor Molecules

A potential barrier to the development of Ad targeting with the aforementioned adaptor molecules for cell-specific delivery lies in the fact that several types of targeting

Tab. 3 Transductional targeting with adaptor molecules.

Targeting molecule	*Target cell recognition site*	*Ad recognition site*	*Type of molecule*	*Target cell*	*Investigator*

protein ligands require posttranslational modifications, such as the formation of disulfide bonds. This fact poses a problem especially for Ad capsid proteins that do not undergo such posttranslational modifications and are mostly localized in the nucleus during assembly of the virions. In addition, recombinant or chemically engineered adaptor molecules have to be specifically tailored for each particular targeting situation. To overcome these problems, a new general targeting strategy, which combines genetic modifications of the Ad capsid with a protein bridge approach, was recently developed, allowing the direct formation of vector–ligand complexes with monoclonal antibodies against cell surface antigens for targeting of Ad vectors. This capsid modification method entails the genetic incorporation of the Fc-binding domain derived from staphylococcal protein A into the Ad fiber protein. Significant augmentation of transduction efficiency using EGFR or CD40 specific monoclonal antibodies was achieved by applying this scheme.

Another approach of capsid modification with a protein bridge is avidin-based targeting with metabolically biotinylated Ad vector. In this strategy, a biotin acceptor peptide (BAP) was genetically fused to the Ad capsid fiber protein, which, during propagation would be biotinylated by the endogenous biotin ligase in 293 cells to produce covalently biotinylated virions. The resulting biotinylated vector could be retargeted to new receptors by conjugation to biotinylated antibodies via tetrameric avidin, resulting in increased transduction 10- to 30-fold over untargeted Ad-Fiber-BAP-TR in the case of biotinylated anti-CD59 or anti-CD71 antibodies in HeLa cells. In addition to the many advantages of targeting with adaptor molecules, the combination of genetic capsid modification and adaptor proteins is useful especially for the screening of targeting molecules and would enable dual targeting with plural antibodies.

3.4 Genetic Capsid Modification with Incorporation of Larger-sized Targeting Molecules

Transductional targeting using adaptor molecules requires a more complicated procedure, especially for clinical usage. However, as noted above, attempts to alter Ad tropism by genetic modification of the Ad fiber have had limited success due to structural conflicts between the fiber and the targeting ligand. Additionally, adaptor molecule systems may only work effectively in situations not requiring virus replication. Therefore, novel approaches compatible with adenovirus replication are required to apply targeting to oncolytic Ad vectors. Krasnykh and Belousova et al. reported the use of the phage T4 fibritin trimerization motif to facilitate the genetic incorporation of larger targeting ligands into the Ad fiber. They validated this strategy with the human CD40 ligand (CD40L), demonstrating the incorporation of a large sized targeting molecule in the modified Ad5 fiber that had not been accomplished previously. This complex chimera was fully functional, conferring specific transgene expression in CD40 expressing cells.

4 Transductional and Transcriptional Dual Targeting

As stated above, various transductional and transcriptional approaches have been

devised to improve targeting of Ad vectors. Transductional targeting alters the natural infection pathway of the Ad vector to enhance gene delivery to the target tissue and to reduce transgene expression in the liver. However, genetic modifications of Ad to ablate CAR recognition have not reduced hepatic transgene expression. Secondary interactions between the RGD motif in the Ad penton base and cell surface integrins, which normally mediate internalization of the virion after primary attachment to CAR, may account for some of the residual hepatocyte transduction. These findings suggest the need for complementary approaches to achieve improved targeting.

Transcriptional targeting has achieved exceptional specificity to the target cells while maintaining a "liver off" profile. However, transcriptional targeting alone is of little merit if the target cells are poorly transduced. Also, no promoter is entirely specific without having to sacrifice promoter strength. On the basis of these considerations, combining the complementary approaches of transductional and transcriptional targeting, neither of which is perfect or "non-leaky" by itself may be a rational approach.

4.1 Combination of Targeting with Adaptor Molecule and Transcriptional Targeting

The first report of dual targeting by combining both transductional and transcriptional targeting was accomplished in the pulmonary endothelium. The transductional targeting utilized was on the basis of a bispecific antibody consisting of anti-ACE (pulmonary endothelium marker) and anti-Ad5 knob Fabs while transcriptional targeting was achieved with the endothelial-specific promoter flt-1. Transcriptionally targeted Ad vectors were complexed with transductional targeting proteins to redirect the transduction of cells in a specific manner. This approach resulted in a synergistic, 300 000-fold improvement in the selectivity of transgene expression for the lungs in comparison to the usual site of vector sequestration, the liver. For targeting brain tumors and osteosarcoma cells, the bispecific antibody consisting of anti-EGFR and anti-Ad5 knob Fabs was utilized for transductional and OS promoter, which is TSP for osteosarcoma, was utilized for transcriptional targeting, respectively, showing enhanced transduction of reporter genes while retaining specificity. The aforementioned fusion protein consisting of EGF, one of the EGFR ligands, and sCAR was also utilized for dual targeting. Ad vectors constructed with a reporter or the *HSV-tk* gene driven by the SLPI promoter, which is one of the TSPs for ovarian cancer, demonstrated enhanced transduction and therapeutic effect in ovarian cancer both *in vitro* and *in vivo*.

4.2 Genetic Capsid Modification Coupled with Transcriptional Targeting

Genetic capsid modification has demonstrated the ability of the cyclic RGD-4C peptide to retarget Ad tropism toward αv integrins, leading to enhanced gene delivery to a repertoire of cell types. However, vectors modified in this manner are not selective in that they can transduce a wide variety of cells. In fact, RGD-modified vectors were originally developed to broaden the tropism of Ad-based vectors and achieve enhanced infectivity. Strategies to maintain the increased

transduction afforded by RGD modification, but on a more cell-selective basis, have been exploited by combination with transcriptional targeting using TSPs. Work et al. combined transcriptional targeting using the endothelial-specific promoter, flt-1, with genetic fiber modification using the RGD motif for targeting endothelial cells, showing that double modification substantially shifted transduction profiles toward vascular endothelial cells in rat hepatocytes and endothelial cells. Nicklin et al. also combined transcriptional targeting on the basis of the flt-1 promoter with genetic fiber modification using the human endothelial cell-binding peptide SIGYPLP, demonstrating efficient and selective transduction of some cancer cell lines.

The combination of genetic capsid modification and transcriptional targeting with TSP gives full play to its abilities in CRAd, since the enhanced infectivity achieved by transductional targeting with capsid modification would lead to robust replication in target cancer cells, producing progeny virus that can go on to infect the surrounding cells. These replication and lateralization functions of CRAds greatly influence their efficacy. As noted in the previous section, fiber-modified Ad vectors, such as Ad5RGD and Ad5/3, show enhanced infectivity in various cancer cells by exploiting CAR-independent infection pathways. Cox-2 promoter-based CRAds with RGD fibers or Ad5/3 chimeric fibers have been constructed, demonstrating dramatic improvements in oncolysis of pancreatic, esophageal, and ovarian cancer cells both *in vitro* and *in vivo*. For melanoma treatment, a tyrosinase promoter–based CRAd was generated with an Ad5/3 chimeric fiber, also resulting in enhanced oncolysis.

5 Conclusions

In any treatment modality, a low therapeutic index resulting from poor curative effects in target cells and/or high toxicity to nontarget cells presents great obstacles hindering successful treatment of the disease. In this regard, Ad vectors can be targeted at the level of transduction and transcription to overcome these issues, contributing enhanced specificity and efficiency of therapeutic transgene expression. Transcriptional targeting is practical only for specificity, while transductional targeting can achieve both increased efficiency and specificity. Each targeting strategy possesses both advantages and disadvantages, perhaps making neither one alone adequate for gene therapy goals.

On the basis of the above considerations, combined transductional and transcriptional targeting represents a viable targeting method for the following two reasons. First, combined targeting enables both efficient and specific transduction that is essential for effective therapy. Additionally, increased transgene expression resulting from transductional targeting approaches that provide enhanced gene delivery would make it possible to apply TSPs that show high specificity, but have been disregarded due to their low promoter activity. Second, transgenes were screened stringently for specificity through both transductional and transcriptional targeting.

The number of gene therapy strategies carried out to date, however, has fallen short of expectations. It is obvious that seeking better efficiency and specificity are major considerations that need to be addressed. Current methodology for dual targeting may be too complicated at present for clinical usage. As introduced above, radically modified Ad vectors with

large-sized targeting molecules have been generated and they mainly contribute to simplifying clinical protocols through the combination of transcriptional targeting portion inside the capsid. Further investigation of Ad biology and identification of novel targeting molecules will lead to an improvement of current gene therapy approaches.

Keywords

Adeno-associated Virus
A nonenveloped single-stranded DNA virus that may be modified to produce a gene transfer vector.

Adenovirus
A nonenveloped double-stranded DNA virus that may be modified to produce a gene transfer vector.

***Ex vivo* Gene Transfer**
Transfer of genetic material to cells cultured outside the body of a living organism.

Gene Therapy
The introduction of genetic sequences into cells of a living organism, resulting in an alteration of cell or tissue function in a manner that corrects or treats a pathological process.

Gene Transfer Vector
Reagent used to deliver genetic material to the interior of cells.

Herpes Simplex Virus
An enveloped neurotropic double-stranded DNA virus that may be modified to produce a gene transfer vector.

***In vivo* Gene Transfer**
Transfer of genetic material to cells by introduction of a vector into the body of a living organism.

Lentivirus
An enveloped single-stranded RNA virus that may be modified to produce a gene transfer vector.

Nonviral Vector
Gene transfer vector that does not contain viral components.

Replication defective
A virus that has been modified to prevent its replication in target cells following gene transfer.

Tropism
The natural host cell range of a vector.

Viral Vector
Gene transfer vector made by genetic engineering of a virus.

Gene therapy may be defined as *the introduction of genetic sequences into cells of a living organism, resulting in an alteration of cell or tissue function in a manner that corrects or treats a pathological process.*

This might be accomplished in one of two broad ways: (1) The therapeutic genetic material is transported *ex vivo* into cells taken from a patient – the cells can be subsequently reintroduced, with or without expansion, as an homologous cell transplant. The reintroduced cells engraft and produce a therapeutic product that can alter the biology of the transduced cell to correct a genetic abnormality or deficiency, or may serve as a factory for production of a protein product used by other tissues exposed to the circulation. (2) The therapeutic genetic material is introduced into the cells of the body by direct *in vivo* gene transfer. Direct *in vivo* gene transfer may be used if procurement of appropriate cell explants requires unacceptably invasive procedures, or for gene transfer to essentially nonregenerating tissues (e.g. brain or heart).

The genetic material transferred (''transgene'') may encode a complete therapeutic gene to replace a defective function, or coding sequences whose products interfere with an acquired or inherited pathologic cellular function. Gene transfer may also be used to enhance normal function to achieve a therapeutic effect, such as the induction of an immune response or the reversal of autoimmune activity. Finally, a large effort in gene therapy has been directed toward the use of gene transfer to destroy unwanted tissue, such as malignant cells, or fight infectious agents, such as human immune deficiency virus (HIV).

The diverse potential gene therapy applications suggest that genes as molecular medicines hold great promise for the future. In part this promise is beginning to be realized, but much more research (and testing in patients) is required before gene therapy becomes standard medical practice.

1 Introduction

In this article, we discuss the science and the current status of gene therapy. This includes a review of methods used for gene transfer, current attempts to apply gene therapy to treat disease, and a discussion of serious adverse reactions to gene therapy. One example of gene therapy will be described in more detail in order to better acquaint the reader with the steps needed to develop this type of therapy. Finally, an attempt will be made to make some projections regarding the future of gene therapy research and practice by describing where the field may be headed in the next 10 years.

2 The Science of Gene Transfer

A major effort in gene therapy research has concerned the development of efficient, safe methods to introduce genetic information into cells either outside or within the body. These gene delivery tools are referred to as *gene vectors* and can be constructed from modified viruses (''viral vectors'') or directly from chemical constructs (''nonviral vectors'').

The advent of gene cloning and the ability to make recombinant viruses in the early 1980s portended an era in which viral gene vectors would become the working tools for gene therapists (Table 1). All that was needed was the removal of a critical gene from the virus that allowed it to grow or cause disease (Table 2) and replace that gene with one that is useful to the cell. Gene therapy researchers soon found that reporter genes like the *Escherichia coli lac*Z gene encoding β-galactosidase could be introduced into almost any tissue by various recombinant viruses, and β-gal activity detected using a colorigenic agent. Depending on the target cell, a nonintegrating or integrating vector could be used to introduce the reporter gene. Curing a disease using this technology should have been a simple matter of replacing the reporter transgene with a therapeutic gene. So why did this clear path to success fail to rapidly yield new therapeutic products? To answer this question, it is important to understand the technology of virus-mediated gene transfer and the nature of clinical studies targeted by this approach to treatment.

Why choose viruses? It has been known for many years that viruses can deliver their genes to cells by the process of virus infection. Depending on the class of virus, a variety of highly evolved mechanisms for redirecting cellular processes for making new virus particles come into play. Viruses are essentially inert particles outside the body and are vulnerable to the outside world, making their expectant viability short-lived, in the absence of available hosts. The life cycle of viruses, in the simplest terms, involve virus attachment to a susceptible cell, entry into the cell, capsid removal in a process referred to as *uncoating* to expose the virus genome in an active form, either in the cytoplasm or nucleus. The virus genes are transcribed and expressed as proteins or active RNA molecules, requiring at least partial use of the cellular transcriptional and translational machinery. The most sophisticated viruses have hundreds of genes (e.g. vaccinia), whereas the most simple have as few as four to six genes (e.g. polyoma virus and adeno-associated virus). The viral genome, single- or double-stranded DNA or RNA, is replicated and encapsidated into new virus particles that are released by cell lysis or by a

Tab. 1 Major viruses used to construct viral vectors.

	Genome	*Genomic integration?*	*Envelope?*	*Latent infection?*	*Helper virus?*	*Cellular receptor*	*Route of cellular entry*	*Disease caused by wild-type virus*
Lentivirus	ssRNA; 9.5 kb	Yes	Yes	Yes	No	CD4, CXCR5 ([a]phosphatidyl serine)	Plasmalemma ([a]endosome)	AIDS
Adenovirus	dsDNA; 35 kb	No	No	No	No	CAR, integrin $\alpha v\beta 5$	Endosome	Respiratory infection; conjunctivitis; gastroenteritis
Adeno-associated virus	ssDNA; 5 kb	Yes	No	Yes	Yes	Integrin $\alpha v\beta 5$, FGF-1R	Endosome	None known
Herpes simplex virus	dsDNA; 150 kb	No	Yes	Yes	No	Glycosaminoglycan, nectin1α and HVEM	Plasmalemma	Cold sore; rarely encephalitis

[a]Although wild-type HIV enters cells through the plasmalemma, vectors pseudotyped with the vesicular stomatitis virus G-spike glycoprotein enter through the endocytotic pathway.

Tab. 2 Properties of some viral vectors.

	Vector	*Transgene insert capacity [kb]*	*Genes removed from vector genome to prevent replication/toxicity*	*Complementation of essential functions*	*Easy preparation of high titers and pure stock?*	*Easy insertion of transgene sequences?*	*Toxicity*
Lentivirus	HIV-based	6	All except 5′ portion of gag	Transient plasmid transfection	No	Yes	Insertional mutagenesis
Adenovirus	E1, E3 deleted Ad5	8	E1, E3	Complementing cell line	Yes	No	Inflammation
	'Gutless'	30	All	Complementing cell line and helper virus	No	No	Inflammation
Adeno-associated virus	AAV2-based	4.5	All	Helper virus or transient plasmid transfection	No	Yes	Insertional mutagenesis
Herpes simplex virus	Genomic HSV-1 vectors	30–40	ICP4, ICP27, ICP22, ICP47, ICP0, U_L41	Complementing cell line	Yes	No	Minimal
	Amplicon	120	All	Transient BAC transfection	No	No	Minimal

process called *budding* in which the virus capsid is enclosed in a membrane or envelope. These nascent particles are then competent to invade other cells. For details of viral replication and life cycles, see excellent and exhaustive chapters in Field's Virology. Summary figures of the life cycles of major viruses used as vectors are shown below.

Viruses have evolved sophisticated mechanisms for either rapid spread or the ability to remain relatively quiescent in cells of the body until an opportunity presents itself for transmission to a naïve host. Many viruses (e.g. adenovirus) do not persist in the host but rather rapidly replicate and produce large numbers of infectious particles that can be spread to other susceptible hosts. Vectors based on such viruses are less useful for long-term gene delivery but can be used for applications that require transient transgene expression, such as the induction of immunity or destruction of tumors. The life cycle of other viruses (e.g. retroviruses and lentiviruses) involves a persistent phase in which the virus genome may become integrated into a host chromosome and can thus be passed on to daughter cells following cell division. Vectors created from these viruses can be useful for applications in which persistent transgene expression is required. Herpes viruses persist in the host as nonintegrated forms that either remain associated with nondividing cells or can replicate their genetic information in synchrony with cell division. Most viruses that persist in the host have evolved sophisticated means for transiently avoiding host detection by the immune system, often reaching a stalemate between their elimination by the immune system and their disease-causing activity. Most human infecting viruses that persist do so by a system referred to as *latency* where few, if any, viral genes are expressed in cells where latency is established and virus persistence generally lasts for the life of the host.

Early studies of viral vector-mediated gene transfer for therapeutic purposes have been focused on a few viruses (Tables 1 and 2). The choice of viral vector for a specific application depends on the biology of the wild-type virus and the degree to which the virus life cycle and genes have been characterized. As more insight is gained into virus biology, it is likely that additional viral gene transfer vectors will be developed.

3 Principles of Vector Engineering

3.1 Retroviruses

It has been known for some time that retroviruses can integrate their genomes into the host cell by a process of reverse transcription, using reverse transcriptase to allow the RNA tumor virus genome to become integrated into the DNA genome of a cell. Virus entry into the nucleus is largely dependent on cell division and thus these viruses most efficiently infect dividing cells.

One of the best-studied retroviruses is the mouse Moloney leukemia virus. It was discovered in the 1980s that ''packaging'' cell lines could be engineered to express the virus coat protein and envelope protein constitutively. On transfection of these packaging cells with a DNA copy of the virus, infectious packaged particles were produced, even though the vector genome contained only terminal repeat elements and the packaging signal from the original virus – the internal sequences

having been replaced by nonviral genes. These infectious packaged particles could be used to transduce other cells, and by virtue of their terminal repeat elements, the nonviral genes were incorporated into cellular DNA. Following successful transfer of the adenosine deaminase (*ADA*) gene in preclinical studies, this first virus gene transfer vector was used in the first gene transfer clinical trials in the early 1990s in an attempt to treat the ADA-deficiency form of severe combined immunodeficiency (SCID). Gene transfer with these first-generation vectors was not efficient enough to produce a therapeutic outcome, and indeed the study design almost ensured failure. An initially unrecognized shortcoming of retroviruses and lentiviruses is the propensity for the vector genome to integrate into the cell genome, preferentially near sites of active transcription. This process can lead to rare insertional mutagenesis events and activation of cellular genes that have oncogenic potential. In a more recent clinical trial using a retroviral vector to treat X-lined SCID, two of the patients cured of the disease by gene transfer developed leukemic transformation as a result of insertional mutagenesis (see Sect. 5.2). Investigators are now attempting to engineer retroviral vectors, which are either directed in their integration activity or lack the ability to activate cellular genes.

3.2 Lentiviruses

Vectors constructed from modified lentiviruses, a group of RNA viruses closely related to the oncogenic retroviruses (Figs. 1 and 2), have come to the forefront in the last five years because of their efficiency of gene transduction, their larger capacity for foreign DNA, and their ability to infect nondividing cells. Engineering human lentiviruses to create a vector requires retention of the natural integrase function part of the nucleocapsid and the viral polymerase (Fig. 3). Methods have been developed in which elements of lentiviruses, the Moloney virus, and the envelope components of vesicular stomatitis virus (VSV-G) have been incorporated into three expression plasmids, which can be transfected into cells for vector production (Fig. 4). Transfection methods are not as efficient as using packaging cell lines for retroviral vectors, but lentiviral vectors can be concentrated by centrifugation since the VSV-G envelope component is stable. Another advantage of VSV-G is that it utilizes a common cell surface proteoglycan, which is ubiquitously expressed

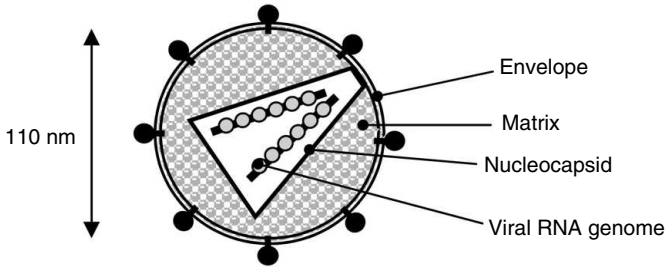

Fig. 1 The structure of Human Immunodeficiency Virus – A schematic depiction of a mature HIV-1 virion is shown, to illustrate key structural components of this prototypical lentivirus.

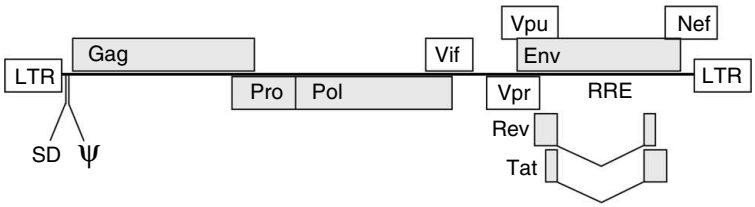

Fig. 2 The HIV-1 genome – The HIV-1 RNA genome is illustrated diagrammatically (not to scale) to demonstrate overlapping genomic locations and splicing of viral genes. Abbreviations: LTR, long terminal repeat (containing promoter for viral transcripts); SD, major splice donor; Ψ, packaging signal; RRE, rev-response element. The names of viral genes are shown within the boxes. *gag* encodes the core antigens, *pol/pro* encodes the reverse transcriptase and protease enzymes necessary for genomic integration and posttranslational processing of viral proteins respectively, and *env* encodes the viral envelope proteins necessary for cell entry. *tat* encodes a transactivator of viral transcription and *rev* encodes a splicing/export regulator – see Fig. 3.

on many cells as a receptor, and thus the host range for the lentiviral vector is greatly broadened. It should be noted that despite the use of human immune deficiency virus (HIV) components for many applications, this vector does not cause AIDS or other diseases. Other lentiviruses may also be suitable for the construction of lentiviral-based vectors. Nevertheless, lentiviral vectors have the same propensity for random integration that has been observed with retroviral vectors, although chromosomal breaks are less targeted by lentivirus than by oncogenic retrovirus since the lentivirus has the ability to cut and religate double-stranded DNA as part of the enzyme systems that are contained within the particle. Lentiviral vectors have proven especially useful in transduction of brain and bone marrow stem cells. They have yet to be tested clinically, but this is likely to occur within the next few years.

3.3 Adenoviruses

After retroviruses, adenoviruses have been used most often for gene transfer (Fig. 5). Replication-defective viruses lacking the tumor-causing gene of adenovirus, *E1a*, had been made in the early 1980s and propagated in cell lines that contained the *E1a* gene integrated into the cell chromosome (see Figs. 6, 7). Such cell lines were designated as complementing cells since the missing viral function was supplied *in trans* on infection. The deletion of E1a prevented the virus from replicating in most wild-type cells (Fig. 7), although there was leaky expression of the other viral functions, including structural proteins and the viral polymerase. Transduction of a number of target tissues in experimental models was demonstrated using early adenoviral (AdV) vectors. Deletion and complementation of further adenoviral genes enabled generation of more efficient and less toxic vectors. One attractive property of AdV vectors is their remarkable ability to express transgenes at very high levels. Because the wild-type virus causes a respiratory infection, it was initially thought that Ad vectors would prove to be ideal for gene transfer to lung, for example, in the common inherited respiratory disease, cystic fibrosis. Unfortunately,

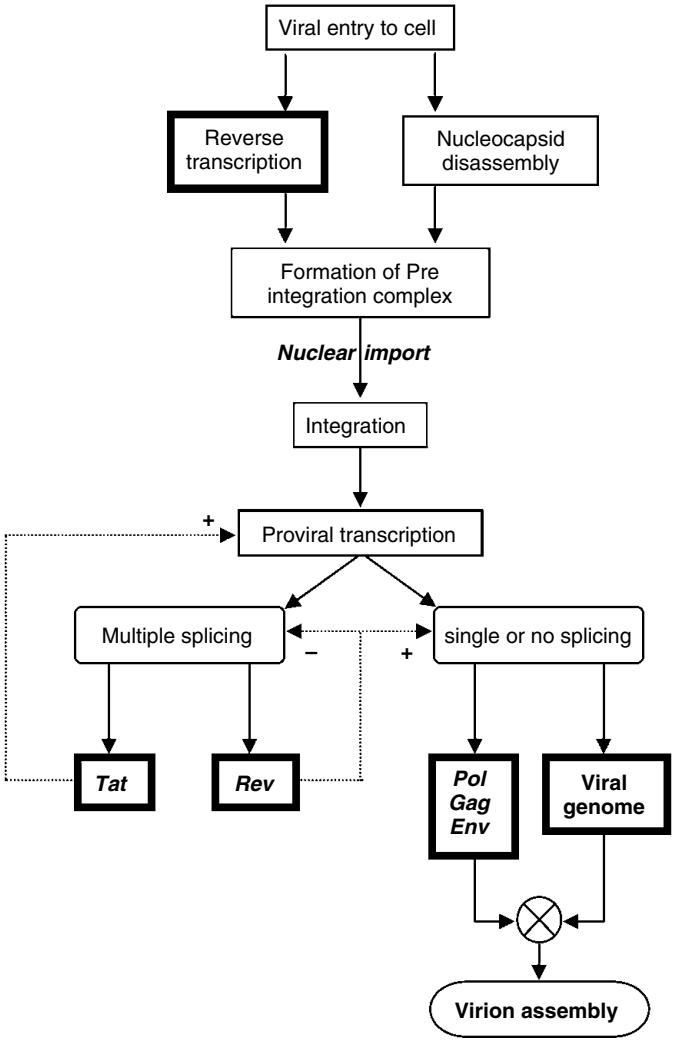

Fig. 3 Major events in the life cycle of lentiviruses – The early part of the life cycle is depicted in the upper portion of the diagram; entry, reverse transcription, formation of the preintegration complex (PIC) and nuclear import of the PIC culminate in the integration of proviral DNA into the host cell genome. The late part of the cycle is characterized by transcription of viral genes. All of the viral genes are encoded by a single primary transcript, and the expression of different proteins is controlled by regulation of RNA splicing and posttranslational protein processing. Initially, multiply spliced RNA isoforms encode regulatory proteins (*tat* and *rev*) that *trans*activate proviral transcription, and drive a shift toward the production of unspliced or singly spliced RNA. The latter encodes the virion structural proteins and forms the viral genome, enabling assembly of virions. Vectors are constructed by deleting all viral genes from the genome contained in the particle, thereby disrupting replication at multiple levels – see Fig. 4.

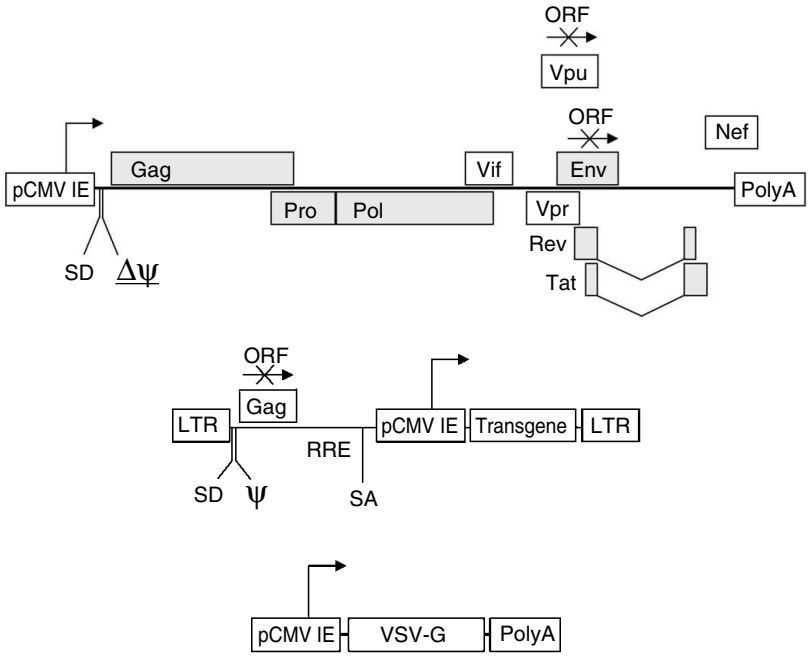

Fig. 4 Construction of replication-defective lentivirus vectors – The system described by Naldini et al. is illustrated. Replication-defective lentiviral vectors may be generated by cotransfection of mammalian cells with the three plasmids shown. A. The ***packaging construct*** provides all of the genes that encode viral structural proteins. Thus, gag-pol, rev, and tat are expressed from this construct. The genes encoding these essential proteins are not incorporated into the virion, however, as the viral LTRs and packaging signal (ψ) are deleted from this vector. In addition, the accessory gene *Vpu* and envelope gene contain frame-shift mutations, abolishing expression of the relevant proteins. B. The ***transfer vector*** contains an expression cassette for the therapeutic or experimental transgene, in addition to the viral LTRs and packaging signals. This vector sequence is transcribed, and the resulting RNA is packaged into lentiviral particles generated from the structural proteins encoded by plasmid A. As the transfer vector contains no sequences encoding functional viral genes (the *gag* gene is truncated and frame shifted), the resulting vectors are replication defective. C. The ***envelope plasmid*** contains an expression cassette encoding a viral envelope protein to replace that encoded by the lentiviral *env* gene, which is deleted from the packaging construct. The G-spike envelope glycoprotein from Vesicular Stomatitis Virus is commonly used to pseudotype lentiviral vectors.

AdV vectors have not proven useful for this application for two major reasons. First, adenoviral receptors are not present on the apical (airway) surface of airway cells, and so intrabronchial or aerosol application of the vector does not give rise to efficient infection of the appropriate target cell required for cystic fibrosis transmembrane conductance regulator (CFTR) expression in the lung. Second, innate and acquired immune response to vector enhanced by the leaky gene expression in the first-generation Ad vector constructs made them susceptible to immune elimination. The immune response to Ad vectors has proven to be a difficult problem for many

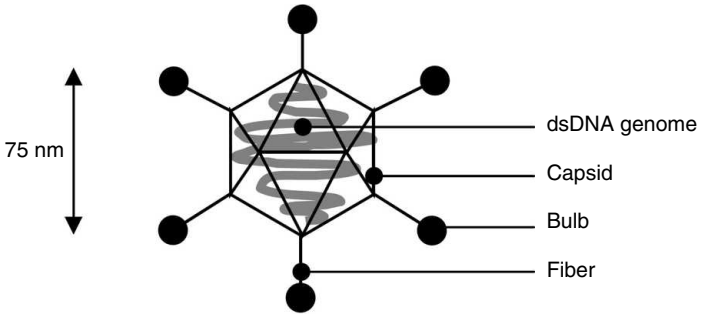

Fig. 5 The structure of Adenovirus – A schematic depiction of a mature adenovirus virion is shown to illustrate key structural components of the virus.

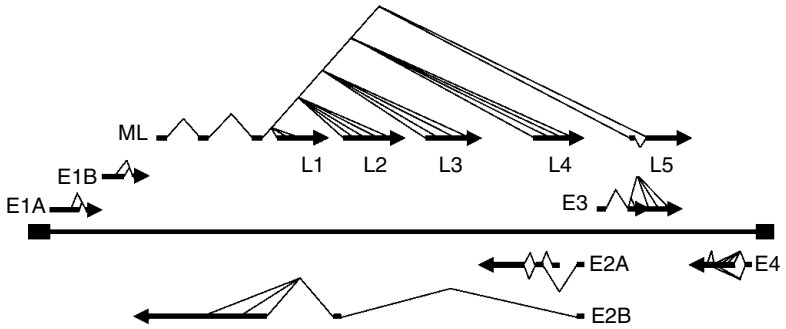

Fig. 6 The adenovirus genome – The adenoviral genome consists of 35 kb of dsDNA, in which the viral gene-encoding sequence is enclosed by two inverted terminal repeats (grey boxes). Although there are only eight basic transcriptional units, approximately 40 transcripts are produced by a bewildering array of alternative splicing events. In particular, the major late promoter gives rise to transcripts that share a tripartite leader sequence, culminating in a splice boundary with one of a possible 18 coding sequences. These are grouped, according to the polyA signal at which the transcripts terminate, into L1, L2, and so on. Viral transcription depends on the presence of the viral gene E1A (see Fig. 7); first-generation vectors were deleted for E1A and E1B and the genes supplied *in trans* using special cell lines. Later vectors are deleted for other genes, for example E3, in addition to E1. The so-called ''gutless'' vectors contain only the packaging signals and transgene DNA, the viral genome being supplied *in trans* by use of a helper virus to express structural proteins, and thus allow the generation of virion-like particles. These vectors can accommodate up to 30 kb of transgene sequence, but are difficult to prepare in high titer and purity.

proposed applications. Alterations to the vector, which eliminate all of the viral components from the vector genome, improve vector stability *in vivo*, but this is not sufficient to eliminate immune rejection of AdV-infected cells. This was most dramatically demonstrated by the finding that AdV inoculation of liver in immune-competent mice results in high levels of hepatocyte transduction, but expression is lost.

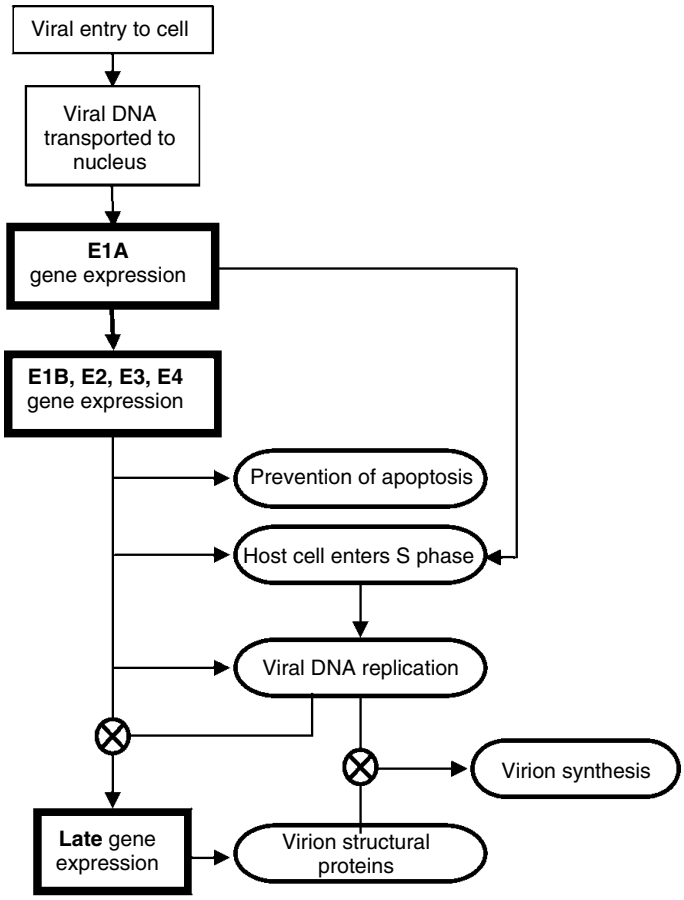

Fig. 7 Major events in the life cycle of adenovirus – The major events in regulation of viral gene expression are shown. Following entry to the nucleus, expression of the viral gene *E1A* is essential to allow expression of the remaining components of the viral genome. The gene expression program of adenovirus results in the subversion of a number of cellular processes, facilitating the production of progeny virions. There is no latent infection and the result of infection is cell lysis and release of adenoviral particles. Deletion of the E1 region halts the viral transcriptional program, and the resulting particles can be used as gene transfer vectors. Later versions of these vectors have multiple genes deleted to enhance the cloning capacity of the vectors and reduce cytotoxicity resulting from leaky expression of the remaining viral genes.

In contrast, the use of immunodeficient mice in the same experiments resulted in long-term gene expression. In addition to immune rejection, AdV vectors cannot be administered to patients with high levels of circulating antibody, and the vector cannot be readily repeat dosed in patients, even those without preexisting immunity, since vector inoculation results in high-titer antibody production. There have been

attempts to protect AdV from immune recognition by coating the particle and AdVs of alternative serotypes or from other species or have been isolated with different coat protein structures in the hope that these particles will avoid immune recognition. The AdV particle itself, however, has the ability to induce cytokines (for example interleukin-6) that can result in elimination of the virus genome. A liver gene transfer clinical trial, using high-titer AdV, led to the death of one patient as a result of a vector-induced cytokine storm, leading to organ failure (see Sect. 5.1). There are two important uses of AdV vectors that are likely to be effective in the future. The first is the use of AdVs carrying immune-activating genes in the treatment of solid tumors, and the second is the use of recombinant AdVs for vaccination against newly arising infectious agents. Both applications take advantage of high-level transgene expression, efficient gene delivery, and immunogenicity of the vector substrate.

3.4 Adeno-associated Viruses

Adeno-associated virus (AAV) was initially discovered as a contaminant of adenoviral preparations (Figs. 8, 9 and 10). AAV-based vectors have enjoyed a broad appeal following their initial development. The reasons for this include the following: (1) AAV causes no known disease; (2) the AAV genome can be manipulated as a simple plasmid; (3) the small size of AAV allows the particle to infiltrate many different tissues; (4) certain tissues (e.g. muscle) are transduced very efficiently. Although its small size (22 nm) does not allow packaging of more than 5 kb of foreign sequence, this is sufficient to accommodate most gene coding sequences as cDNAs (i.e. the coding sequence of a gene with the introns and flanking regions deleted). *In vitro*, wild-type AAV integrates into a specific location on chromosome 19q, but this specific integration event is dependent on *replicase,* a viral gene that must be eliminated from vectors because of its considerable toxicity to cells. AAV replication requires several helper functions that can be provided by either adenovirus or herpes simplex virus. Like adenovirus, AAV is highly susceptible to neutralization and cannot be easily repeat dosed, but AAV vector-mediated transgene expression in some tissues provides for long-term expression; the lack of induction of immunity to the transgene product may reflect low infectivity in antigen-producing cells, such as the dendritic cells located in the skin. The optimal method for producing AAV is still

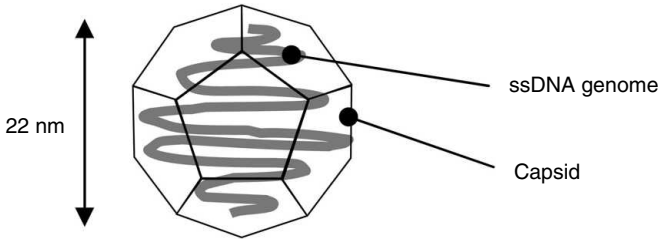

Fig. 8 The structure of adeno-associated virus – A schematic depiction of a mature adeno-associated virus virion is shown, to illustrate key structural components of the virus.

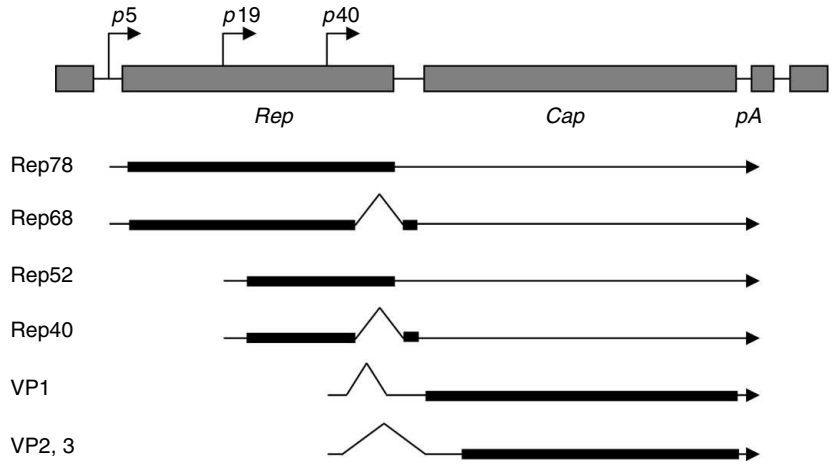

Fig. 9 The adeno-associated virus genome – The AAV genome consists of 5 kb of ssDNA. The coding sequences are flanked by inverted terminal repeats (grey boxes). There are two major genes, *rep* (encoding proteins necessary for gene expression, genomic integration, and replication) and *cap* (encoding the structural components of the virion). There are three viral promoters giving rise to six transcripts by alternative splicing. All of the transcripts terminate at a single polyA signal. Seven proteins are encoded by the six transcripts because the VP2,3 transcript can be translated using one of two different translational start codons. Gene transfer vectors are generated by deletion of *rep* and *cap*, supplying these genes *in trans* by cotransfection of a plasmid, to allow generation of particles. Unfortunately, the products of the *rep* gene are toxic to host cells, and so packaging cell lines have not been possible to generate.

under development, but the most common approach is a triple-plasmid transfection method in which one plasmid is the vector, another expresses the replicase and capsid functions, and the final plasmid provides the adenovirus helper functions. This method produces AAV vector particles without contamination from helper virus since the adenovirus packaging signals have been removed, but is not very efficient. The scale-up manufacture of AAV is also complicated by the remarkably low transduction efficiency of AAV, compared with other vectors. Transduction with AAV *in vivo* thus requires very high doses of virus per cell. Although AAV may integrate into the host genome during its normal life cycle, this is inefficient and cell division is usually required. In contrast to other vectors, AAV appears to require concatemerization in the nucleus for expression, a process that can take weeks for maximum transgene expression. Unless the efficiency of AAV transduction can be improved, its utility as a vector for the treatment of patients will be limited; manufacturing considerations will preclude treatment of more than a few patients at the required doses of $>10^{12}$ per patient. High vector dosing also risks provoking toxic immune responses. Despite these concerns, AAV remains promising. For certain applications, such as gene transfer to the heart, it may prove to be the vector of choice. In addition, new serotypes are proving to be more efficient in some tissues such as liver where previous vectors based on AAV type 2, for

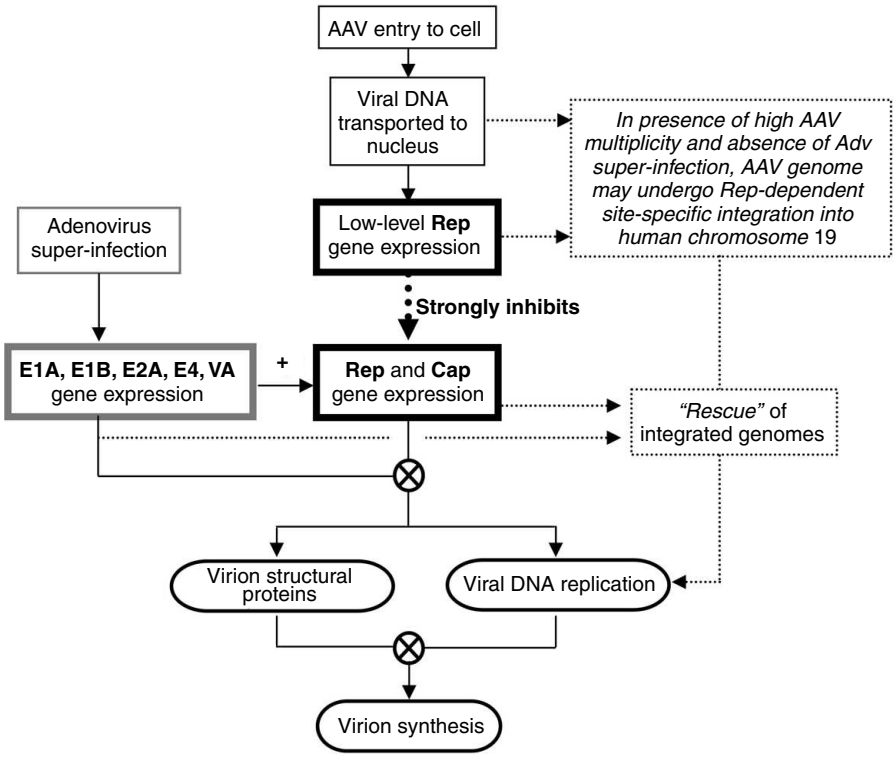

Fig. 10 Major events in the life cycle of adeno-associated virus – Following entry of AAV into the cell, one of two chains of events may ensue the following: 1. In the absence of super infection with a helper virus (AdV is shown, but HSV can also provide helper functions), concatemerized AAV genomes may undergo *rep*-dependent site-specific integration into human chromosome 19, giving rise to a latent infection. Alternatively, the viral genome may persist in the cell nucleus. Low-level expression of rep proteins is strongly inhibitory to expression of viral transcripts. 2. Infection of an AAV-harboring cell with adenovirus, or transfection with a plasmid containing the minimal essential AdV helper functions (E1A, E1B, E2A, E4, and VA) allows high-level expression of *rep* and *cap*, and also forces the cell to enter the S-phase of the cell cycle. This allows replication of AAV viral DNA, synthesis of virion components and assembly of AAV virions. High-level expression of *rep* and *cap*, in association with AdV helper functions can rescue integrated genomes from the chromosome of a latently infected cell. Replication-defective vectors are generated by deletion of *rep* and *cap* from the AAV genome. The vector particles are prepared by cotransfection of packaging cells with a *rep/cap* plasmid, an AdV helper function plasmid, and a gene transfer plasmid containing the transgene of interest and the AAV packaging signals. As the resulting particles are deficient in the *rep* gene, integration into the host chromosome is very inefficient and occurs randomly, but with a predilection for transcriptionally active genes.

example, were considerably less effective. Perhaps, when increased manufacturing and transduction efficiency is achieved, opportunities for engineering better vectors may arise.

3.5 Herpes Simplex Virus

The last vector under serious consideration for human studies is Herpes simplex virus

(HSV) type 1 (Figs. 11, 12, 13 and 14). The wild-type virus causes the common cold sore, and is transmitted through the skin by direct contact with a lesion from an infected individual. The wild-type virus can replicate in skin and mucous membranes but does not persist in the epithelium, instead entering sensory nerve terminals in the skin from which they are transported in a retrograde manner to the nerve cell body in sensory ganglia (Fig. 13). In the sensory ganglia, the lytic viral life cycle is curtailed within days, after which the wild-type virus enters a latent state, with concomitant silencing of lytic genes. During latency, only the latency locus is transcriptionally active, and latently infected nuclei accumulate a stable intron called the *latency-associated transcript* or LAT RNA. The ability to persist in neurons for life suggests that HSV may be engineered for gene transfer to nerves and that vector delivery can result from simple skin inoculation. The general strategy for engineering HSV vectors from the wild-type virus is to eliminate genes that contribute to virus replication and reactivation from latency while taking advantage

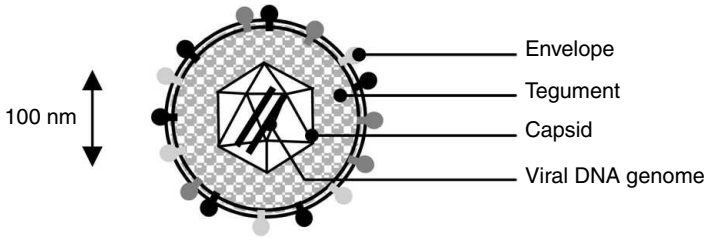

Fig. 11 The structure of herpes simplex virus – A schematic depiction of a mature HSV-1 virion is shown to illustrate the key structural components of the viral particle.

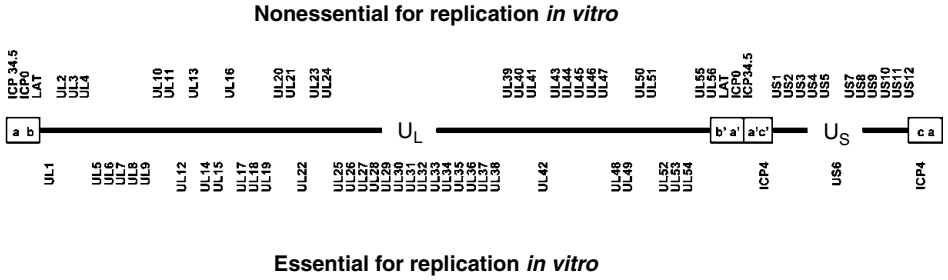

Fig. 12 The HSV-1 genome – The HSV-1 genome is illustrated diagrammatically. The genome is 154 kb and encodes 84 genes. The genome is divided into unique long and short segments flanked by repeat sequences. Genes that are essential and nonessential for viral replication *in vitro* are indicated. Nonessential genes (which encode a variety of functions that optimize the interaction of HSV with the host organism) can be removed from the virus without compromising replication *in vitro*, allowing their replacement with transgenes of interest. The capacity for the insertion of foreign DNA sequences into the HSV genome is large; genomic vectors can accommodate around 40 kb of transgenic material and amplicons (particles that have all viral genes removed and supplied in trans) can accommodate 120 kb of foreign sequence.

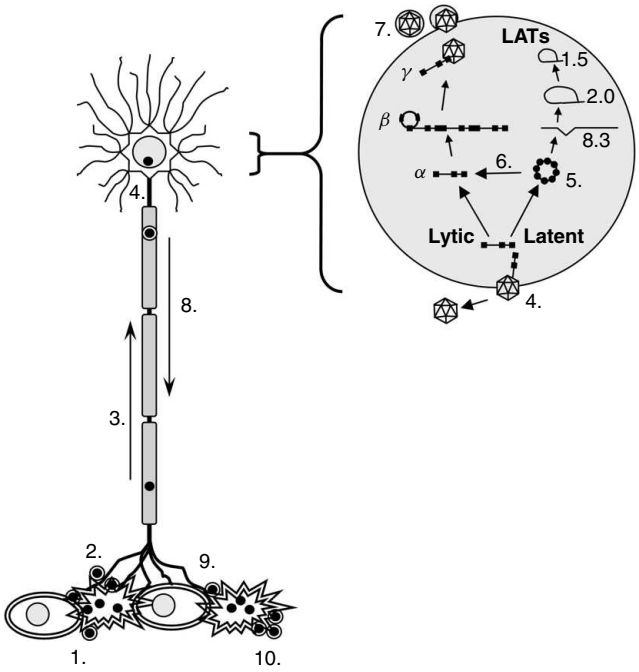

Fig. 13 The life cycle of HSV-1 *in vivo* – The key events occurring during infection of a human host are depicted schematically as follows: 1 – Lytic cycle of replication at epithelial port of entry; 2 – Virions released from epithelia enter sensory nerve terminals; 3 – Nucleocapsid and tegument undergoes retrograde axonal transport to soma; 4 – Viral DNA enters neuronal nucleus and either initiates lytic cascade of gene expression or becomes latent; 5 – During latency, viral genome remains episomal and nuclear. Only the LAT genes are expressed; 6 – Immunosuppression, intercurrent illness, or other stimulus ''reactivates'' lytic infection; 7 – Virions formed by budding from nuclear membrane; 8 – Nucleocapsid and glycoproteins transported separately by anterograde axonal transport; 9 – Virion assembly and egress from nerve terminal; 10 – Recurrent epithelial infection at or near the site of primary lesion.

of the latent genome as a platform for transgene expression (Fig. 14). The virus depends on expression of four genes, activated upon entry into the nucleus and referred to as *immediate early functions* for replication to occur. In the absence of these genes, other viral functions fail to be expressed or are expressed at exceedingly low levels. Thus, despite the fact that the virus contains approximately 84 genes (Fig. 12), engineering HSV vectors is not as complex as it may seem. Two of the immediate early genes are essential functions, but complementation of all four genes is required for high virus vector yield on production in complementing cells. The latency promoter elements have been partially characterized and can be used to drive the transgene expression for considerable time periods in sensory nerves. While

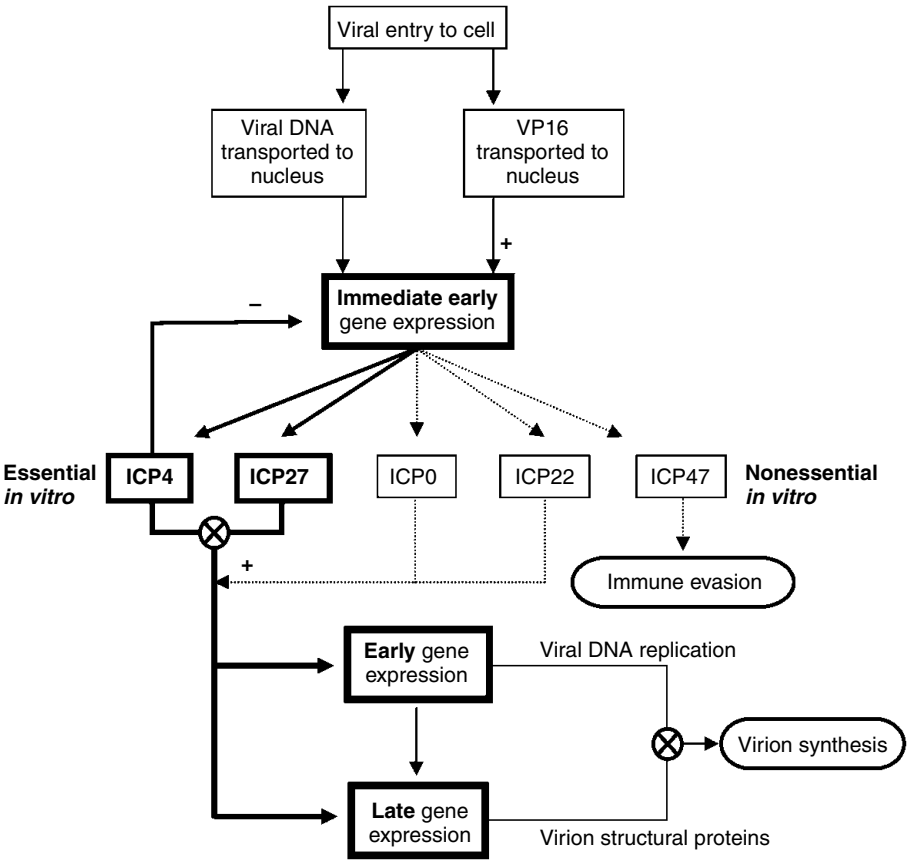

Fig. 14 Regulation of HSV-1 gene expression during lytic infection – This flow chart illustrates the important regulatory events in gene expression occurring during lytic HSV-1 infection. In order to proceed to the later stages of infection, during which the viral genome is replicated and new virions assembled, both of the essential immediate-early genes *ICP4* and *ICP27* must be expressed. Deletion of one or other essential *IE* gene results in a replication-defective virus by eliminating early and late gene expression; these vectors are easily propagated and prepared to high titer and purity in cell lines expressing ICP4 and ICP27. Later vectors have multiple *IE* genes deleted to reduce cytotoxicity. In addition, many of the large number of genes that are nonessential for replication *in vitro* can be deleted to allow insertion of multiple or large transgene sequences. Herpes amplicon genomes contain the HSV origin of replication and packaging signals, in addition too the transgene of interest, but do not contain any viral coding sequences. A BAC containing the HSV genome expresses all viral structural genes in a cotransfection preparation, to allow generation of particles. Although the amplicon system may be thought advantageous owing to the absence of viral genes and large capacity for insertion of transgenic material, (120 kb), amplicons are very difficult to prepare in useful amounts and current technology strongly favors the use of replication-defective genomic vectors.

multiple essential viral genes have been complemented in cell lines engineered for this purpose, a packaging cell line has not yet been produced that takes full advantage of the large genome for delivering foreign DNA. This may be difficult since a number of the virus functions are toxic to cells and their expression requires coordinated regulation, a feat difficult to accomplish using virus genes embedded in cellular chromosomes. Nevertheless, efforts are ongoing to eliminate more virus functions, creating additional room for foreign sequences. The large genome of HSV of 152 kb in length suggests its potential utility for transferring multiple genes and perhaps even genomic sequences. Current vectors can accommodate up to 50 kb.

Another class of HSV-based vectors is referred to as *amplicons*. These are plasmids that mimic defective interfering particles that arise spontaneously during high multiplicity passage of the virus in cell culture. Amplicons can be generated with wild-type or conditional mutant virus as a helper, provided the amplicon contains a packaging signal and an origin of replication. As the viral genes are supplied *in trans*, the capacity of insertion of cloned DNA is large. Unfortunately, the *Ori* signal increases the recombination frequency, and it is therefore difficult to avoid recombination between the amplicon and helper virus, so that completely pure vector stocks are difficult to obtain. This problem can be ameliorated to a substantial degree by using helper plasmids for amplicon packaging, but virus reconstitution may occur. Manufacture of amplicons is a difficult task for use in patients, since consistent preparations are difficult to achieve. Thus, vectors that are produced by complementation are more likely to be developed as gene therapy products, at least with current technology. As is the case with AdV and AAV-based vectors, a substantial proportion of the population has been infected with HSV and has antibodies against the virus. However, antiviral immunity is not effective in preventing HSV infection, rather it is the extent of virus replication and frequency of reactivation that is controlled by the immune response. Immune competent individuals can have HSV reactivation events, but this frequency is considerably greater in immune-compromised individuals. Reactivation, of course, does not occur with replication-defective vectors.

3.6 Vector Targeting

Over the past decade, substantial emphasis has been placed on manipulating the host range of viral vectors. Targeting could be used (1) to transduce cells that are not naturally infected by the wild-type virus or (2) to increase the uptake of vector into a limited subset of cells. In the best-case scenario, a vector could be engineered to be defective in its natural targeting function, but redirected to recognize an epitope on a desired target cell, allowing systemic vector inoculation, to achieve distributed, yet targeted, transduction. Enveloped viruses have been retargeted by using different envelope glycoproteins from other enveloped viruses. In addition, novel ligands have been inserted into the coding sequence of specific virus envelope genes. However, virus binding to target cells has not always led to infection, since a second fusion step is required either at the cell surface or within the endosome compartment (Figs. 15, 16). Recent studies with AAV have discovered sequences that can be modified without disrupting virus uncoating. Although efficient retargeting has

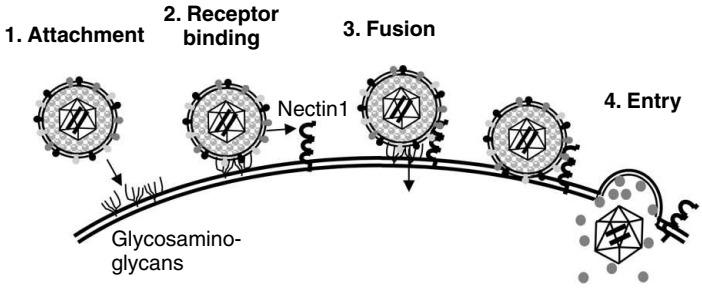

Fig. 15 Cell entry of an enveloped virus – HSV-1 is shown for illustration. Following an initial attachment event (involving interaction of HSV glycoproteins gC and gB with cell surface glycosaminoglycans), a specific receptor interaction occurs between viral glycoprotein gD and cell surface nectin-1 (also called HveC). This results in fusion of viral envelope with the cell membrane, a process dependent on viral glycoproteins gB and gH/L. The nucleocapsid and tegument proteins then enter the cytoplasm, leaving the viral glycoproteins on the cell surface. Subsequently, the nucleocapsid and some of the tegument proteins are transported to the cell nucleus. The viral DNA is uncoated and enters the nucleus with some of the tegument proteins, initiating viral gene transcription (see Fig. 14).

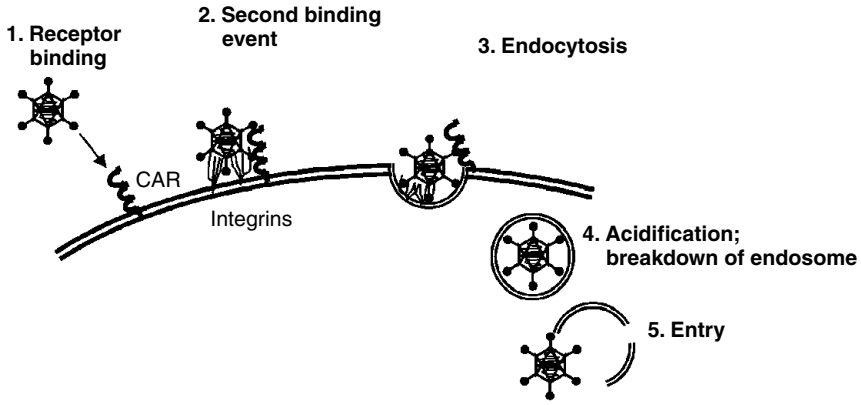

Fig. 16 Adenovirus is shown for illustration. Following an initial receptor binding event, involving interaction of the terminal bulb of the virus fibre protein with the coxsackie-adenovirus receptor (CAR), a second receptor interaction occurs between the AdV penton base protein and cell surface integrins. This results in the endocytosis of the receptor and virus. As the endosome matures, and its environment acidifies, viral components cause the endosome to break down, releasing the partially degraded viral particle into the cell. The nucleocapsid is then transported to the nucleus, where uncoating and nuclear entry of the viral genome are followed by viral gene expression.

not yet been achieved with AAV vectors, enhancement of entry into cells that express low levels of AAV receptor has been achieved by modification of the capsid to display a cell-specific receptor on the AAV virion. The most effective retargeting of viral vectors has involved the modification of coat protein components of adenovirus. Adenovirus infects cells by binding to the coxsackie/adenovirus receptor (CAR) using the extended knob structure of the hexon capsid protein at the particle surface. The virus penton base binds to a specific integrin, $\alpha V\beta 5$, using a specific motif arginine-glutamate-aspartate (RGD). This dual receptor binding recognition is typical of many viruses and ensures specificity. The adenovirus is endocytosed and is released from endosome as it acidifies. A number of strategies have been used to retarget adenoviruses. These include extension of the hexon, using an antibody ligand or a receptor ligand, or engineering the knob function directly by genetic engineering. In addition, the RGD amino acid motif has been altered, so that different integrins can be recognized. This combination has specifically altered receptor interactions that lead to adenovirus infection, in a quantitatively significant manner. Such retargeting holds promise for safe, directed *in vivo* use, especially for targeting cancer cells involved in metastasis.

3.7 Regulation of Gene Expression

If gene delivery cannot be restricted to the cell of interest, targeting of gene expression can be attempted using promoters with tissue specificity. It should be noted that promoter function in the background of a virus genome may be unpredictable. In addition, some tissue-specific promoters are complex, requiring large amounts of sequence (including elements located within introns) to be active, and most vector systems cannot accommodate such large sequences. Considerable effort has gone into determining the critical motifs for promoter specificity and a variety of interesting sequences have been characterized, including locus control regions, matrix attachment functions, transcription factor recognition sequences, and insulator elements. Transcriptional control has proven to be a complex problem to unravel; native promoters in their minimum state have not proven satisfactory. Moreover, as indicated earlier, the context of the gene is important, such that some promoters are quite active until the virus genome becomes integrated or is subject to chromatin formation. Engineering vectors that respond to chromatin remodeling for gene expression has not been satisfactorily worked out, so that gene control in vectors often relies on empirical rather than rational methods. There are exceptions; ''housekeeping'' gene promoters tend to be functional most often (if not most vigorously), although targeted gene expression involves another level of complexity in design. For some vectors, the virus contains naturally occurring strong constitutive promoters, such as the retrovirus LTRs, or tissue-specific promoters such as the nerve-specific latency promoter of HSV. While this is a promising area of investigation for further gene vector development, the use of enhancer elements out of context can lead to an expression that is not appropriately controlled.

A related issue concerns control of when and how long the gene product should be expressed. Some vector-expressed hormones, for example, are highly active in small doses – long-term expression could be harmful or could lead to malignant transformation. It would be highly useful

if a gene switch were available for use in vectors, in which a safe and bioavailable drug could be used to turn gene expression on and off. Several systems have been developed (Table 3). The common theme shared by these systems is that a chimeric transcription factor both (1) recognizes a specific target promoter driving the therapeutic transgene, and (2) is activated by a drug. These systems require the constitutive expression of one or more transcriptional activator gene products. There are several problems associated with all of the available systems: the promoters are usually ''leaky'' (low-level transcription persists even in the absence of the activating drug or presence of the repressor); the constitutively expressed chimeric transcription factors are frequently immunogenic; maintenance of activator gene transcription is as difficult as effecting long-term expression of any transgene; and the targeted promoter may become unresponsive due to methylation, chromatin structure, and so on. Despite these difficulties, evidence for gene switch function in animal models appears promising; perhaps these systems will be improved in various ways, including humanization of the activator gene products to reduce immunogenicity. Another strategy for achieving the same end result might be engineered gene products that are constitutively expressed, but functionally inert in the absence of an ''activator'' drug. Such a system might be simpler to apply, but more difficult to design or apply broadly and may only work in special cases. This remains a fertile area of investigation for the field.

3.8 Nonviral Vectors

A compelling argument for the gene therapy field has been that if nonviral vectors could be developed with similar efficiency and maintenance of transgene expression could be done as viral vectors, several difficult problems in the field would be addressed. These include scalable and more controlled manufacturing processes, since DNA can be readily produced in bioreactors to very high concentrations. The products would be more consistent and better characterized, and delivery could be simple, involving direct injection into tissue. Theoretically, the immune response to nonviral vectors should be attenuated because there are no protein components in the particles – if true, repeat dosing might also be possible. These arguments have been especially attractive to the pharmaceutical industry and thus a considerable amount of resources has been invested in the field of nonviral gene delivery.

Despite these efforts, several problems have arisen that have been very difficult to address. The first is that DNA alone has proven to be highly immunogenic, particularly when CpG repeat sequences are present, and when used with various delivery agents such as cationic liposomes. The second is that targeting is generally not possible, even when specific ligands are attached to the DNA or the delivery vehicle, and gene delivery by nonviral vectors is relatively inefficient compared to viral vector-mediated gene transfer. Third, transgene expression is highly variable and generally very short lived. There have been some exceptions to these general observations. DNA delivery to some tissues such as skeletal muscle is reasonably efficient, and nonviral vector-mediated DNA delivery has proven to be useful for immune priming as part of vaccine strategies.

Tab. 3 Examples of inducible promoter systems.

Type	*Inducer/ repressor*	*DNA response element*	*Chimeric Transcription factor(s)*				*Mechanism of regulation*
			Name	*DNA binding domain*	*Ligand Binding domain*	*Transactivation domain*	
Tet-off	Tetracyclines	Bacterial tet operon sequences (tetO)	tTA (tet transactivator)	Bacterial tet repressor		HSV VP-16	tTA binds to tetO in absence of tetracycline
Tet-on	Tetracyclines	Bacterial tet operon sequences (tetO)	rtTA (reverse tet transactivator)	Mutated bacterial tet repressor		HSV-VP-16	rtTA binds to tetO in presence of tetracycline
Progesterone regulated	Mifepristone (RU486)	Yeast Gal4 upstream activating sequence (UASG)	GL-VP	Yeast Gal4 transcription factor	Mutated human progesterone receptor	HSV VP-16 or human NFκB p65	GL-VP binds to UASG in presence of RU486
Ecdysone regulated	Ecdysone, muristerone	Drosophila ecdysone response element	1.VgEcR	Drosophila ecdysone receptor		HSV VP-16	VgEcR forms active complex with hRXRα or drosophila USP in presence of ecdysone
			2. Human retinoic acid receptor X or drosophila ultraspiracle (USP)				
Rapamycin regulated	Rapamycin	ZFHD1 response element	1. ZFHD1-FKBP 2. FRAP-p65	Human ZFHD1 none	Human FKBP Truncated human FRAP	None Truncated human NFκ B p65	Rapamycin binding brings together functional units of bipartite transcription factor

4
Clinical Applications and Genes

4.1
Single Gene Disorders

Gene delivery to treat Mendelian single gene disorders would allow the fundamental genetic abnormalities to be addressed, rather than the current best practice of intermittently delivering gene products or devising some other compensatory strategy for the genetic lesion. The list of potential gene therapy targets in this category is very large – theoretically, any genetic disease could be treated this way. There are, however, a few examples that have been instructive in terms of understanding the factors likely to determine a successful outcome, and some disease targets are attractive, because the factors governing successful development of therapy are likely to be less stringent than in other diseases. The following paragraphs present a selection of applications, including some where clinical efficacy has already been demonstrated and others where practical gene therapy seems a remote prospect at present.

4.1.1 Hematological Disease

These disorders provide an attractive target for the gene therapist. The diseases are often very severe or fatal and have limited effective therapy at present. Many of the diseases are well characterized at a molecular level, so that the genes that should be delivered are well known. Finally, many of these conditions result from defects in genes necessary for the function of cells during or after differentiation from bone marrow multipotent precursors. Consequently, the transduction event may be carried out *ex vivo* in autologous harvested bone marrow stem cells, so that the vector only enters the target cells, and a degree of selection or expansion is possible before the cells are returned to the host. A list of possible disease targets in this category is shown in Table 4.

Gene therapy for SCID has been ongoing for more than a decade, beginning in 1990. While there are some 60 genetic defects that lead to the SCID phenotype, the availability of patients and a clear understanding of the disease process has focused attention on two genes, ADA deficiency and the gamma c chain of the cytokine receptor (γc). ADA deficiency leads to toxicity to developing immune cells (T and B lymphocytes) and γc deficiency results in a defective growth factor receptor on T and B cells that is needed for responsiveness to cytokine induction of proliferation and maturation of immune lymphocytes. Current management of ADA deficiency is carried out by infusing the ADA protein into the blood, which is taken up by immune cells primarily macrophage. This results in partial restoration of the immune system. The enzyme is PEGalated to enhance stability in the serum and to increase uptake. The first landmark SCID-ADA clinical trial was carried out by French Anderson and Michael Blease, who were then members of the National Institutes of Health (NIH). The patients were given autologous bone marrow cells derived from the circulation that had been infected with a Moloney-based retroviral vector carrying the ADA gene. Infusion of these cells did prove to be safe, but patients continued to receive PEG-ADA for safety reasons. Other trials have continued along these lines until a recent study in Italy carried out by Claudio Bordignon has attempted this treatment in the absence of PEG-ADA therapy. Patients appear to be responding without toxicity and it is likely that the potential success of this trial

Tab. 4 Possible disease targets for gene transfer to hematopoietic stem cells.

Disease	*Gene*
Red Cell Defects	
β-Thalassaemia	β-Globin
Sickle-cell disease	β-like globin
G6PD deficiency	G6PD
Porphyria	Ferrochelatase, others
Cytoskeletal defects	Spectrin
Leukocyte defects	
Chronic granulomatous disease	gp91phox, p47phox
Leukocyte adhesion defect	CD18
Stem-cell defects	
Fanconi anemia	FANC A–E
Immune deficiency syndromes	
Severe combined immunodeficiency (SCID)	γc, ADA, JAK3 kinase
Wiskott–Aldrich syndrome	WASP
CD40 ligand deficiency	CD154
Agammaglobulinemia	BTK
Lysosomal storage disease	
Gaucher disease	Glucocerebrosidase
Hurler's syndrome	α-Iduronidase
Leukodystrophies	X-adrenoleukodystrophy ALDP
Metachromatic leukodystrophy	Arylsulphatase A

can be attributed to the removal of PEG-ADA therapy. ADA expression should lead to selection of the gene-repaired cells *in vivo*, whereas continued use of PEG-ADA prevents this selection. This brings up an important point for gene therapy, which is that the most efficient outcomes may occur in circumstances where transduction occurs in a tissue where there is cellular turnover, and the transduced cells acquire a selective growth advantage. This seems to have contributed to the unprecedented clinical success of the SCIDX gene therapy trial described in the section below.

A number of other targets for HSC gene therapy are contemplated, including hemoglobinopathies, leukodystrophies, lysosomal storage diseases, porphyrias, and leukocyte defects.

4.1.2 Restoration of Circulating Proteins

Some hereditary diseases are caused by genetic defects that abolish the expression of circulating proteins. Hemophilias are the commonest of these disorders. Absence of circulating clotting factor VIII (hemophilia A) or IX (hemophilia B) results in defective blood coagulation, with a tendency to bleed spontaneously into joints (hemarthrosis), following dental extractions or surgical procedures, or following even minor trauma causing life-threatening hemorrhage. Both diseases are transmitted as Mendelian X-linked traits and are therefore usually manifested only in boys. Current treatment involves infusion of purified protein factors, providing temporary resolution of the clotting defect at large expense, inconvenience, and at a finite risk of transmitting infection,

where factors are obtained from pooled blood donations.

These diseases are attractive targets for gene therapists for several reasons. First, they are relatively common and disabling. Second, the blood levels of the clotting factors necessary to restore physiological clotting function are low; levels of >1% normal are rarely associated with spontaneous hemorrhage; levels above 5% normal are associated with posttraumatic bleeding only; and levels above 20% normal are associated with a normal phenotype. This means that complete restoration of the blood levels produced physiologically (by the liver and endothelium) is not necessary to have a clinical impact, and also that the regulation of expression levels might not be as critical as in some diseases, where, for example, stoichiometry with other components of a multiprotein complex is important, or the levels of a potently bioactive protein controlled closely to prevent toxicity. Finally, the requirements for restoration of function are that the protein should be present in the bloodstream, and so the site or tissue of transduction might not be critical, as long as the ''depot'' tissue has access to the circulation. This means that transduction of more accessible sites than the site of physiological production (the liver) might be possible, or that engineered cells created by *ex vivo* transduction might be able to correct the underlying defect.

Using animal models of hemophilia (there are both mouse and dog models), transient restoration of hemostatic levels of factors VIII and IX was demonstrated using first- and second-generation adenoviruses. However, the inflammatory response that occurs in response to adenovirus was responsible for limiting the time span of gene expression, an effect that was partially mitigated using a gutless AdV vector. Similar studies using lentiviruses in mouse models have shown a sustained increase in levels of factor IX, but not of factor VIII owing to an immune response to the human protein used in the mouse model. More recently, adeno-associated viral vectors have been shown to allow sustained expression of clotting factors at therapeutic levels, following transduction of either liver or muscle in animal models. In one clinical trial, hemophilia B patients have been treated with hepatic arterial infusions of an AAV2 vector carrying the factor IX gene. At low dosage (2×10^{11} particles), no toxicity or elevation of factor IX above background was detectable. One patient received an intermediate dosage (1×10^{12} particles). Circulating factor IX levels of 10 to 12% were detectable within 2 to 3 weeks after transduction. Unfortunately, the levels of factor IX then dropped back to the baseline as the levels of circulating transaminases increased, indicative of hepatocellular injury. A similar dose of vector produced a therapeutic level of factor IX lasting 1 to 2 years in the canine model. It is unclear at present whether the pattern seen in the single reported patient will be reiterated, or whether there will clinical benefit, in other patients. Another study using AAV2 injected into muscle reported a transient increase in factor IX levels at a lower vector dose, but no measurable increase at a higher vector dose. Finally, a phase I trial used endogenous fibroblasts transduced with the factor VIII gene *ex vivo* to investigate cell-based delivery systems. Following expansion, $1–4 \times 10^8$ cells were reimplanted into the omentum of six patients. Four of these had detectable elevations in serum factor VIII levels, but these were transient and all had returned to baseline by one year. It seems that better understanding of the processes regulating antibody responses to factors VIII and

IX, the immune response to viral vector components, and the regulatory events involved in long-term gene expression and implanted cell senescence, may be necessary to take this work forward.

α1-antitrypsin (α1AT) deficiency is another example of a genetic disease associated with loss of a circulating protein. This serine protease inhibitor is normally produced in the liver and secreted into the circulation. Patients with loss of the circulating enzyme inhibitor develop abnormal lung proteolysis and a severe form of emphysema. As one primary site of pathology is the lung, it has been suggested that therapy directed at local extracellular expression in the lung might be easier to accomplish than systemic delivery, and equally therapeutically efficacious for the lung disease. However, to prevent the liver disease that accompanies α1AT deficiency in the circulation, it will be necessary to express normal α1AT in the liver. This is because the liver pathology is caused by misfolding of a mutant protein rather than loss of its function, and so local synthesis of wild-type protein will be necessary to suppress production of the mutant. Animal studies have been carried out using adeno-associated virus and adenovirus vectors expressing α1AT. By hepatic or muscular delivery of the vectors, it is possible to produce detectable levels of circulating protein for sustained periods. One reported clinical trial used a liposome complex to deliver the AAT gene to the nasal epithelium of subjects with α1AT deficiency. Other clinical trials have yet to commence, including one aiming to express circulating α1-AT in skeletal muscle using an AAV vector.

4.1.3 Respiratory Disease

Cystic fibrosis (CF) is the commonest autosomal recessive genetic disorder in the western world, with an estimated gene carrier frequency of 1 : 20, resulting in 1 : 1600 livebirths being affected by the condition. CF is a multiorgan disease affecting the respiratory system, pancreas, digestive system, skin, and reproductive organs. The product of the *CF* gene, the CFTR is an integral membrane protein involved in ionic flux in exocrine glands. Its loss results in extremely thickened secretions causing bacterial colonization, repeated infection, and bronchiectasis in the lungs, and exocrine dysfunction in the pancreas. The latter is amenable to enzyme replacement therapy; however, despite optimal antibiotic therapy, CF patients generally die in their teens or in their 20s from the respiratory complications of the disease.

Gene therapy has focused on the introduction of the normal *CFTR* gene into bronchial airway epithelial cells to restore normal CFTR function and thereby alleviate the respiratory problems that cause fatality. In principle, the airway epithelium should be easily accessible to viral and nonviral vectors applied topically, through aerosols or bronchoscopic instillation. As the nasal epithelium is histologically similar to that found in the bronchioles and exhibits similar functional deficits in cystic fibrosis, some studies have focused on gene transfer to nasal epithelium to show proof of principle. Early studies showed proof of principle that a number of different vector platforms could introduce the *CFTR* gene into airway epithelium, resulting in expression of CFTR. Despite early optimism, however, clinical gene transfer to correct the abnormal pulmonary phenotype of CF has proved very difficult and therapeutic results have yet to be achieved. Latest clinical gene transfer trials show that adenovirus and adeno-associated virus vectors are extremely inefficient in transducing the bronchial

epithelium, and there are major problems with repeat dosing each of these vectors (as would be necessary because of short-lived gene expression) owing to immunity. Although nonviral techniques, including liposomes and cationic lipid formulations, can be repeatedly administered, they appear even less efficient than the viral techniques, and are not entirely devoid of toxicity – one study reporting fever, muscle and joint pain in half of the subjects after aerosol delivery. Recent advances have included identification of factors such as mucus and glycocalyx that contribute to the poor efficiency of transduction *in vivo*. Although measures designed to mitigate these effects may enhance gene transfer, unfortunately, the location of receptors for adenovirus and AAV on the basal (nonairway) surface of the bronchiolar epithelium may prove an insurmountable obstacle to the use of these vectors for topical gene transfer in CF, unless their tropism can be redirected to apical receptors. Recently, other viral vectors have been developed that may transduce airway cells via the apical (airway) surface, including lentivirus pseudotyped with envelope glycoproteins from viruses that naturally infect the airway epithelia via the apical surface. Finally, inefficient transduction of epithelia has been demonstrated using nonviral vectors and oligonucleotides via the bronchial circulation, raising the possibility that gene delivery to the basal surface of the cells may be achievable. It remains to be seen whether these modified vectors or other approaches can solve the problems of efficiency, gene expression longevity, and toxicity inherent in techniques used hitherto.

4.1.4 Neurological Disease

Gene transfer to the brain presents a number of formidable challenges. Brain tissue is inaccessible to vectors from the circulation, enclosed in dense bone, extremely sensitive to functional disruption by mechanical manipulation, nonregenerating and physiologically vital. This means that *ex vivo* transduction cannot be carried out, except in rare circumstances where there is good reason to think that bone marrow stem cell transduction will allow correction of a neurological phenotype. For example, in the severe childhood cerebral inflammatory type of adrenoleukodystrophy, bone marrow transplantation early in the course of the illness appears to arrest the progressive cerebral disease, and it is reasonable to suppose that genetic modification of endogenous bone marrow stem cells might also be efficacious. For most neurogenetic diseases, however, *in vivo* gene transfer will be necessary to correct the genetic abnormality present in the brain or spine. This might be achieved through direct inoculation of vector into the area of the brain in which the pathological process is manifest. For example, replacement of the *Parkin* gene in juvenile onset Parkinson's disease might be targeted to the substantia nigra as the bulk of the initial pathology appears here. Alternatively, some viruses are transported into the CNS from peripheral sites, or within the CNS from one location to another, by axonal transport. This may allow vector inoculation at a remote and more accessible site, for example, muscle inoculation in gene therapy targeted at diseases of the motor neuron.

The pathology in many types of hereditary neurological diseases is widely distributed, and there is no good method at present for widespread *in vivo* gene delivery in the brain, as would be needed to correct the phenotype of recessive diseases like Friedreich's ataxia, fragile X

mental retardation, or Hallervorden-Spatz disease. Consequently, clinical optimism at present is limited to diseases in which the pathology is localized, or rare conditions in which the missing gene product is normally located extracellularly or can be taken up by cells adjacent and remote to those transduced. Examples of the latter groups of diseases include the rare mucopolysaccharidoses with CNS involvement, where successful phenotypic outcomes have been seen following gene transfer in animal models.

Two further barriers present obstacles for gene therapy of single-gene diseases of the CNS. First, most of the adult-onset and many of the childhood-onset conditions are inherited in an autosomal dominant pattern and are caused by pathological gain of function or dominant negative effects. Examples of these diseases include the spinocerebellar ataxias, Huntington's disease, inherited prion diseases, and familial Alzheimer's diseases, the commonest forms of dystonia and some developmental diseases. Gene therapy in these cases would depend on gene targeting, possibly with gene replacement, rather than gene delivery on its own. There has been progress in this field, including development of RNA interference technology, but there have been no clinical gene therapy trials in these diseases. Second, the majority of these disease run their course over years and decades, and, as the brain is not an accessible site for repeated vector inoculation, long-term expression of transgenes would be highly desirable before gene therapy for these disease could be contemplated. It is likely that, for these type of applications, success will be achieved by exploiting the properties of viruses that persist long-term in the nervous system as part of their natural life cycle.

4.1.5 Muscle

Duchenne muscular dystrophy (DMD) is a common (1 : 3500 male births) genetic disease of muscle that results in progressive muscle wasting and death by the age of 15 to 20 from respiratory impairment or cardiac disease. It is caused by the loss of a muscle protein, dystrophin, which forms part of a large complex of proteins that localize to the sarcolemma of muscle fibers and function to maintain the integrity of the muscle cell membrane during contraction. The dystrophin gene is very large (the cDNA is >10 kb) and therefore can only be accommodated within gutless adenovirus or herpes simplex virus vectors – both of which are inefficient vehicles for transduction of muscle. Much work has been carried out in trying to develop truncated functional versions of the dystrophin gene that may be accommodated in adeno-associated virus vectors, which appear more promising as vectors in muscle tissue. A group of conditions, the sarcoglycanopathies, are closely related to DMD. They are caused by mutations in genes encoding other components of the protein complex of which dystrophin is part. These genes are smaller and can be readily accommodated within adeno-associated virus vectors. Successful correction of either the dystrophin- or sarcoglycan-deficient phenotypes presents a number of significant challenges, however, even if a useful vector system can be developed. First, the tissue compartment requiring transduction by the vector is vast and is distributed throughout the body, necessitating many multiple points of inoculation or systemic delivery. Second, functional recovery of an individual muscle is likely to depend on the transduction of a threshold proportion of muscle fibers, by introduction of a transgene at a number of sites along the syncitial muscle

fiber, so inefficient or incomplete transduction would likely be ineffective even if distributed over the large tissue compartment. Although a number of preclinical and clinical studies have shown proof of concept that dystrophin and other missing proteins can be expressed transiently in dystrophic muscle, no clinical studies have yet demonstrated any phenotypic benefit.

4.2 Delivery of Proteins for a Pharmacological Action

Gene therapy has much broader potential application than the delivery of genes that are missing in inherited Mendelian recessive diseases. There are many examples of potently active biological proteins whose delivery to specific sites might be useful to correct the abnormalities in certain diseases. Delivery of these proteins might be best accomplished by gene transfer, either because of convenience or costs issues (it is very expensive to manufacture purified recombinant proteins, and difficult to continuously administer them to sites such as the brain or joints), or because of biological necessity (for example, proteins that act intracellularly, or proteins intended to act at the cell surface of targeted cells only, would have to be expressed within the target cell unless some form of highly efficient protein transduction could be developed). The following paragraphs describe some potential applications of gene therapy to allow protein pharmacology rather than gene function replacement.

4.2.1 Transplantation

Rejection is a serious and common consequence of organ transplantation, necessitating the use of potent and toxic immunosuppressant drugs, often with incomplete suppression of rejection. Rejection of transplanted tissue depends on host CD4 and CD8 T-cells becoming activated in response to the transplantation of foreign antigens. There has been much work focusing on molecular definition of the events that follow stimulation of the T-cell receptor by antigen bound to the surface of antigen presenting cells (APC). It appears that interaction of T-cell CD28 with antigens CD80 and CD86 present on the antigen presenting cells favors immune activation, whereas signaling through another T-cell receptor, CTLA-4, results in downregulation of the immune response. Systemic blockade of the CD28 – CD80/86 interaction in animal models, using a chimeric antibody, results in systemic immune suppression. Recent work has examined the possibility of expressing the blocking antibody locally in the allograft by gene transfer; although this improved graft survival, it also resulted in systemic immune suppression. A similar approach to blocking the interaction between T-cell ligand CD154 with the APC receptor CD40 resulted in suppression of acute rejection, but not chronic rejection. Following costimulation, T helper cells secrete cytokines, with particular profiles that correlate with either rejection (Th1 response) or lack of rejection (Th2 response). Consequently, it has been suggested that creating a Th2 response in the transplanted tissue may prevent rejection. As most cytokines are associated with severe adverse side effects on systemic administration, the local production of Th2 cytokines, for example IL-10, in the graft has been suggested, using gene transfer. This approach enabled modest prolongation of graft survival in animal models. Other parallel approaches have focused on genetic modification of antigen presenting cells, causing them to synthesize immune

tolerance–inducing factors like TGF-β, or factors that specifically cause elimination of activated T cells, for example, *Fas* ligand. Finally, another approach to the induction of immune tolerance using gene transfer relies on the observation that hosts carrying allogeneic bone marrow transplants exist in a state of mixed host-donor hematopoietic cell chimerism, in which specific tolerance to donor antigens develops. On the basis of this observation, gene transfer strategies have been devised in which donor MHC molecules are expressed in host hematopoietic cells using *ex vivo* gene transfer. In several animal models, this seems to induce hyporesponsiveness to the transplanted antigens, allowing prolonged graft survival without compromising systemic immunity. None of these approaches has yet proven sufficiently successful in preclinical studies to warrant testing in a clinical trial, although the field is moving rapidly and the potential applications for gene transfer expanding in parallel with understanding the processes involved in transplant rejection.

4.2.2 Ischemic Heart Disease

Ischemic heart disease is the leading cause of death in the western world, and is most commonly caused by atheromatous occlusion of the coronary vessels. The blood supply to the myocardium becomes compromised and there may be a supply/demand mismatch resulting in cardiac ischemia or infarction. Conventional therapy includes addressing factors that may contribute to the development of atheroma, drugs that improve cardiac perfusion or reduce cardiac oxygen and energy demand, or various re-vascularization procedures. The success rate of these procedures is less than perfect, and restenosis is common after revascularization procedures like angioplasty or bypass grafting. Consequently, there has been considerable interest in gene therapy approaches that might help to encourage endogenous neovascularization in areas of ischemic myocardium through the local expression of potent peptide factors that encourage growth of new blood vessels (for example vascular endothelial growth factors, VEGF1 and VEGF2, and fibroblast growth factors FGF1 and FGF4), or the introduction of genes encoding transcription factors that are instrumental in executing the coordinated neovascularization response (for example hypoxia-inducible factor-1α, HIF1α). Transfer of these genes to ischemic myocardium or limb tissues has been demonstrated in preclinical studies using adenovirus and adeno-associated virus vectors in addition to nonviral vectors. First- and second-generation AdV gene transfer, as elsewhere in the body, gives rise to nonsustained gene expression and a local inflammatory response. In many of the preclinical studies, expression of the growth factor or transcription factor resulted in significant angiogenesis. Clinical studies have demonstrated the feasibility of intracardiac or intracoronary administration of the gene transfer reagents encoding angiogenic growth factors. Most of the studies have been small and primarily aimed at assessing safety rather than efficacy. Even so, markers of cardiac ischemia that would not be expected to be susceptible to placebo artifact, such as SPECT scanning or angiography, were improved in two of the trials examining VEGF2 expression in the myocardium or endocardium. A single double-blind placebo-controlled trial examined intracoronary gene transfer using an adenovirus vector encoding FGF-4. This trial did not demonstrate any statistically significant benefit from the treatment. Understanding the factors, for example,

the longevity of gene expression, that underlie successful revascularization is still incomplete and it is expected that further advances in gene delivery technology and vascular biology will pave the way for success in this field.

4.2.3 Neurological Disease

The common sporadic form of Parkinson's disease does not have a known or defined genetic basis, yet many potential protein-based interventions have been identified through work in tissue culture and animal models. These include intracellular proteins (for example antiapoptotic factors to prevent cell loss or enzymes to enable functional rescue of the abnormal neurochemical phenotype following cell loss) or extracellular proteins (for example growth factors that might allow restoration of the damaged basal ganglia circuitry). One recent study described the intraputaminal infusion of recombinant glial cell-line derived neurotrophic factor (GDNF) in PD patients, with beneficial effects on functional imaging surrogates of cell integrity. The infusion of GDNF may prove to be clinically efficacious and was associated with few minor adverse effects. The route of administration is, however, cumbersome and expensive; therefore, *GDNF* gene delivery has many possible advantages over the local infusion of recombinant factor. These advantages might include the capacity for prolonged local synthesis and delivery of the factor *in situ*, in addition to convenience and cost issues. However, it will be essential to develop vectors that allow regulated gene expression and sustained transgene expression before *GDNF* gene delivery might be contemplated.

Using a different approach for *PD* gene therapy, a clinical trial is about to commence using an AAV vector to transfer a gene encoding the enzyme glutamic acid decarboxylase (GAD) to the brain. This strategy is based on a number of observations concerning the functional abnormalities present in the basal ganglia of patients with PD. Neurons of the subthalamic nucleus (STN) are generally overactive in PD and secrete an excitatory neurotransmitter, glutamate, which acts to increase the firing rate of postsynaptic neurons in the internal *globus pallidus* and *substantia nigra pars reticulata*. It is known that electrically evoked reduction in STN overactivity in PD can be therapeutically efficacious. GAD is involved in the synthesis of an inhibitory transmitter, γ-amino butyric acid (GABA). STN neurons expressing GAD produce mixed excitatory/inhibitory postsynaptic responses. This may functionally alleviate the effects of STN overactivity by partially antagonizing the postsynaptic responses to STN overactivity. The clinical trial has recently begun to recruit patients and will address toxicity and dosing issues rather than therapeutic effectiveness in the first instance.

Other examples of gene transfer–mediated protein pharmacology in neurology might include the targeting of neuroimmunological regulatory molecules in diseases with a prominent inflammatory or immune component, such as multiple sclerosis (MS). For example, it is known that the antiinflammatory cytokine β-interferon is weakly efficacious when administered systemically in relapsing-remitting MS. Various animal models of autoimmune myelin destruction have shown that pathological effects can be mitigated by expression of a range of antiinflammatory cytokines in the cerebrospinal fluid and extracellular fluid of the CNS parenchyma, following transduction of the meninges as depot sites for production. It is possible that this may be

a viable way to deliver immunomodulatory molecules to the CNS.

4.2.4 Cancer Gene Therapy

Despite recent advances in clinical oncology and radiotherapy, many types of cancer are still associated with a poor prognosis, and many of the current best treatments are highly toxic. Gene therapy thus provides an attractive experimental approach to developing novel therapeutic reagents to tackle malignancy. Of human clinical gene therapy trials carried out so far, the majority have been in patients with various cancers, reflecting both the desperate need for better treatments and the perceived potential for this technology to yield favorable results.

The aims of cancer gene therapy are rather different to those of other gene therapy applications, in that the gene therapist seeks to selectively destroy target cells. This has been accomplished in a number of ways, including the following:

(a) *Suicide gene therapy*. The transgene product is toxic to expressing cells. An example is the HSV-thymidine kinase-ganciclovir (TK-GCV) system in which expression of viral TK allows activation of a prodrug (GCV) that interferes with DNA replication in rapidly dividing cells.
(b) *Radiosensitization*. The transgene product enhances the toxicity of gamma irradiation in the tumor. TNF-α is an example.
(c) *Immunotherapy*. The transgene product stimulates an immune response directed against tumor. Examples include CD80, TNFα, GM-CSF, IL-2, interferon-γ, and IL-12.
(d) *Restoration of cellular functions altered during oncogenesis*. Many tumors acquire means of avoiding apoptosis in response to the mutations in cellular DNA that often occur during oncogenesis. A common example is the loss of p53 signaling that occurs in many types of solid tumors. Replacement of p53 function in this instance can cause the malignant cells to undergo apoptosis. Other examples might include delivery of other tumor suppressor genes that are mutated in the tumor, or targeting oncogene products or their related cellular pathways to suppress tumor growth.
(e) *Disruption of tumor blood supply*. Most tumors excite an angiogenic response that allows continuing, and adequate, metabolic support for the expanding the tumor mass. Gene therapy can be designed to interfere with this process, causing the tumor to outgrow its blood supply and undergo necrosis.

The mode of action of these reagents is to effect selective destruction of malignant cells. It follows that some means of targeting is essential to prevent destruction of normal tissue. This might be accomplished in several ways. Firstly, strategies might be designed that rely on limiting the expression of a universally toxic gene product to cancer cells. For example, targeted viral delivery, by engineering the tropism of the vector, or targeted transgene transcription in malignant cells, by using specific regulatory elements in the transgene expression cassette, might accomplish the limited spatial expression of a toxic suicide gene product. Secondly, strategies might be deigned that rely on the differential toxicity of a gene product expressed in both normal and malignant cells. Gene products that are directly and selectively toxic to cancer cells could be expressed by both normal and malignant cells, with a preferential effect on the latter. An example might include the HSV-TK

system, where the rapid cell division characteristic of malignant cells renders them especially sensitive to disruption in cellular DNA synthesis. Alternatively, gene products could be expressed within a tissue, in order to induce an immune response, which is preferentially directed against the tumor, by virtue of its abnormal antigenic signature. The first of these general approaches is still in early stages of development, as the problems inherent in effecting targeted vector transduction and cell-specific vector-mediated transcription have yet to be fully overcome. In addition, these targeting strategies will depend upon better definition of tumor-specific features, such as tumor-restricted cell surface receptors and cis-acting regulatory elements that are preferentially active in cancer cells. This type of strategy is extremely attractive, however, because there is a theoretical possibility that avid and highly specific targeting would allow systemic administration of the vector, with resulting selective destruction of metastatic tumor deposits. This is rarely achievable in current practice, with few notable examples, such as the ablation of metastatic well-differentiated thyroid tumors through targeting a defined cellular phenotype, the uptake of iodine, allowing selective sequestration of radioactive iodine. It is hoped that similar molecular targeting through gene therapy will allow parallel approaches to be taken in targeting defined cellular processes unique to tumor tissue.

Various gene transfer vectors have been used in preclinical and clinical trials of cancer gene therapy, including replication-deficient lentiviruses, adenoviruses and herpes simplex viruses, and conditionally replicating HSV and adenoviruses. It is not yet known which vector is optimal, and it is likely that different vectors will show utility for specific applications. For example, the high-level transient expression and immunogenicity of AdV may have application for suicide gene therapy and immunotherapy applications in rapidly dividing tumors, whereas the long-term gene expression and capacity for multiple transgenes seen with HSV vectors may make them good candidates for use in slower growing tumors where multiple simultaneous pathways must be targeted to achieve tumor eradication, for example, glioblastoma.

5 Adverse Events

Considering the number of patients treated with gene therapy in clinical trials, there have been relatively few serious adverse events that have threatened the lives of participants. Nevertheless, those that have occurred have been rather dramatic.

5.1 Multiple Organ Failure Secondary to Cytokine Storm

In the late 1990s, a dose-escalation phase I trial was carried out by the Human Gene Therapy Institute at the University of Pennsylvania. This trial involved the use of replication-defective adenovirus, carrying the gene encoding ornithine transcarbamylase (OTC), to treat inherited OTC deficiency. OTC normally functions as part of the urea cycle, to detoxify nitrogen produced during hepatic amino acid metabolism. The disease phenotype varies in severity; the most significant disease is associated with a completely defective gene. Failure to detoxify hepatic nitrogen leads to hyperammonemia and metabolic coma, which may be fatal if left untreated. It was hoped that successful

safety testing of the AdV-OTC vector would eventually lead to the treatment of children suffering from this fatal disease, following successful gene transfer in preclinical studies. However, following review of the protocol, the study was redesigned to enroll adult patients with mild disease. One such patient, Jesse Gelsinger, received the highest dose of vector (3.8×10^{23} infectious particles) at the top end of the dose-escalation schedule. Within hours, he developed a fever, accompanied by biochemical evidence of hepatic damage. Inflammatory cytokines appeared in the blood, followed by signs of disseminated intravascular coagulation, and respiratory and multiorgan failure. He died within four days of receiving the vector. A second patient had received a similar dose of vector, but did not experience severe side effects.

It was concluded from this study that adenovirus introduced through the hepatic portal vein was not confined to the liver, and that the virus had a greater propensity to infect Kupffer cells than hepatocytes in humans. Kupffer cells are reticuloendothelial cells, which were probably responsible for the release of high levels of circulating cytokines following transduction with recombinant adenovirus. This result differed enormously from the experience in mouse models of OTC deficiency, in which the AdV vector largely infected hepatocytes by the same route of administration. Studies in primates showed toxicity similar to that observed in the patient who died.

This outcome demonstrated that the initial immune response to very high doses of vector can be potentially life threatening. Indeed, high doses of any virus will probably result in toxicity, due to the significant load of virus proteins, rather than the transgene. A fire storm of criticism directed at the field of gene therapy followed this unfortunate adverse event. The development of stricter control over gene therapy clinical research was an inevitable result. This outcome at Penn essentially eliminated the use of adenovirus-based vector for liver gene transfer and reduced the interest in using adenovirus *in vivo* for applications other than cancer gene therapy or vaccines, where the immunogenicity of the vector would be advantageous. This has, in turn, focused attention on other vector systems and accelerated progress in other areas.

5.2 Leukemia Secondary to Insertional Mutagenesis

The one true cure of an inherited disease by gene therapy was achieved in the treatment of severe combined immunodeficiency (SCID). There are 60 genetic defects that can lead to the SCID phenotype. Deficiency of the common γc chain of the cytokine receptor results in failure of maturing B and T cells to respond to cytokine induction for both proliferation and maturation. The γc gene is located on the X chromosome, and correspondingly, the disease is inherited as a Mendelian X-linked recessive trait. Death at an early age, secondary to recurrent infections is the usual outcome, unless the children can be treated by donor-matched bone marrow transplantation, which has approximately an 80% success rate. Children without matched donors are treated by transplant with a relatively low success rate and at considerable risk.

Replacement of the missing γc chain gene by *ex vivo* gene transfer to autologous CD34+ hematopoietic stem cells was carried out in patients after successful outcomes in preclinical studies, using a retroviral vector encoding the γc cDNA under transcriptional control of the retroviral

LTR promoter. The transduced cells were reintroduced into the patients, and initial results showed repopulation of bone marrow with differentiating cell lineages and appearance of the missing differentiated cell types in peripheral blood. Correspondingly, there was recovery of immune functions, with many of the 10 treated patients no longer experiencing recurrent infections and dependence on antibiotic therapy (see above).

Unfortunately, after an interval of three years, it became apparent that two of the patients had developed clonal expansion of a T-lymphocyte subpopulation, with peripheral lymphocytosis, bone marrow infiltration and splenomegaly – clinical signs of leukemia. In each case, the clone, which in retrospect was detectable in samples from the patients at earlier time points in the follow-up process, contained a single copy of the retrovirus integrated into the host cell chromosome 11, within or near the *LMO2* gene. The leukemia cells contained additional dyskaryotic abnormalities, including a t(6 : 13) translocation in one patient and clonal populations with various abnormalities including trisomy 11 in the other. Both patients are undergoing chemotherapy at the time of writing this review.

It is acknowledged that there was no reason to suspect that this outcome would occur – a decade of clinical trials using retroviruses to transduce hematopoietic stem cells preceded the SCIDX trial, without a single case of leukemia occurring. In all reports of mice receiving retrovirally transduced HSCs, there is one description of a single animal that developed myeloid leukemia secondary to integration of the vector within a protooncogene that was previously implicated in leukemogenesis. LMO2 is a leukemogenic oncoprotein, as determined by murine transgenic overexpression experiments, which is activated in human childhood acute leukemia. It is transcriptionally active in progenitor cells, which may explain the propensity of the vector to integrate within this gene. It is unclear how integration into this gene contributed to the formation of leukemia in the SCIDX trial patients. The prolonged latency between retroviral integration and malignant clonal emergence argues that additional factors must have been involved, other than insertional mutagenesis following the transduction event. For example, unregulated expression of the γc chain from the viral LTR promoter may have contributed to malignant transformation; there are reported precedents of leukemias that are dependent on γc cytokine signaling. Furthermore, the disease may have provided unique circumstances resulting in oncogenic interaction between multiple factors. The combination of LMO2 upregulation, unregulated γc expression, and the disease-related immune deficiency preventing detection and eradication of malignant clones may have allowed subclones with additional oncogenic mutations to emerge. These possibilities are currently being investigated further.

The implications for the development of gene therapy mediated by integrating vectors are significant. First, there will be more interest in the integration of vectors into protooncogenes, and preclinical trials and toxicity studies will have to address site of integration issues. Second, vector design may be modified to incorporate tissue-specific regulatory elements, self-inactivating viral LTR sequences and insulators to prevent the inadvertent activation of neighboring genes following integration. Third, it may be desirable to incorporate a suicide gene into the vectors so that transduced clones that become

malignant can be eradicated pharmacologically. Finally, research in understanding the processes that determine the site of vector integration may be expanded, with the aim of learning how to manipulate the mechanisms involved and direct insertion into an inert part of the genome.

While there is still great skepticism regarding the future of gene therapy, the majority of workers remain optimistic that many of the problems encountered are not substantially more difficult than those seen in other fields where new technology is under development, including transplantation and cancer chemotherapy.

6
From Bench to Clinic – HSV-mediated Gene Therapy of Pain as an Example

One example of therapeutic gene transfer is the use of HSV vectors in the treatment of chronic pain. Chronic pain is defined as pain that persists beyond the course of the acute insult, or pain that accompanies a chronic primary process that cannot be cured. Although the majority of chronic pain can be effectively treated with existing remedies, a significant minority of patients cannot, resulting in substantial morbidity and cost. The neuroanatomic pathways involved in pain are identical to those involved in the perception of acute painful stimuli, but alterations in gene expression in neuronal and nonneuronal elements at many levels of the neuraxis produce an altered substrate that result in symptoms that are refractory to medical management. The traditional pharmacologic approach to chronic pain is epitomized by the search for small molecule agonists that would be selective for elements in the pain pathway, but most of those components are not unique to nociceptive neurotransmission. Opioid receptors, for example, are present at all levels of the neuraxis, including the central and peripheral terminals of primary nociceptors, second-order neurons in dorsal horn of spinal cord, and nuclei in the brain and brain stem and are also found in nonneural tissues including bladder, gut, and inflammatory cells. Even though opiate drugs are highly effective, their continuous use for treatment of chronic pain is limited by side effects that occur because activation of receptors in nonnociceptive pathways results in sedation, constipation, urinary retention, and respiratory suppression. Continued use results in tolerance so that increasing doses of the drug are required to achieve maintain the therapeutic effect and abuse is a potential problem. The gene therapy approach to the treatment of chronic pain exploits gene transfer to achieve local release of neuroactive peptides to reduce pain. HSV-based vectors are uniquely suited to this purpose because subcutaneous inoculation of the vector can be used to transduce dorsal root ganglia (DRG) in an anatomically predictable manner to effect the release of analgesic peptides from axonal terminals of the DRG neurons in the dorsal horn of spinal cord.

Animal models have been developed that recapitulate the essential features of inflammatory pain, neuropathic pain, and pain caused by metastatic cancer, which can be used to predict the response of human patients to analgesic drugs. We tested HSV vectors in each of these models. We constructed an HSV vector containing the coding sequence for human proenkephalin under the control of a human cytomegalovirus immediate-early promoter (HCMV IEp) in a vector background deleted for a single essential immediate-early HSV gene (*ICP4*), termed *vector SHPE*. We demonstrated *in vitro* that neurons transduced with the vector

produce human proenkephalin, and release enkephalin into the medium, and demonstrated *in vivo* that subcutaneous inoculation of the vector resulted in transduction of DRG neurons and production of proenkephalin *in vivo*. In the formalin test, a model of inflammatory pain created by injection of a dilute solution of formalin, inoculation with SHPE produced a substantial and statistically significant reduction pain that was reversed by intrathecal naltrexone, a relatively selective delta opiate receptor antagonist. The effect of vector inoculation was maximal in animals tested one week after vector administration, waned over the subsequent three weeks, but could be reestablished by reinoculation of the vector.

Pain resulting from nerve damage (neuropathic pain) can be modeled by selective ligation of a single spinal nerve. Subcutaneous inoculation of SHPE into the plantar surface of the foot one week after selective L5 spinal nerve ligation provided an antiallodynic effect that began one week after inoculation and persisted for five weeks. Like the analgesic effect of SHPE in the formalin model of inflammatory pain, the antiallodynic effect of SHPE inoculation in neuropathic pain was reversed by intraperitoneal naloxone, and reinoculation of the vector after the initial effect had waned promptly reestablished the allodynic effect. The antiallodynic effect of SHPE-mediated enkephalin expression was continuous throughout the day, was additive with morphine, shifting the ED_{50} for morphine from 1.8 mg kg^{-1} to 0.15 mg kg^{-1}, and the effect of SHPE-mediated enkephalin expression persisted in the face of tolerance to morphine. Animals treated with the maximum dose of morphine (10 mg kg^{-1} twice a day) developed tolerance by one week, so that morphine no longer provided any antiallodynic effect. In contrast, animals that had been inoculated with SHPE continued to demonstrate an antiallodynic effect even after three weeks of morphine treatment.

An important consideration in moving from preclinical animal studies to human trials is the selection of an appropriate condition so that the potential risks of the novel therapy are justified, and even though chronic pain is a cause of significant suffering, the condition itself is not life threatening. Therefore, we examined the analgesic effect of the subcutaneous inoculation of SHPE in a murine model of pain resulting from cancer metastatic to bone. Tumor-bearing mice develop a spontaneous pain behavior that can be rated. Animals inoculated with a control vector manifested spontaneous pain-related behavior that increased over the subsequent two weeks, while mice inoculated with SHPE one week after establishment of the tumor showed a substantial and statistically significant reduction in pain-related behavior, and an effect that was synergistic with morphine and could be reversed by intrathecal naltrexone.

On the basis of the preclinical data in the several different rodent models of pain, we are moving forward with plans for a human trial. The plans for this phase I/II safety/dose-escalation trial of the proenkephalin-expressing vector was reviewed by the recombinant DNA Advisory Committee (RAC) of the NIH in June 2002, and the request for an investigational new drug (IND) waiver to the Food and Drug Administration has been submitted. The HSV vector for the human trial will be deleted for two IE HSV genes (*ICP4* and *ICP27*) and contains deletions in the promoters for two other IE genes (*ICP22* and *ICP47*). The proenkephalin transgene has been

placed in both copies of ICP4, so that in the unlikely event of recombination with a latent wild-type virus, the recombinants would be replication defective. In the trial, we will enroll patients with cancer metastatic to a vertebral body, resulting in pain refractory to maximal medical management. The primary outcome of this phase I/II trial will involve standard measures of safety assessed by common criteria. Secondary measures will include an evaluation of the focal pain using an analog pain ''thermometer'', global measures of total pain using a similar tool, as well as assessment of pain-related phenomena such as sleep and depression and the concurrent use of analgesic medication, including opiate drugs.

In animal models, HSV-mediated gene transfer to DRG neurons achieved by subcutaneous inoculation is effective in expressing peptides to be released locally from sensory neurons to achieve focal therapeutic effects. The proposed human trial will allow us to determine whether the same approach may be used in the treatment of patients, and will be the first step in the use of this therapy for pain and polyneuropathy. Proenkephalin is not the only transgene that may be used in gene therapy for chronic pain. In other studies, we have found that HSV-mediated expression of glutamic acid decarboxylase, antiinflammatory peptides (interleukin 4 or the tumor necrosis factor alpha soluble receptor), or the glial cell derived neurotrophic factor, all have analgesic effects in different models of chronic pain. HSV-based vectors may ultimately serve as the platform to deliver a number of different genes whose products have analgesic properties in the treatment of specific types of chronic pain.

7
Future Prospects – What will Gene Therapy Likely be About in 10 Years?

Gene transfer as a method to alter the biology of cells has almost unlimited potential providing safe and effective methods for gene delivery and expression can be developed. It appears likely that this can be achieved and indeed certain human viruses have largely accomplished this task. Vectors that integrate have great potential for gene delivery to dividing cells where long-term expression is required. The retroviruses are currently the vector of choice and lentiviruses in particular may become the dominant vector type since cell division is not required for vector entry into the nucleus and integration can be mediated by the vector integrase. However, integration is essentially random with a propensity for integrating at sites of open chromatin and active genes. The problems associated with gene inactivation by insertional mutagenesis or the activation of potential oncogenes is not just theoretical, posing safety concerns with the use of these vectors. Future work on the development of these viruses will endeavor to target integration, remove promiscuous enhancers in the vector LTRs, and attempt to take advantage of tissue-specific enhancers that may limit expression to certain stages of development or cell type. Also, the possibility exists that certain phage integrases may be useful if expressed from the vector along with movable elements that might achieve targeting to specific loci or chromosomal sites. Another important development may result from a better understanding of mechanisms of vector uncoating and gene expression. For example, AAV transduces many cell types with poor efficiency, requiring large multiplicities to

achieve transgene expression. Uncoating may be enhanced through use of different serotypes or through manipulation of the capsid. AAV may also be delivered in recombinant form within the genome of larger vectors such as HSV, where transient expression of rep, for example, may induce excision and subsequent integration of the AAV genome into a safe site within chromosome 19. HSV has a very large packaging potential, which can be fully realized if there were a packaging cell line available. The engineering of such cell lines is possible and may be achieved in the coming years. Other possibilities for improvement involve the establishment of precise methods of vector targeting and transgene expression. There are likely to be numerous viral or cellular genomic sequences that act in cis to influence transgene expression and these must be discovered, characterized, and applied in the context of the virus genome. The rules that govern gene expression in the virus genome are still unclear. Engineering the virus coat or envelope will continue until suitable methods are developed. Secondary targeting at the nuclear membrane may also be possible. The future will also include multigene therapies requiring the interaction of multiple gene functions to achieve a therapeutic outcome including genes, which trigger the differentiation and survival of stem cells that can rebuild damaged tissues. In general, gene transfer may become a very important tool for directed tissue development.

Diseases that are the most likely targets for gene therapy within the next 5 to 8 years will include the modification of responses in the host that either lead to improved immunity to infectious diseases or cancer, alter the host response to painful stimuli, reduce autoimmune reactions, and improve transplant tissue survival or improve the outcome for damaged tissue such as ischemia in the heart. Also, in the short term, it is likely that certain metabolic diseases such as hemophilia or inborn errors of metabolism that result in immunodeficiency or toxic metabolic states will show signs of success. Longer term, the use of gene transfer for tissue engineering, and stem cell applications for tissue repair will began to unfold. While these comments are only speculative, there is reason to believe that many of these applications are nearing the era of real benefit to patients and even if only a few of these applications are successful in the near term, gene therapy as a practical modality of medical therapy will have reached its early stages of promise.

Keywords

Chloroplast
A cytoplasmic organelle that is central to the photosynthetic process in plants.

Heteroplasmy
The occurrence of multiple forms of mitochondrial DNA (mtDNA) in the same individual.

Mitochondria
Cellular organelles containing the protein machinery for oxidative phosphorylation.

Oxidative Phosphorylation
A cell metabolism process by which cellular energy (ATP) is produced from ADP.

The mitochondria of eukaryotes contain a genome of their own, the mitochondrial DNA (mtDNA). The mitochondrial genome of metazoans is a covalently closed circular molecule with a size of about 16 kilonucleotide pairs (kntp). Considerable length differences exist between organism groups (e.g. ciliata >40 kntp, fungi 17–176 kntp, higher plants 200–800 kntp). In vertebrates, the genome encodes 2 rRNAs, 22 tRNAs, and 13 proteins involved in oxidative phosphorylation. This is a multicopy genome with a predominantly maternal inheritance, and in vertebrates, a high substitution rate. A number of mtDNA mutations in humans have been associated with muscular or neurological disease, and the accumulation of mutations in this genome may result in premature aging and contribute to the natural aging process. MtDNA has been one of the main tools used in studies of human evolution and has provided some of the strongest evidence for an African origin of modern humans. This review is biased toward the vertebrate genome due to the wealth of information available from this group. A number of unique characteristics set vertebrate mitochondrial DNA apart from the mtDNA in other organisms, justifying this focus.

1 Structure and Function

1.1 Structure of the Mitochondrial Genome

The mitochondria of multicellular animals (Metazoa) as well as of other eukaryotes contain a genome of their own: mitochondrial DNA. Most mtDNAs are organized as covalently closed circular molecules (or appears as such when a gene map is constructed). Linear molecules have been observed in the coelenterates (hydra), fungi (hansenula, candida), ciliates

(paramecium, tetrahymena), chlorophyte algae (Chlamydomonas), and chrysophyte algae (Ochromonas). Metazoan mtDNA genome range from about 14 kilonucleotide pairs (kntp) in the nematode *Caenorhabditis elegans* to about 42 kntp in scallop, *Placeopecten magellanicus*. All metazoan mtDNA genomes are organized as a single molecule, except that of the cnidarian *Hydra attenuata*, which appears to consist of two 8-kntp circles. By contrast, the mtDNA of other organismal groups are highly variable in size. For instance, the genome of *Paramecium aurelia* exceeds 40 kntps; fungi are sized between 17–176 kntps and higher plants have a genome size of 200 and 800 kntp. Particularly in plants, the genome is divided into a number of circles, with the subgenomic circles ranging from 60 to 240 kntp. In certain protozoans (order *Kinetoplastida*), the mtDNA is found in certain compartments of the mitochondria (kinetoplasts) and consists of maxicircles (14–39 kntp) and minicircles (0.6–2.5 kntp).

1.2 Gene Content and Function

In contrast to the enormous size variation among the mtDNAs of different species, the gene content is to a large extent conserved. Metazoan mtDNA contains the genes for two rRNAs homologous to the 16 S and 23 S ribosomal RNAs of *Escherichia coli*, 22 tRNAs, and 13 open reading frames (ORFs). Six of these ORFs encode enzymes, or components thereof, that are involved in oxidative phosphorylation (cytochrome *b*, CO subunits I−III, ATPase6 and ATPase8). The other seven ORFs encode subunits of the respiratory chain NADH dehydrogenases (commonly referred to as ND1 and ND4L). In addition, a single noncoding region termed the *displacement loop* or D loop is found between the coding sequences (See Fig. 1). The term ''D loop'' refers to the short three-stranded structure formed by displacement of the heavy (H) strand by a short, newly synthesized, H-strand segment. Although noncoding, the D loop contains a number of regulatory signal sequences necessary for the initiation of H-strand replication and for both H-strand and L-strand (light strand) transcription. Extensive length variation has been observed between the D loops of different metazoans and appears to be due to different types of directly repeated segments. While the D-loop region spans about 1 to 2 kntp in vertebrates, it is only about 100 ntp in some species of sea urchins. The intraspecific variability in the length of the D loop is also extensive in some species and is similarly caused by variation in the number of directly repeated segments.

In addition to the homologs for the protein-coding genes in the mtDNA of all metazoan species, plants carry the genes for several other subunits of the respiratory chain (e.g. ATP synthetase F1 complex, and ATP synthetase subunit 9), as well as genes not previously found in mitochondrial genomes, such as the gene for reverse transcriptase. Also, all plant mtDNA carry the gene for 5 S rRNA, not present in animals and only occasionally in fungal mtDNA.

In protozoans, the genome (maxicircle) contains the same protein-coding genes as in metazoan mtDNA and in addition, components of complex I (ND7 and ND8) that are found in the nuclear DNA of metazoan species or the chloroplast DNA of plants. Other components that have been found in the protozoan mtDNA genome are genes for apocytochrome *b* and CO subunits I, II, and III. In some fungi, a number of additional ORFs have

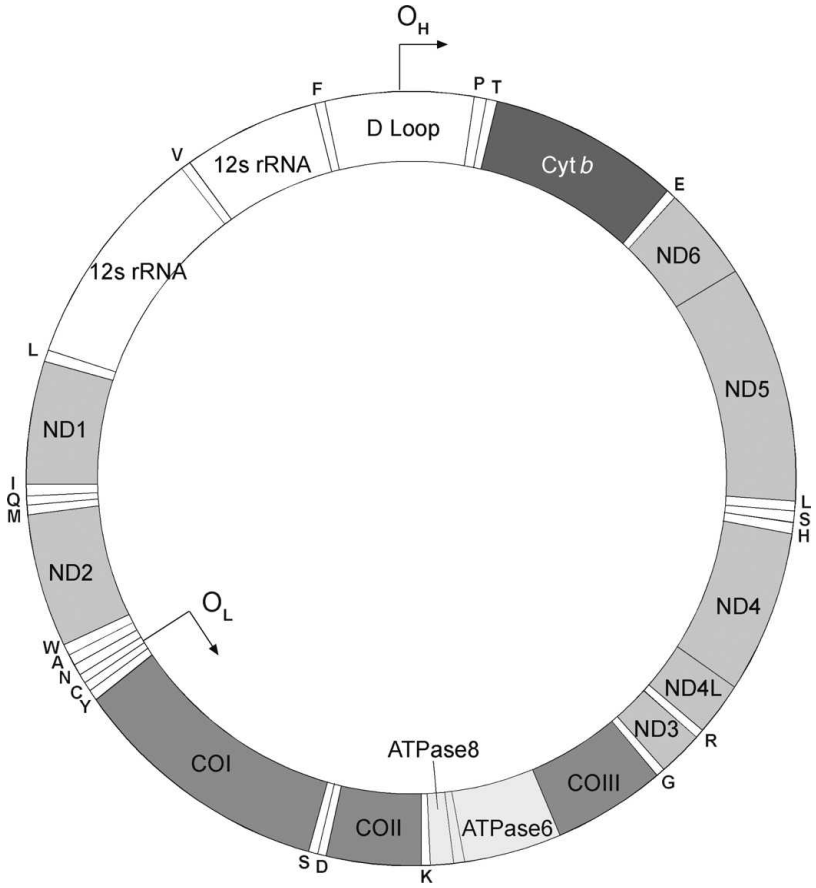

Fig. 1 Outline of the mammalian mitochondrial genome. The location of genes encoding the 2 rRNAs and the 13 proteins are indicated. The locations of the tRNA genes are indicated as white bars in between the protein-coding genes and labeled using standard nomenclature. The major noncoding region (D loop) is located between the tRNA phenylalanine and tRNA proline genes. The origins and direction of replication for the heavy (O_H) and light (O_L) strands are also shown.

been identified, but except for a few (e.g. the variant 1 protein (VAR1) thought to encode a mitochondrial ribosomal protein), no function has been assigned to the products of these ORFs. The genes involved in the translation process also vary in distribution among taxa. While the tRNA genes are present in the mtDNA of most taxa, the number of rRNA genes located in the mtDNA varies between 28 for aspergillus to zero for trypanosomes. The genes for the ribosomal proteins are located in the mtDNA of bryophytes and to some extent in angiosperms and some protists, but are lacking entirely from the mtDNA of other organisms.

1.3 Gene Organization

Most vertebrates and invertebrates have a conserved gene content, but the gene order

may vary considerably between phyla. For instance, among five vertebrate species: human, mouse, bovine, rat, and Xenopus (phylum Chordata), the gene order is identical. The gene order in species from the phyla Echinodermata and Anthropoda differ from the vertebrate gene order by a minimum of two translocations and three inversions. By contrast, species from the phylum Nematoda have such deviating gene orders that no simple scheme has been constructed to account for the differences relative to the gene order of vertebrates.

The organization of animal mtDNA is extremely compact and in contrast to that of nuclear genes, the genome lacks introns (excluding parts of the D loop for which no functional role has been defined). As the only exception to date, the sea anemone (Metridium) apparently contains intron sequences. Also, the coding sequences of many species display variable degrees of overlap, either between the 3′-ends of two genes that are encoded from opposite strands of the molecule or between genes encoded by the same strand. For example, ATPase8 overlaps with ATPase6 by 2 to 46 ntps in vertebrates and in higher invertebrates and ND4L overlaps with ND4 by 7 ntp in vertebrates.

The genome size of fungal mtDNA spans a wide size range (17.6–176 kntp) while being relatively conserved with respect to gene content. This size variation is due to expansion of AT-rich intergenic spacer regions and the existence of large introns. For instance, in species of Podosora, the *CO1* gene covers a total of 24.5 kntp (26% of the genome) and includes 16 introns. The fungi mtDNA genome also appears to encode two proteins associated with introns: intron-encoded maturases, which function in intron excision during posttranscriptional processing of precursor RNAs, and intron-encoded site-specific endonucleases, necessary for intron transposition. In the light of the enormous diversity in genome sizes among fungi, it is not surprising to find that gene order or gene organization differ considerably among species. It is believed that the fungal mtDNA genomes, as a result of the high frequency of intergenic noncoding iterated spacer sequences, can change in organization to exhibit a higher frequency of recombination.

Our understanding of genome organization in higher plants may be biased, since information is to a large extent based on flowering plants. As is the case in fungi, the large and diverse genome size (200–2400 kntp) in flowering plants is due to the occurrence of intron sequences. To an even larger extent than in fungi, plant mtDNA appear to have a propensity for rapid structural change coupled with a low rate of sequence divergence. The plasticity of the genome has been related to the existence of repeated blocks, several kntps long, that occur in both orientations and function as recombination hotspots. Recombination between such regions will generate ''minicircles,'' which can join other ''minicircles'' carrying the same repeat motif. Possibly as a consequence of this organization, the gene order is not strongly conserved among plant species, and genetic exchange between the chloroplast and mitochondrial genomes appears to occur frequently. In contrast to fungi, most of the noncoding mtDNA in plants show no distinctive nucleotide bias (e.g. no AT-rich spacer as in fungi).

1.4 Genetic Code

On the basis of comparisons between the predicted amino acid sequences (using

nucleotide sequence data) and protein sequencing, mitochondrial DNA has a unique genetic code. For example, rather than functioning as a stop codon as it does in nuclear DNA, the triplet TGA specifies tryptophan in all mtDNAs except those of plants. This alteration is likely to have occurred before the divergence of Fungi, Protista, and Metazoa. With the exception of cnidarians, the AGA and AGG triplets of mtDNA specify serine instead of arginine as in the nuclear genome. This alteration appears to have occurred after the cnidarian ancestral lineage diverged from that leading to all other invertebrates. In echinoderms, the AUA codon specifies isoleucine and AAA specifies asparagine instead of lysine. The AAA codon is also thought to specify asparagine in platyhelminths, indicating that the specificity of AAA has changed from lysine to asparagine on two independent evolutionary lineages.

The metazoan transcription machinery also employs unorthodox translation initiation codons. All four ATN triplets are being used as initiation codons in mtDNA in different species (although the subset of codons used varies considerably between species). Finally, the translation terminations of some mammalian mitochondrial proteins end either in T alone or TA, instead of the complete termination codon TAA or TAG. The primary transcript of the mtDNA is a multicistronic RNA, and precise RNA cleavage and posttranscriptional polyadenylation will generate the complete termination codons.

1.5 Transcription and Replication

Transcription of vertebrate mtDNA is initiated at two promoters, heavy-strand promoter (HSP) and light-strand promoter (LSP) located in the major noncoding region of the mtDNA. These promoters mainly direct the synthesis of transcripts from one strand, although they have been shown to be bidirectional under certain circumstances. The evolution of separate promoters for the different strands may be a characteristic that has evolved in the mammalian lineage, since in amphibians (Xenopus) the promoters have a much more pronounced bidirectionality and in birds (chicken) the single available promoter is completely bidirectional. At least two proteins are necessary for transcription initiation: mitochondrial transcription factor 1 (mtTF1) and mtDNA polymerase. The mtTF1 binds −10 to −40 ntps upstream from the promoter and initiates transcription together with the mtRNA polymerase. The function of the mtTF1 is highly conserved among mammals since the mouse and the human mtTF1 can be experimentally exchanged with each other. MtTF1 shows sequence similarity with nuclear high mobility group (HMG) proteins and a nuclear rDNA transcription factor (pol1). There is no known difference between the HSP and LSP promoters with regard to the proteins required for proper initiation of transcription, supporting the hypothesis that they originated by duplication. Termination of transcription of mammalian mtDNA appears to occur at a single site located at the 3′ terminus of the rRNA region.

Mammalian mtDNA has two origins of replication – one for each strand – and a similar organization appears to exist in all vertebrate mtDNA. The origin for heavy-strand (O_H) synthesis is located within the D loop, while that for the light strand (O_L) is surrounded by a cluster of tRNA genes (Fig. 1). Replication always begins at the O_H and synthesis of the light strand is not initiated until

the O_L has been displaced as a single-stranded molecule. The replication event begins with the synthesis of an RNA strand and later shifts into the synthesis of a DNA strand. In the case of the mouse, RNA synthesis appears to begin at the transcription promoter, and therefore replication priming at the O_H depends on transcription promoter function. One transcription initiation event could thus serve for both transcription and replication priming. The transition from RNA to DNA is over a set of conserved sequence blocks (CSB) in the D loop and mediated by an RNAase MRP (mitochondrial RNA processing) enzyme. Priming from the O_L is through a DNA primase that recognizes the target site (O_L). With regard to O_H priming, a stretch of about 15 ribonucleotides is synthesized before the transition to DNA is made. In this case, the transition is located in a tRNA gene: this is the second occasion during which a tRNA gene sequence forms part of the regulatory sequences in mtDNA. After priming and transition to DNA, the mitochondrial γ-polymerase extends each of the strands. This enzyme has the 3′ to 5′ exonuclease activity associated with proofreading activity.

2 Origin of Mitochondria

The difference in the genetic code, circular genome organization and the localization of the mtDNA relative to the nuclear genome suggest that mtDNA has a separate evolutionary origin from the nuclear genome. Two alternative hypotheses have been presented: (1) the mitochondrion and its genome arose through a process of intracellular compartmentalization and functional speciation, occurring within a single kind of cell (autogenous origin), or (2) the mitochondria are evolutionary remnants of endosymbionts, probably of bacterial origin (xenogenous origin). Phylogenetic analyses of mitochondrial sequence data have been performed to address these hypotheses. The most informative analyses have been based on comparisons of ribosomal RNA sequences because of the presence of these genes in all the genome types compared, their functional constancy and equivalence, and the highly conserved primary and secondary structure of the rRNA allowing for precise and relatively unambiguous alignment of sequences. Analyses of rRNA sequences have suggested a new primary subdivision of living organisms. Instead of the five kingdoms (Animalia, Plantae, Fungi, Protista, and Monera) previously recognized, it has been suggested that organisms should be divided into three primary lineages: the archaebacteria, the eubacteria, and the eukaryotes. Archaebacteria contain two major divisions of organisms: (1) sulfur-dependent, extremely thermophilic bacteria, and (2) methane producers and extreme halophiles. Phylogenetic analyses as well as a wealth of other information clearly indicate that archaebacteria have a different origin than eubacteria (containing plastid genomes such as mitochondria and bacteria), although there is still debate over whether they are monophyletic (having a single origin) or paraphyletic (having multiple genetic origins).

In the phylogenetic tree, the mitochondrial tRNA sequences are found in the eubacterial group, showing that they must have a different evolutionary origin than the eukaryotic cells in which they are presently found. In particular, the closest contemporary relatives of mitochondrial rRNA are members of a subgroup of

purple bacteria, providing unambiguous evidence in favor of the endosymbiotic origin of mitochondria of animals, fungi, plants, and ciliates from within aerobic eubacteria. Extant relatives of the aerobic eubacteria family that form intracellular associations with eukaryotes include rhizobacteria, agrobacteria, and rickettsiae.

Although the general origin of mitochondria and mtDNA has been elucidated, a number of issues remain to be determined. Was there a single event of symbiosis or multiple events? Are mitochondrial and plastids monophyletic or polyphyletic? Did mitochondria and plastids (chloroplasts) arise simultaneously or serially? How has lateral gene flow among chloroplasts, plastids, and the nuclear genome affected the present gene content of the different genomes?

It is well known that genes can be transferred between the mitochondrion and the chloroplast, as well as between the chloroplast and the nucleus. Among animals, a number of copies of mtDNA fragments have been inserted into the nuclear genome, but no examples of expressed sequences have been reported. In the mungbean and the cowpea, a copy of the mitochondrial *COII* gene has been found in the nucleus and is transcribed. This transfer is estimated to have occurred 60–200 million years ago, while the loss of mitochondrial COII expression appears to be much more recent. The probable pathway of gene transfer in this case involved reverse transcription of an RNA intermediate. The frequency of transfers that are followed by successful expression appears to be relatively low in higher organisms. This may be partly because, to accomplish expression of the gene, the transcription control element must be present and the gene must contain the sequence of the signal peptide necessary for transport into the mitochondria.

3
Genetics of Mitochondrial DNA

3.1
Inheritance

The mitochondrial DNA of most metazoan species is predominately maternally inherited. In interspecific crosses of mice, the mtDNA of 5–10 mitochondria in the midpiece of the sperm is able to enter the egg and become established in the zygote. The contribution in mice is on the order of 10 paternal mitochondria in 10 000 maternal mitochondria per generation. In humans, one case has been observed where paternal contribution has been documented. Given the very large number of transmissions that have been examined in different human studies, all consistent with an exclusively maternal mode of inheritance, the circumstances under which paternal contribution can occur in humans must be very unique. When paternal contribution occurs, it may generate individuals with multiple types of mtDNA. Low levels of paternal contribution of mtDNA have also been reported in Drosophila. In bivalves (mussels), the contribution appears to be almost equal among sexes, and in forest trees, the mitochondria are inherited through the paternal parent. Hence, there is wide variation between different organisms with respect to the pattern of inheritance of the organelle.

3.2
Heteroplasmy and Segregation

In metazoan species, single individuals frequently contain a population of

molecules differing either by point mutations or in length: a state known as *heteroplasmy*. A heteroplasmic state could arise within individuals through mutational mechanisms, or the mutant mtDNA might be acquired through paternal contribution. The high frequency of some of the variant molecules (50–90%) implies that forces other than the mutation rate are involved in determining the frequency of variant molecules. Mutated mtDNA may increase in proportion as a consequence of selection or strong segregation (genetic drift) during oogenesis or embryogenesis. Different tissues may show different frequencies of variant molecules due to the independence of cellular division and mitochondrial replication.

A number of reports have described the stability of the heteroplasmic state between generations in metazoans, suggesting that segregation during oogenesis is limited. In contrast to these studies, extremely rapid and dramatic shifts in the frequency of different mtDNA types have been reported over a single generation in some mammalian species (Holstein cows). Also, in studies of mtDNA mutations associated with human disease, dramatic changes in the frequency of different mutations have sometimes been seen from one generation to the next. However, the rules governing the transmission and segregation of mitochondria between sexual generations are at present only partly known. Analyses of single cells have shown different levels of heteroplasmy. The mitochondrial vesicles within each of these cells continuously fuse and divide and the mtDNA content of individual vesicles may vary from zero to approximately 15 copies. However, it is not known whether mtDNA distribute among vesicles during the process of fusion.

3.3 Recombination

Recombination in mitochondrial DNA is quite common in plants, where it gives rise to the large number of different sized molecules present. Particular recombination sites (repeats) in plant mtDNA appear to function as hot spots for sequence exchange. Also, in fungi, mtDNA appears to participate in recombination. In mammals, mitochondria are usually inherited from the mother through the egg cytoplasm. In humans, the egg cytoplasm contains a large number of mitochondrial particles whereas the sperm midpiece only carries five to ten. During fertilization, these paternal mitochondria are labeled for degradation through the ubiquitin pathway, resulting in an exclusively maternal inheritance pattern. This uniparental mode of inheritance means that recombination between maternal and paternal mitochondria should not occur.

As early as 1980, Giles and colleagues demonstrated maternal inheritance in human mitochondrial DNA. This was confirmed in intraspecific mouse crosses, while in interspecific crosses, paternal contribution was observed. On the basis of phylogenetic and linkage disequilibrium (LD) analyses, evidence of recombination has been claimed between paternal and maternal human mitochondrial DNA. The results of these studies have been controversial, with criticisms focusing mainly on the statistical method used and a biased dataset. Reanalyses of the dataset using the standard LD measure *D'* show that there is no association of linkage disequilibrium with physical distance.

Paternal mtDNA has been detected in the muscle tissue of a single patient suffering from myopathy while the blood, hair

roots, and cultured fibroblasts of this individual contained only maternal mtDNA. This individual was later shown to harbor recombinant mtDNA, demonstrating that it is possible for paternal mitochondria from the sperm to escape the degradative ubiquitin pathway and potentially recombine with maternal mtDNA. While this may happen in isolated cases, the absence of evidence of recombination in large datasets of human mtDNA sequences suggests that it is rare and does not contribute significantly to the evolution of human mitochondrial DNA.

3.4 Substitution Rate

The substitution rate in the human mitochondrial genome is typically 5 to 10 times higher than that of nuclear DNA, a figure that is consistent across vertebrates. The reason for this higher rate is thought to be due to either a high rate of nucleotide misincorporation or low DNA polymerase repair efficiency. A high concentration of oxidative radicals (superoxide anions H_2O_2) by-products of oxidative phosphorylation have been implicated as a contributing factor to this high substitution rate. These compounds react with lipids, proteins, and nucleic acids and form thymine glycols and 8-hydroxyguanosine in DNA, which may inhibit replication and transcription, leading to longer exposure of triple-stranded DNA to mutagenic compounds. In addition, studies on the reliability of mitochondrial DNA replication have shown that the net average fidelity of the human mitochondrial DNA polymerase (pol γ) is about 1 error per 1–20 million base pairs, a rate that is 1000-fold higher than the error frequency expected for the replication of nuclear DNA. Also, the high turnover rate of mitochondria in tissues would provide more rounds of replication during which errors could be generated. Compounding these factors is an enhanced chance of fixation of new mutations due to low functional constraints on mitochondrial products.

However, an elevated rate of substitution has not been detected for invertebrate, or plant mtDNA, or for chloroplast DNA, where the rate appears to be similar or lower than the substitution rate of nuclear genes. For instance, in plants, the mtDNA substitution rate has been found to be about sixfold lower than that of nuclear genes and threefold lower than that of chloroplast DNA.

4 Mitochondrial Dysfunction and Human Disease

The mitochondrial genome supplies parts of the protein machinery that is necessary for efficient oxidative phosphorylation, using a series of five multiple-subunit enzymes located within the mitochondrial inner membrane. The components needed for oxidative phosphorylation are encoded by both nuclear and mitochondrial genes. The nuclear genome provides a total of 65 subunits, compared to the 13 mitochondrially encoded subunits. A genetic defect in oxidative phosphorylation could be due to mutations in genes of either the nuclear or the mitochondrial genome. On the basis of the number of different genes involved, it may be assumed that nuclear mutations causing mitochondrial malfunction should predominate by a factor of 5. However, differences in the frequency by which new mutations are introduced in the two genomes (see Sect. 3.4), as well

as the clonal inheritance pattern of mitochondrial DNA, may compensate for this difference and indeed result in a higher proportion of mitochondrial dysfunction being due to mtDNA mutations.

4.1 Point Mutations

Point mutations resulting in amino acid replacements have been found to be associated with Leber's hereditary optic neuropathy (LHON) and neurogenetic muscle weakness, ataxia, and retinitis pigmentosa (NARP). A number of different point mutations have been associated with these symptoms, some (like the one at ntp1 1778) account for more than 50% of the LHON cases, while a number of others are private mutations that either alone, or through synergistic effects, cause a similar phenotype. The segregation of the main LHON mutation may occur very rapidly: the proportion of mutated genomes has been found to rise from less than 50% to almost fixation in a single sexual generation.

NARP patients have a very diverse set of symptoms ranging from ataxia and dementia to proximal neurogenic muscle weakness. They have in common a missense mutation at ntp 8993, resulting in a change of amino acid 156 of the ATPase6 from a leucine to an arginine.

Since the mitochondria have their own set of tRNAs, mutation in any of these may cause systemic effects by partial or complete inhibition of mitochondrial mRNAs. A number of different point mutations have been found to be associated with diseases such as myoclonic epilepsy with red-ragged fibers (MERRF) and mitochondrial encephalomyopathy, lactic acidosis, and stroke-like symptoms (MELAS). Patients suffering from MERRF (point mutation at ntp 8344) have uncontrolled myoclonic epilepsy and mitochondrial myopathy that may translate into symptoms such as hearing loss, dementia, myoclonus, and respiratory failure. The severity of the symptoms appears to be related to the proportion of mutated genomes, and the disease has a progressive development. Therefore, an individual with a moderate proportion of mutated mtDNA (20%) and no symptoms at age 20 may have developed severe complications by the age of 65. This progression is believed to be due to the age-related decline of oxidative phosphorylation. Similarly, most MELAS patients have point mutations in the tRNA for leucine (ntp 3243), which also result in an inactivation of an overlapping transcription termination sequence.

4.2 Deletion-insertion Mutations

Insertions/deletions of the mtDNA have been found in patients with Kearns–Sayre syndrome (KSS), chronic external ophthalmoplegia (CEOP) and Pearson's syndrome. The majority of cases of KSS and CEOP involve the deletion of the region in between, but not including, the origins of replication (O_H and O_L). Conceivably, deletions that encompass the two origins of replication, inhibit replication and such mutations are lost during mitochondrial regeneration. More than 95% of cases carry deletions between O_H and O_L: the most frequent deletion (between ntp 8468 and 13 446) occurs in 30 to 50% of patients. In most of the CEOP, KSS, and Pearson's syndrome cases, only a single type of deletion is found, suggesting that these mutations have been generated by a single event, either through slip-replication, homologous recombination, or topoisomerase cleavage. Since most cases are single spontaneous mutations with no family history, they are

likely to have been generated *de novo* in a specific cell lineage during embryogenesis. This may also explain the large differences in the proportion of genomes carrying deletions between tissue types. In many KSS and CEOP patients, there is a progression of the severity of the disease with age, concomitant with an increase in the proportion of deleted mtDNA in the muscle fibers. The deleted genomes in these diseases may be postulated to accumulate over time simply as a consequence of replicative advantage (i.e. their shorter length). In the case of point mutations, such as those described in Sect. 4.1, additional factors (e.g. selection) must be invoked to explain the rapid shift observed between generations or tissue types.

Duplications extending from the *COII* gene to the cytochrome *b* gene, and spanning both origins of replication, have been found in the mtDNA of patients with Pearson's syndrome. Because of the added number of replication origins, these mutations may have a replicative advantage that contributes to their rapid accumulation.

Cases of respiratory failure, lactic acidosis, and failure of muscle or kidneys have also been found to be associated with extremely low amounts of mtDNA. In a case of lethal mitochondrial myopathy, only 2 to 12% of the normal amount of mtDNA was detected. Similar symptoms have been observed in AIDS patients as a result of zidovudine treatment, which is intended to block viral DNA replication, but, as a side effect also has a similar effect on mtDNA.

4.3 Mutations and Neurodegenerative Diseases

The diseases discussed thus far are but a few of those in which mitochondrial mutations have been implicated. Some families with diabetes mellitus have been shown to carry a deficiency of oxidative phosphorylation coupled with an mtDNA deletion, which, in the heteroplasmic state, removed O_L and large parts of the mtDNA genome. Also, mtDNA mutations have been implicated in neurodegenerative diseases (e.g. Parkinson's, Alzheimer's, Huntington's). The brain tissue of Parkinson's disease patients has been shown to contain mtDNA deletions and a deficiency of complex I has been reported in both the brain and muscle tissue. Most Parkinson's cases are sporadic, and only occasionally will family members be affected, as would be expected if the decline in oxidative phosphorylation were genetically based. Similarly, some Alzheimer's patients have complex IV defects and most of the cases appear to be spontaneous (with a fraction being autosomal dominant). Attempts have been made to correlate the frequency of mtDNA deletions with Alzheimer's disease, but at present there is no strong evidence that these patients carry aberrant levels of mutations compared with age-matched asymptomatic controls. In addition, decreased level of CO activity was recently reported in certain brain regions of a patient with schizophrenia. This finding indicates that mitochondrial dysfunction may also be involved in the etiology of psychiatric disorders.

4.4 Contribution of Mitochondrial Mutations to Aging

A confounding factor in the analysis of mitochondrial diseases is the natural accumulation of mutations with age. A number of studies have shown that insertion–deletion mutations in rat skeletal

muscle and deletions in human hearts tend to accumulate with age. Similar studies indicate that certain point mutations may also accumulate with age. Taken together, these studies suggest that there may be a progressive accumulation of mtDNA mutations, which may in turn contribute to the decline in oxidative phosphorylation that is characteristic of aging individuals. Therefore, it has been postulated that biological aging is related to and partially caused by the accumulation of mitochondrial mutations. One concern is that the frequency of mutations in asymptomatic aging people appears to be too low to be able to exert a significant effect on oxidative phosphorylation. Also, experiments from cell hybrids indicate that the main age-related decline in oxidative phosphorylation is under the control of nuclear, rather than mitochondrial, genes. However, the age-dependent accumulation of mtDNA mutations is still important in the prognosis for carriers of mtDNA disease mutations. Recently, a mouse model in which the proofreading activity of the mitochondrial polymerase had been partly altered showed the accumulation of a high number of mutations and also symptoms of premature aging. This provides evidence that high levels of mtDNA mutations may result in symptoms similar to that observed during biological aging.

5 Tracing Human History Using Mitochondrial DNA

5.1 Pros and Cons of Using Mitochondrial DNA for Evolutionary Studies

MtDNA has been heavily utilized for studies of human evolution. This is largely due to a handful of appealing features that set mtDNA apart from nuclear DNA. Possibly the most important factor is that, like the Y chromosome, mitochondria are uniparentally inherited. While the lack of apparent recombination means that only the history of women in a population can be investigated, it allows the tracing of a direct genetic line where all polymorphism is due to mutation (however, see Sect. 3.3). The high substitution rate in the mitochondrial genome compounds this advantage and allows for phylogenetic resolution of more closely related individuals than is possible with nuclear DNA sequences of similar length. If mtDNA is evolving 5 to 10 times faster than nuclear DNA, then 5 to 10 times the amount of nuclear sequence data would be required to give the same amount of phylogenetic data. Also, as the mitochondrial genome is of an immediately finite length (~16 500 ntp), a wealth of data from the same locus is available for comparison. In fact, over 10 000 human mitochondrial hypervariable region sequences (from the mitochondrial D loop) have been produced to date, many for the purpose of forensic analyses. The D loop is an important source of information for forensic scientists for many of the same reasons that it appeals to population geneticists. It can be possible to extract mtDNA from sources when the nuclear DNA is degraded beyond use. This is mainly because many more copies of the mitochondrial genome exist in each cell. In fact, mtDNA has been extracted, amplified and sequenced from the fossilized remains of Neanderthal bones at least 30 000 years old.

However, estimation of the number of nucleotide substitutions between a pair of sequences is not a straightforward task. If the genetic distance between two mtDNA sequences is very high, there

is the likelihood that the same site may have undergone substitution more than once (multiple substitution). Another confounding factor coupled to a high genetic distance is parallel substitution, in which the same site undergoes the same nucleotide substitution in multiple lineages independently. In either case, two substitutions would have occurred, but neither will be observed in a pairwise comparison. Both these situations will lead to underestimation of the genetic distance between the sequences and will affect the calculation of the time at which they diverged. In a sample of 53 mitochondrial D-loop sequences, it was found that some sites had undergone parallel substitution in up to 10 separate lineages. This means that at some loci, a large percentage of sequences share polymorphisms by chance rather than by descent.

The problem of multiple substitutions is illustrated in Fig. 2. While the substitution rate has remained relatively constant, the accumulation of substitutions between these species is not linear over time. In fact, the rate of accumulation of pairwise synonymous substitutions ranges from 17 per million years in species that diverged 2 million years ago to 4.5 per million years in species that diverged 20 million years ago. This is due to a saturation of mutations, making multiple substitutions more common. However, in agreement with the molecular clock hypothesis, the rate of accumulation of nonsynonymous substitutions (and therefore amino acid replacements) remains fairly constant.

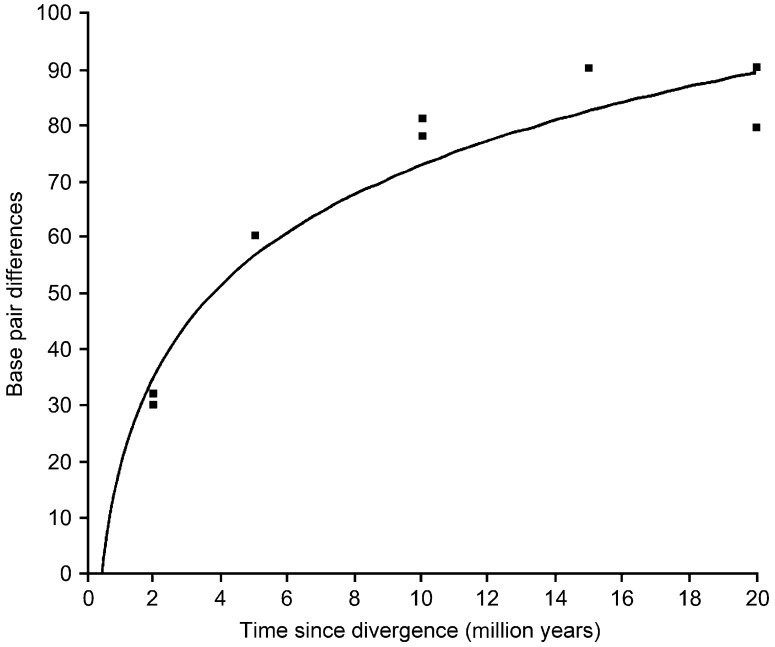

Fig. 2 Total nucleotide substitutions between pairs of mitochondrial cytochrome *c* oxidase subunit II gene (684 bp) from various bovid taxa *versus* time since divergence (from Janecek, L.L., Honeycutt, R.L., Adkins, R.M., Davis, S.K. (1996) Mitochondrial gene sequences and the molecular systematics of the Artiodactyl subfamily Bovinae, *Mol. Phylogenet. Evol.* **6**, 107–119).

Of course, this is an extreme example and, because there is considerably less time depth, the problem is not so pronounced for analysis of human mitochondrial DNAs. Nevertheless, due to these complications, it is necessary to use a mathematical model to estimate the number of nucleotide substitutions between pairs of sequences.

5.2 Mitochondrial Genomics

Prior to the year 2000, few studies presented phylogenetic analyses based on the complete mitochondrial genome, but rather focused on particular sites that are thought to be variable, or the rapidly evolving mitochondrial control region (D loop). One of the human population genetics studies that stands out above all others employed mtDNA genetic variation to study the evolutionary relationships between individuals of diverse origins. In 1987, a group of researchers at the University of California campus at Berkeley presented data that indicated a recent African origin of modern humans. This landmark study was based on restriction fragment length polymorphism (RFLP) variation among the mtDNA of 147 humans from five populations. In this study, 12 restriction enzymes were used to cut the mtDNA of each of these individuals at an average of 370 positions. Using this technique, Cann and colleagues assayed a total of about 9% of the mtDNA of each individual and identified 195 polymorphic sites. The 147 individuals included in the study yielded 133 distinct mitochondrial haplotypes, which were assembled into a phylogenetic tree using the maximum parsimony method. The oldest group (clade) on the tree was comprised of mtDNA types derived from African people and, given the number of differences between the two most divergent mtDNA types, the common ancestor of all the haplotypes was estimated to have existed (in Africa) between 140 000 and 280 000 years ago.

The mitochondrial D loop comprises about 1100 ntp and makes up less than 7% of the complete mitochondrial genome. Sequencing the D loop for use in molecular population genetics has been popular due to the high degree of polymorphism that can be found in this relatively short sequence. The advantage of copious amounts of published data from the human D loop continues to make it an attractive source of phylogenetic information. The main problem of the D loop stems from extensive heterogeneity in substitution rate that results from an extreme rate of substitution at some sites. The consequence of this is a high frequency of multiple substitutions and, as a result, specific algorithms for estimating genetic distance have appeared in an attempt to take this into account. Nevertheless, information gleaned from D-loop sequences has added significantly to our level of understanding of human evolution and the genetic relationships among populations.

Since 2000, when the first large-scale study utilized complete mitochondrial genomes, more than 2000 complete or near complete human mitochondrial genomes have been published. Complete mitochondrial genomes provide increased phylogenetic resolution of closely related lineages, as well as facilitating more accurate estimations of genetic dates for demographic events since all substitutions are available, including singleton changes (present in just one lineage). While RFLP data can define some major clades, the complete genome data provide more topological support and also distinguish a

number of additional clades. In addition, the availability of complete mitochondrial genomes has allowed a more detailed analysis of the pattern of selection across the mitochondrial coding region as well as comprehensive surveys for evidence of mitochondrial recombination.

5.3 Human Migration Patterns

Our understanding of the global pattern of the movements of modern human peoples is based on a synthesis of physical and cultural anthropology with molecular data from multiple genetic systems and loci (see Fig. 3). Also taken into account are geological factors such as the degree of glaciation, which can affect migration paths and raise or lower sea levels.

Analyses of mtDNA have provided important information about human evolution and migration for nearly 20 years. The earliest and some of the strongest evidence for the ''recent African origin'' hypothesis have been based on mtDNA. This hypothesis is now a general (but incomplete) consensus and states that anatomically modern humans evolved in Africa 100 000 to 200 000 years ago, and all extant humans are descended from a small number of females that lived at that time. MtDNA analyses in concert with studies of nuclear DNA and physical evidence have also shown that modern humans exited Africa in the last 100 000 years to the Levant, the Mediterranean region between Turkey and Egypt. From there, they radiated toward East Asia, Europe, Australia, and eventually to the Americas. As modern humans

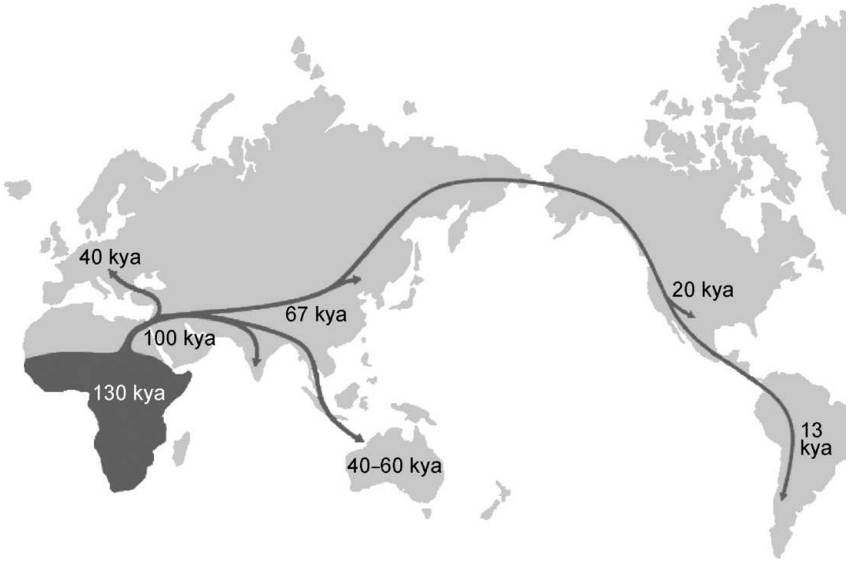

Fig. 3 The origin and dispersal of modern humans. Evidence from mitochondrial genomes bolsters the hypothesis that the place of origin was sub-Saharan Africa between 100 000 and 200 000 years ago and that the dispersal from Africa occurred within the past 100 000 years. The earliest known fossil and archaeological evidence on each continent, shown on the map, is consistent with this view (redrawn after Hedges, S.B. (2000) A start for population genomics, *Nature* **408**, 652–653).

advanced across the world, they must have encountered archaic humans that were resident in their new range. A key question is whether there was total replacement of these previous occupants or if admixture between modern and archaic forms has contributed to the contemporary human gene pool. While barriers to fertility are slow to develop, making admixture biologically feasible, the absence of evidence of this from clonal loci such as mtDNA and the Y chromosome suggests that archaic forms such as *Homo erectus* have not contributed significantly to current human genetic variation.

5.4 Natural Selection in Mitochondrial DNA

There are several examples of non-neutrality of mtDNA mutations, such as cytoplasmic male sterility in plants and in humans, and in a muscle disease known as *mitochondrial myopathy*. Effects of natural selection in mitochondrial coding regions are also evident in the discordance between the numbers of synonymous and nonsynonymous substitutions. Also, when mitochondrial lineages are subdivided into groupings that are thought to reflect their historical habitat, a larger proportion of nonsynonymous substitutions are seen among the ''arctic'' lineages relative to the ''tropical'' and ''temperate'' lineages in the *ATPase6* gene. This could be due to changing environmental pressures on mitochondrial lineages as humans moved from the African climate to exploit new habitats.

This may be especially important in cold environments as mitochondrial oxidative phosphorylation (OXPHOS) employs dietary calories to produce ATP, which can be utilized to generate heat for body temperature maintenance. Mitochondrial lineages may therefore vary functionally depending on their long-term environment and the rate of evolution of lineages from different habitats could be quite different.

Keywords

Cytokine
One of a class of inducible biologically active proteins that exercise specific, receptor-mediated effects in target cells or in the cytokine-producing cells themselves.

Homology
Degree of structural similarity.

Interferon
One of a group of cytokines with antiviral activity, also displaying antimicrobial, antiproliferative, and immunomodulatory activities.

Interferon Receptors
Transmembrane glycoproteins specifically binding IFN and capable of signal transduction across the cell surface membrane.

Interferon/Type I
Acid-stable species of interferon, including, IFN-α, -ß, -ω, -κ, and -τ.

Interferon/Type II
Acid-labile species of interferon, IFN-γ.

Interferon/Type III
A small family of interferon-like molecules known as IFN-λs. Alternatively designated interleukin-28A and B and interleukin-29.

Subtype
One of two or more molecularly and antigenically related IFNs.

Tumor Cell
Cell that is capable of producing a tumor and that is unresponsive to mediators of normal cell growth control.

The interferons (IFNs), a category of biologically active proteins or cytokines with common antiviral activity, are induced by a variety of pathological stimuli, including viruses, bacteria, protozoa, and foreign antigens, as well as by endogenous cellular interactions. IFNs are secreted locally from induced cells to stimulate, via specific cell surface receptors, host defense mechanisms in the surrounding tissues. Such mechanisms are manifested as a wide spectrum of antiviral, antimicrobial, antitumor, and immunomodulatory actions, and have led to the belief that IFNs could have therapeutic potential in the treatment of many infections and invasive diseases.

Clinical investigations, begun in earnest in the 1980s with the abundant availability of ''recombinant'' IFNs, have demonstrated that IFNs, used as single therapeutic agents, induce beneficial responses in a select number of virus-mediated and malignant diseases, but not in the major human cancers, such as breast, lung, and colon. IFNs also induce significant, undesirable, but reversible, side effects. Nevertheless, IFNs continue to be widely used, for example, in the cancer area, and increasingly so for disease indications such as chronic hepatitis, caused by hepatitis-B and -C viruses, and multiple sclerosis, a chronic degenerative disease of unknown etiology.

1 Historical Perspective

The phenomenon of "interference" in virus infections was studied from the end of the 1940s. In 1957, Isaacs and Lindemann discovered a biological substance produced in virus-infected cells that in turn produced an antiviral response in cell cultures infected by the same virus. The word *interferon* (IFN) was coined for this substance. Initially, there were difficulties in characterizing IFN because under laboratory conditions it was made in only minute quantities. Gradually however, with the introduction of large-scale production facilities and the development of efficient purification procedures, the nature of IFN began to emerge. First, it was established that IFN was protein in nature. Second, it was discovered that there were different molecular species (types) of IFN. Third, it became evident that IFNs were associated with a growing number of biological activities beside their antiviral activity. One of these activities, the antitumor action, was the spur to increased efforts during the 1970s to develop IFN as an anticancer agent. Progress was made particularly in the area of purification and in the sequencing of the N-terminal regions of pure IFN proteins. However, the development of rDNA technology in the late 1970s was to revolutionize both the production of IFNs and their characterization. This technology was also to reveal that one type of human IFN, designated IFN-α, was composed of many different, but structurally related, IFN proteins, now known as subtypes. Using nucleotide-sequencing techniques, the amino acid sequences of IFN molecules could be deduced once complementary DNA (cDNA) copies of individual IFN messenger RNA (mRNA) were cloned. Genes for individual IFN proteins were also isolated, characterized, and their chromosomal location established. By comparing the IFN genes of other animal species to those of humans, evolutionary relationships and the ancestry of IFN genes were deduced.

The early 1980s were times of intensive research investigations into all aspects of IFN biochemistry and biology and the period that saw the instigation of many clinical trials to evaluate IFN as a potential therapeutic agent in cancer patients. Reports of initial successes in the clinic were followed by more sober analyses of IFN's worth as an anticancer agent. IFN clearly had potential, but tumor responses were seldom large enough to cure cancer patients. In addition, IFN produced a number of undesirable side effects in patients. The cloning in the mid-1980s of the second major type of IFN, now designated IFN-γ, led to a further expansion of biochemical and biological investigations and more clinical trials.

The period from around 1985 to date has witnessed many new discoveries about IFNs and their biological actions and featured the cloning of their cell surface receptors, responsible for triggering cellular responses following IFN binding. There has been a rationalization of the clinical results leading to the now-accepted view that IFN administrated as a single anticancer agent is beneficial in only a handful of malignancies, for example, hairy cell leukemia (which is extremely rare), renal cell carcinoma, AIDS-related Kaposi's sarcoma and chronic myelogenous leukemia (CML). Nevertheless, further attempts to exploit IFN's potential have and are being made by combining it with other anticancer drugs. IFN-α is now having some success as an antiviral agent in the treatment of hepatitis-B and -C virus infections,

while IFN-β has emerged as a therapeutic agent for multiple sclerosis.

2 Interferon Genes and Proteins

2.1 Identification and Nomenclature

Originally two types of human IFN were defined on the basis of the capacity of the biological activity of IFN preparation to withstand acidification to pH 2. These were designated type I (acid-stable) IFN and type II (acid-labile) IFN. On the basis of the cell source, type I IFN was subdivided into two subclasses: *leukocyte IFN* and *fibroblast IFN*. These were subsequently shown to be antigenically distinct. Type II IFN was often referred to as *immune IFN* to denote its production by stimulated T lymphocytes.

In 1978, an international IFN nomenclature committee recommended that *leukocyte IFN* should become IFN-α, *fibroblast IFN*, IFN-ß, and *immune IFN*, IFN-γ. These designations were widely accepted, but nowadays with increased knowledge of IFN genes, protein structures, and receptors, IFN-α and IFN-β are often classified as type I IFNs and IFN-γ as type II IFN. However, complications arose when it was discovered that IFN-α was heterogeneous and contained many different, but structurally and antigenically related species, now commonly referred to as subtypes. Some groups labeled these subtypes αA, αB, αC, αD, and so on, while others adopted the numerical system of α_1, α_2, α_4, and so on. The latter nomenclature now prevails. However, there is no general correspondence between letters and numbers, for example, $\alpha A = \alpha 2$; $\alpha B = \alpha 8$; $\alpha D = \alpha 1$. When an IFN preparation is a mixture of IFN-α subtypes, these are often designated IFN-αn. The discovery in the mid-1980s of additional IFN-α-like proteins antigenically distinct from the main family of IFN-α subtypes then created another problem. At first, the new IFN-α-like proteins were classified as IFN-α subclass II, with members of the original IFN-α family being referred to as IFNα subclass I. However, a radical departure from the sequence of letters in the Greek alphabet resolved this complex nomenclature. IFN-α subclass II has become IFN omega (ω)! Recently, another human type I IFN distantly related to either IFN-α or IFN-ω and expressed only in epidermal keratinocytes has been characterized; this is designated *keratinocyte-derived IFN*, or IFN-κ. The most recent addition to the human type I IFN family is IFN-ε, which appears distantly related to IFN-β but whose function remains uncertain.

In mice, similar IFN-α subtypes, IFN-β, and IFN-ε are present, but IFN-κ and IFN-ω are absent. However, a type I IFN-like molecule called limitin, which is 30% related to human IFN-ω, has recently been identified in mice. In other animal species (e.g. bovines), besides multiple IFN-α subtypes similar to those in humans, there are frequently several different IFN-ß and/or IFN-ω subtypes, although besides mice IFN-ω is also absent in canines. Further, other classes of IFN-α-like proteins have been identified in certain animal species, but not in humans; the *trophoblast* (τ) and *delta* (δ) IFNs are produced by the trophectoderm and are involved in the maternal recognition of pregnancy in ruminants (e.g. bovines) and pigs, respectively.

All members of the type I (α, β, δ, ε, κ, τ, and ω) and II (γ) IFNs induce antiviral activity. A further small family of human cytokines with limited homology to type I

IFNs have recently been characterized as also having antiviral activity. They have been designated IFN-λ1 (alternatively, interleukin-29 (IL-29)), IFN-λ2 (IL-28A), and IFN-λ3 (IL-28B) and collectively as type III IFNs. Their counterparts probably exist in other animal species, but IFN-λ1 (IL-29) is absent in mice.

The nomenclature system for designating IFNs according to their animal species of origin is reasonably straightforward. The first two letters of the animal name are most often used: human, Hu; murine, Mu; bovine, Bo, and so on. However, Mo is sometimes used for mouse IFN and Ra for rat IFN to distinguish between these murine species. In other cases, no abbreviations are used, as in, for example, chick IFN and rabbit IFN.

2.2 Interferon Genes

The number of IFNs varies among different animal species, but those of the IFN-α family are usually the most numerous. In humans, there are 13 nonallelic IFN-α genes (Note that these genes are designated as *IFNA1*, *IFNA2*, and so on, so that they correspond exactly to the IFN-α proteins they encode), plus four nonallelic *IFNA-like* pseudogenes (i.e. genes that cannot give rise to functional IFN-α molecules). In addition, allelic variants of some *IFNA* subtype genes (e.g. for *IFNA2*) have been found. There is one HuIFN-ß gene (designated *IFNB1*), one IFN-ε gene (designated *IFNE1*) one HuIFN-κ gene (designated *IFNK*), one HuIFN-ω gene (designated *IFNW1*) and several *IFNW*-like pseudogenes. All of these genes and pseudogenes are located on the short arm of human chromosome 9 where they are arranged in tandem. The equivalent site for mouse *IFNA* genes is in mouse chromosome 4. Each of the genes specifying IFN-α, -ß, -ε and -ω proteins has no introns, but the *IFNK* gene contains one intron in the 3′ noncoding region. Lack of introns is an unusual feature among mammalian cytokine genes, in which there are usually three or more introns (IFNs are considered to belong to the cytokine superfamily of multifunctional, intercellular biological mediators). The lack of introns suggests a very ancient origin of the common ancestral gene. It has been predicted that the primordial type I IFN gene arose some 500 million years ago. A split about 400 million years ago appears to have given rise to the first *IFNA* and *IFNB* genes. Since then, the *IFNA* gene has evolved and duplicated many times to give the multiple *IFNA* genes found in present day mammals. Around 100 million years ago, an *IFNA* gene apparently diverged enough to give rise to the *IFNW* gene family, which is found in most mammals. In ruminants, the *IFNW* gene family appears to have split around 60 to 80 million years ago to give the *IFNT* gene family, which is now only found in the Ruminantia suborder Artiodactyls (sheep, cattle). The relationship of the pig IFN-δ gene and the mouse limitin gene to the *IFNA, W, T* gene family remains uncertain. However, *IFNE1* and *IFNK* genes are more likely related to the *IFNB* gene than to the *IFNA, W, T* genes.

In contrast, throughout evolution there appears to have been no duplication of the IFN-γ gene (designated *IFNG*). Only a single *IFNG* gene has been found in all animal species tested. This gene has four exons and three introns, a common organizational feature of many cytokine genes, and is located on chromosome 12 in humans and chromosome 10 in the mouse. The *IFNG* gene also shares other structural features in common with cytokine

genes such as an inducible transcriptional enhancer in the 5′ flanking region found, for example, in the interleukin-2 gene.

The genes for IFN-λ1-3 (type III IFNs) are located on human chromosome 19 and contain introns. These genes appear to have emerged about the same time as type I IFN genes and are widespread in mammals, although the mouse lacks a functional IFN-λ1 gene.

All the active IFN genes have regulatory regions in their 5′ noncoding promoter sequences, which control transcription. In all coding regions, the part of the gene that encodes the mature IFN protein is preceded by a nucleotide sequence specifying an N-terminal signal peptide.

2.3 Interferon Proteins

2.3.1 IFN-α

All IFN-α's are secreted proteins and, as mentioned earlier, are transcribed from mRNA as precursor proteins, pre-IFN-α, containing N-terminal signal polypeptides of about 23 amino acids. The signal polypeptide is cleaved off before the mature IFN-α molecule is secreted from the cell. The mature form of most HuIFN-α subtypes contains 166 amino acids (except HuIFN-α_2, 165 amino acids: (Fig. 1). IFN-α subtypes from the mouse are of a similar size with 166 or 167 amino acids (except mouse IFN-α_4, 162 amino acids). The calculated molecular weight of HuIFN-α subtypes is approximately 18.5 kDa, although apparent molecular weights in sodium dodecyl sulfate (SDS)-polyacrylamide gels vary between 17 and 26 kDa. The amino acid sequences of HuIFN-α subtypes are highly related, with complete identity at 85 of the 166 (amino acid) positions. Many of the positions where amino acids differ from subtype to subtype are conservative substitutions. Interestingly, HuIFN-α subtypes contain four cysteine residues whose positions (1, 29, 99, and 139) are highly conserved (Fig. 1). These four cysteines form two disulphide bridges (1–99, 29–139), which induce folding of the IFN-α molecule and whose integrity is essential for biological activity. IFN-α subtypes are predicted to have a high proportion (ca 60%) of α-helical regions and are folded to form globular proteins. The three-dimensional structure of HuIFN-α_2 revealed by X-ray crystallographic analysis comprises 5α-helices (A–E) connected by loops in the "classic" up-up-down-down configuration. This α-helical "bundle" structure IFN-αs share with many other cytokines, particularly those of the hematopoietin family. Only one of the HuIFN-α subtype sequences contain sites for N-linked glycosylation; however, limited O-linked glycosylation may occur in several. Natural HuIFN-α_2, for example, appears to contain some O-linked oligosaccharides (N.B. Recombinant IFN-α subtypes produced by *Escherichia coli* are nonglycosylated since bacteria lack the biosynthetic machinery to add sugar residues to polypeptides).

Although the mouse IFN-α subtypes, of which 10 have been cloned and expressed, are only approximately 40% related in amino acid sequence to their HuIFN-α subtype counterparts, they are likely to be structurally similar. However, in contrast to HuIFN-α subtypes, most mouse IFN-α subtypes contain one N-linked glycosylation site and are probably glycoproteins when produced from mouse somatic cells.

2.3.2 IFN-ß

Pre-HuIFN-ß contains 187 amino acids, of which 21 comprise the N-terminal

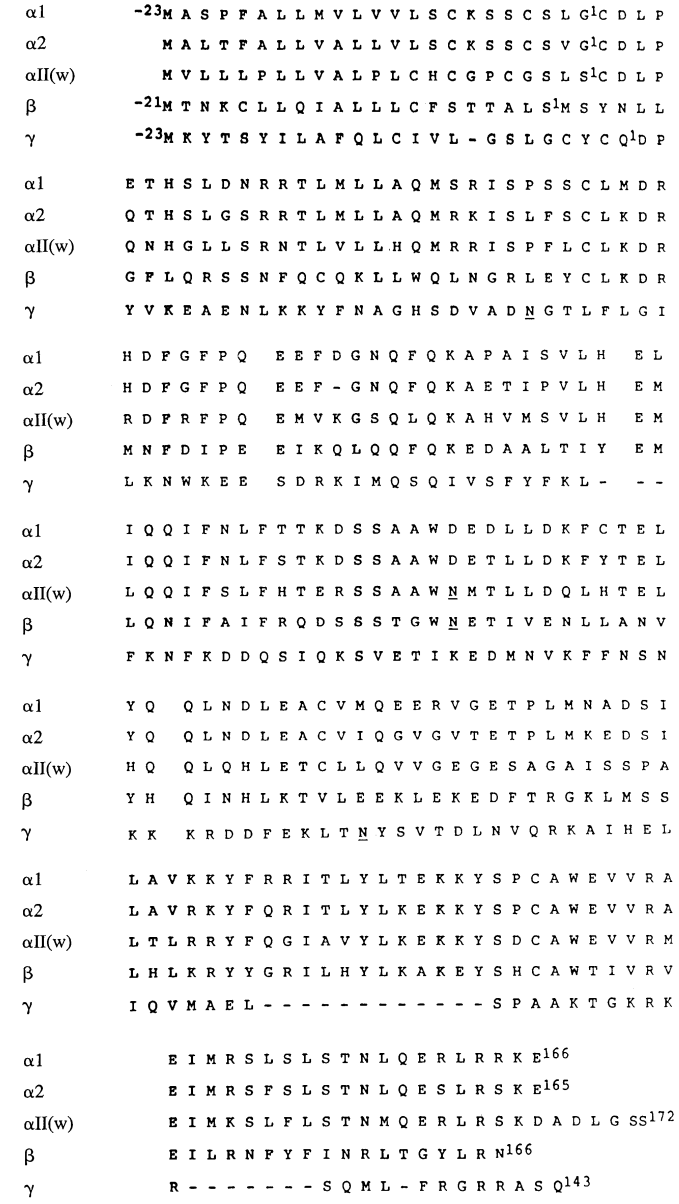

Fig. 1 Amino acid sequences of human IFNs, α_1, α_2, αII (ω), ß and γ. Sequences are aligned to show maximum structural relatedness. Sites of N-linked glycosylation (Asn = N) are underlined.

signal polypeptide. The signal polypeptide is cleaved on secretion to yield the mature HuIFN-ß protein of 166 amino acids, the same size as most HuIFN-α subtypes (Fig. 1). However, HuIFN-ß shows only approximately 30% amino acid

sequence relatedness with HuIFN-α and is antigenically distinct from it. The mature HuIFN-ß molecule lacks the N-terminal cysteine residue at position 1 found in HuIFN-α subtypes, but contains three other cysteines at position 17, 31, and 141. The cysteines at position 31 and 141 are equivalent to those found at positions 29 and 139 in HuIFN-α and are joined to form a single disulphide bond. Replacement of the cysteine residue at position 17 by serine does not result in any loss of biological activity, whereas serine substitution of Cys^{141} does. Unlike most HuIFN-α subtypes, HuIFN-ß's amino acid sequence contains one site, asparagine at position 80, for N-linked glycosylation and it is known that HuIFN-ß produced by human fibroblasts is a glycoprotein of approximately 23 kDa. Like HuIFN-α subtypes, HuIFN-ß is predicted to have a high α-helical content, and folds up as an α-helical bundle of 5 domains.

Mouse IFN-ß contains 161 amino acids and shows some 60% relatedness to HuIFN-ß: in contrast, however, mouse IFN-ß contains only one cysteine residue and thus intramolecular disulphide bonds are impossible. There are three N-glycosylation sites present in mouse IFN-ß, and the rather high apparent molecular weight of 35 kDa probably reflects extensive glycosylation of this molecule. The three-dimensional crystal structure of recombinant mouse IFN-ß has been solved, revealing that the structure consists of five α-helices folded into a compact α-helical bundle (Fig. 2). There are many structural similarities between mouse IFN-β and HuIFN-α_2. Subsequently, the three-dimensional structure of HuIFN-β has also been shown to be similar, but dimers may form through a zinc-binding site present at the interface between two protomers. On the basis of comparative sequence analyses, it is predicted that in all mammalian IFN-α, IFN-ß, and IFN-ω proteins, the five α-helical domains are conserved. Pig IFN-δ, mouse limitin, IFN-ε, and ruminant IFN-τ are

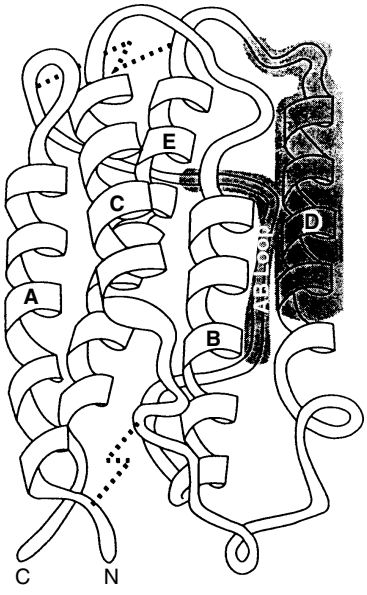

Fig. 2 Schematic drawing of the "side" view of a recombinant MuIFN-ß molecule. Helices A-E and an intervening loop AB are labeled N- and C-termini are marked. The three shaded areas along loop AB, helix D, and loop DE appear to comprise a spatially continuous binding site for the IFN receptor(s). (Reprinted with permission of Senda, et al. (1992) *EMBO J.* **11**, 3193; Copyright EMBO/IRL Press Ltd., UK).

also predicted to have the same basic structure.

2.3.3 IFN-κ

HuIFN-κ, made principally by keratinocytes, is a recently identified novel member of the type I IFN family displaying around 30% homology to HuIFN-α, HuIFN-β, or HuIFN-ω. In distinction to the latter, HuIFN-κ contains an additional cysteine at its C-terminus following the four conserved cysteines, and an insertion of 12 amino acids between the C and D helices. Its full amino acid sequence is therefore predicted to comprise 180 amino acids. However, sequence alignment with other type I IFNs predicts that HuIFN-κ has an overall structure typical of this family. Molecular modeling of HuIFN-κ has indicated a structure consisting of five α-helices as in other type I IFNs.

2.3.4 IFN-ω

The structure of IFN-ω is similar to that of IFN-α subtypes, but there have been sufficient amino acid substitutions to make it only about 60% related and thus antigenically distinct from them (HuIFNω is only 30% related to HuIFN-ß). Like pre-IFN-α, pre-IFN-ω has a signal sequence of 23 amino acids. However, the mature form of HuIFN-ω contains 172 amino acids, six more at the C-terminal end than HuIFN-α subtypes (Fig. 1). The four cysteine residues occur in precisely the same positions, 1, 29, 99, and 139, as they do in HuIFN-α subtypes. With regard to glycosylation, HuIFN-ω resembles HuIFN-ß more than HuIFN-α in having a single N-glycosylation site at Asn78.

IFN-ω is not found in mice or dogs, but three functional IFN-ω subtypes have been identified in sheep, cattle, and horses.

2.3.5 IFN-τ

Over a decade ago, it was discovered that ovine trophoblastic protein-1 (OTP-1), a hormonelike molecule having antiluteolytic activity produced by the preimplantation ruminant conceptus during the second and third weeks of pregnancy, has antiviral activity. This led to the finding that OTP-1 was itself structurally related to type 1 IFN, in particular to IFN-ω. As a consequence, OTP-1 and related proteins have been designated by one group of researchers as trophoblast IFNs or IFN-τ. Preovine IFN-τ contains 195 amino acids; a signal sequence of 23 amino acids followed by the mature polypeptide of 172 amino acids. IFN-τ molecules all contain the precisely conserved cysteines at positions 1, 29, 99, and 139 found both in IFN-α and IFN-ω molecules. Like IFN-ω, some IFN-τ subtypes possess a potential site for N-glycosylation on Asn78. It is predicted that IFN-τ will have a similar three-dimensional structure to IFN-α and IFN-ß (i.e. a bundle configuration of five α-helices).

IFN-τ subtypes are only found in the Ruminantia suborder Artiodactyla (e.g. sheep, goats, cattle), where they appear to have evolved to perform a special antiluteolytic function in early pregnancy. In man and other mammals, the fertilized egg, the conceptus, immediately attaches to the uterine wall and therefore there is no special need to maintain the corpus luteum as in ruminants, where the conceptus undergoes extensive preimplantation development.

2.3.6 IFN-γ (type II IFN)

The nucleotide sequence of HuIFN-γ mRNA contains an open-reading frame of 166 codons. At first, it was believed that the mature HuIFN-γ protein contained 146 amino acids, the 20 N-terminal amino

acids of pre-HuIFN-γ forming the signal peptide. However, this proved incorrect, inasmuch as cleavage of the signal peptide and the mature HuIFN-γ occurred between residues 23 and 24 of the pre-HuIFN-γ (Fig. 1). It was also shown that the N-terminal amino acid of HuIFN-γ was pyroglutamic acid and that several of the C-terminal amino acids of the natural 143 amino acid polypeptide could be cleaved off without loss of biological activity. The predicted molecular weight of the unmodified polypeptide is approximately 17 kDa, but there are two N-glycosylation sites (Asn25 and Asn97), both of which are used to yield fully glycosylated HuIFN-γ molecules of 25 kDa (Note that HuIFN-γ preparations derived from T lymphocytes often contain minor amounts of a 20-kDa molecule representing glycosylation at one site only.). In its native state, HuIFN-γ is not only heavily glycosylated but is also a homodimer of two 25-kDa molecules (subunits). The role of the oligosaccharide side chains is not known. Since unglycosylated HuIFN-γ produced from *E. coli* containing IFN-γ cDNA is biologically active, they appear to be dispensable.

The amino acid sequence of HuIFN-γ shows very little homology with those of type I IFNs (α, ß, κ, ω, or τ). Despite this, rather interestingly the three-dimensional structure of HuIFN-γ (illustrated in Fig. 3), which was reported in 1991, contains some features in common with IFN-ß. Like the type I IFNs, IFN-γ molecules are essentially α-helical in content, with no ß-sheet. IFN-γ subunits have six α-helical regions as opposed to the five present in the IFN-ß structure. On dimerization of IFN-γ subunits, five of the 12 helices are folded to form a structural domain that resembles the folded arrangement of the five helices in IFN-ß. Other similarities in folding topology between IFN-γ and IFN-ß are apparent, suggesting that despite their present low degree of homology, an ancient precursor to both types might have existed.

Mouse IFN-γ containing 133 amino acids is smaller than HuIFN-γ and is only 40% related in sequence. It also is heavily glycosylated and the molecular weight of the natural dimeric molecule is around 38 kDa. Its structure, and those of IFN-γ from other species, are expected to be similar to that worked out for the three-dimensional structure of HuIFN-γ.

2.3.7 IFN-λ (type III IFNs)

The IFN-λs contain 200 amino acids: in sequence IFN-λ1 is 81% related to IFN-λ2; IFN-λ2 is 96% related to IFN-λ3. IFN-λ1 contains an N-glycosylation site that is not present in IFN-λ2 or IFN-λ3. The IFN-λs are distantly related to type I IFNs (15–19% homology) and to the interleukin-10 (IL-10; 11–13% homology) family of cytokines. The 3-D structures of IFN-λs are not yet known, but since cysteine patterns are conserved on alignment of amino acid sequences with those of IFN-α and IL-10, it is predicted that IFN-λs are helical cytokine family members.

3 Regulation of IFN Synthesis

3.1 Type I IFNs

3.1.1 IFN-α

IFN-α can be induced by a whole variety of stimuli, including viruses, bacteria, xenogeneic or allogeneic tumor cells, virus-infected cells, B-cell mitogens, and so on. IFN-α subtypes are produced by stimulated or activated null lymphocytes,

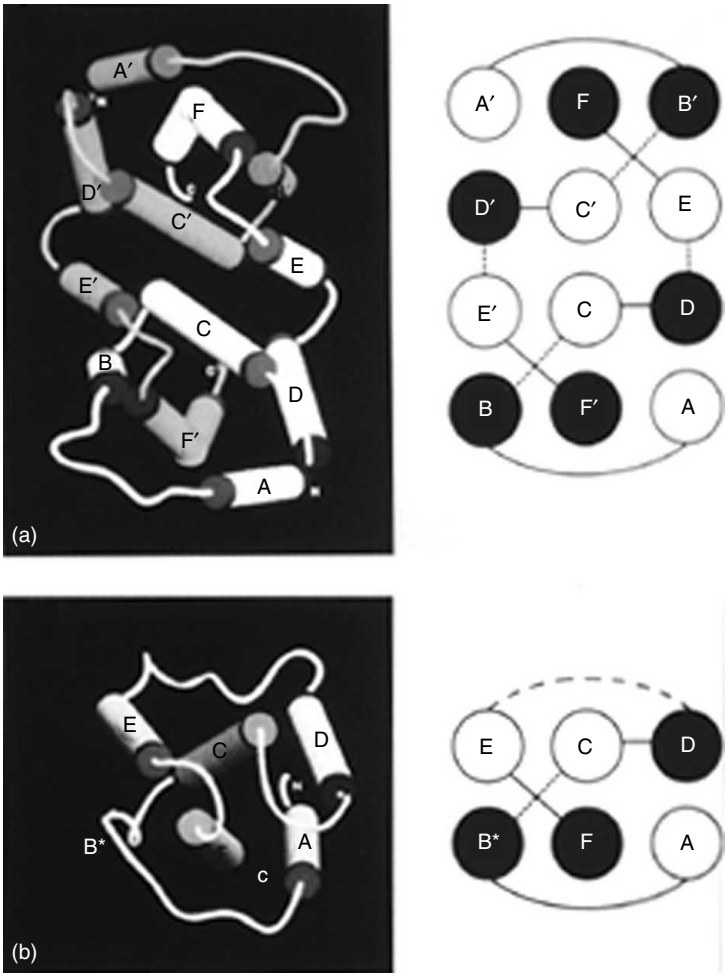

Fig. 3 Schematic drawings of (a) the recombinant human IFN-γ D′ dimer and (b) IFN-ß. On the left-hand side, the α helices are represented as cylinders, and the nonhelical regions are shown as tubes. The N- and C-terminal ends are marked. On the right-hand side, the α-helices are shown as circles, and the nonhelical regions are shown as solid or dashed lines, depending on whether they are above or below the plane of the figure. The regions labeled B* represent a kinked region of IFNß that is not helical, but shows some helical features. (Reprinted with permission of Ealick, et al. (1991) *Science*, **252**, 698. Copyright 1991 by American Association for the Advancement of Science).

monocytes, and lymphoblastoid cell lines of B-cell origin. More recently, plasmacytoid dendritic cells, a subset found mainly in lymph nodes and thymus, have been characterized as IFN producer cells (IPC) that produce large amounts of IFN-α following virus stimulation. The proportion of each IFN-α subtype in the mixtures

of subtypes produced as a consequence of stimulation/activation varies according to the nature of the stimulus and the producer cell type. It is still unclear why so many IFN-α subtypes are required and how their proportions are regulated at the level of their genes (but see below).

Normally, *IFNA* genes are tightly repressed, but when cells are infected by a virus, for example, ''virus-responsive elements'' in the *IFNA* genes are activated leading to derepression. *IFNA* genes contain several IFN gene regulatory elements (IREs), termed positive-response domains (PRDs) and negative-response domains (NRDs), in their 5′ noncoding promoter region whose sequences appear to govern inducibility by various inducers. Such IREs are acted upon by host cell interferon regulatory factors (IRF), a family of 9 known structurally related proteins, which act as transcriptional enhancers (e.g. IRF-1, −3, −5, −7) or repressors (e.g. IRF-2). It is now believed that IRF-3, which is constitutively present and phosphorylated by a serine kinase early after virus infection, plays a key role in IFN-α induction. Phosphorylated IRF-3 dimerizes, translocates to the nucleus, and activates the transcription of an ''early'' *IFNA* (most likely *IFNA4*) gene together with *IFNB*. The newly made ''early'' IFNs act in an autocrine/paracrine manner to activate type I IFN signaling pathways (see under Sect. 4.1.2) leading to transcription of IFN responsive genes, including IRF-7, an inducible transcription factor, which, following phosphorylation in virus-infected cells, activates several other *IFNA* genes plus many host defense genes (e.g. cytokines, chemokines). Thus, IFN-α production appears to be amplified in a controlled manner subject to the virus-dependent, sequential activation of specific IRFs. However, *IFNA* gene transcription leading to synthesis of IFN-α mRNAs continues only for a short interval before the genes are shut down again, even if the presence of the inducer is maintained, though IFN-α mRNA expression can be extended by certain drugs (e.g. cycloheximide, which blocks protein synthesis and hence the formation of labile repressors such as IRF-2).

3.1.2 IFN-ß

The regulation of transcription of the *IFNB* gene has been more closely studied than that of *IFNA* genes. Here, it is known that within the 120 bp 5′ to the transcription initiation site, there are at least six IRE, four PRD (I–IV), and two NRD (I, II). PRDI and PRDII are involved in both positive control and in postinduction repression. Several protein factors have been identified, which bind to PRDI including IRF-1 and IRF-3, transcriptional enhancers, and IRF-2, a repressor. PRDII resembles an NFκB transcription factor binding site and agents that activate NFκB (e.g. viruses, double-stranded RNA, phorbol esters), therefore promote IFN-ß induction. In contrast to *IFNA* gene regulation, active NFκB is probably a requirement for efficient *IFNB* gene transcription.

Although the major regulatory elements within the *IFNB* gene promoter have been identified, the mechanisms by which the gene is differentially induced and shut off are still not completely understood. However, research into the signaling pathways involved in following virus, double-stranded RNA (dsRNA), or cytokine stimulation has increased our knowledge of potential mechanisms for induction. For example, it is apparent that dsRNA, often an intermediate in viral genome-directed

nucleic acid synthesis, can act as a ''proximal'' inducer (e.g. via Toll-like receptor-3) of IRF-3 and NFκB activation, which are then able to activate transcription of the *IFNB* gene. The production of IFN-β appears to be the first stage in the cooperative activation of other IRFs (e.g. IRF-5, IRF-7), which appear to be crucial for transcriptional induction of *IFNA* and *IFNW* genes. In the absence of IRF-2, viral induction of IFN-ß is increased.

3.1.3 IFN-κ

Unlike other type I IFN genes, the *IFNK* gene appears to be constitutively active to some extent, particularly in IFN-κ-producer cells such as keratinocytes. However, IFN-κ mRNA expression is reported to be upregulated by viral infection, by other type I IFNs, and characteristically, by IFN-γ (type II IFN) in monocytes and dendritic cells. Currently, there is no information about which transcription factors are involved in *IFNK* gene activation.

3.1.4 IFN-ω

The *IFNW* gene is virus-inducible, like *IFNA* and *IFNB* genes, and, since there is much sequence identity with many of the *IFNA* subtype genes, it is assumed that its regulation will also be similar to that applying to *IFNA* genes. As a proportion of the antiviral activity present in the IFN mixture secreted by virally induced leukocytes, IFN-ω constitutes approximately 15% of the total.

3.1.5 IFN-τ

The *IFNT* genes are not virus-inducible and are therefore regulated in a different manner to the other type I IFN genes. IFN-τ is produced by trophoblast cells and the temporal pattern of expression depends on the time frame of maternal recognition of pregnancy, which varies from one to three weeks in ruminants. For instance, ovine (Ov) IFN-τ is only produced in large amounts between the 13th and 21st days of pregnancy, although OvIFN-τ mRNA can be detected as early as 8 to 10 days. It is believed that a factor(s) in the luteal phase environment of the uterus is required to trigger and maintain expression of IFN-τ genes. The promoter regions of *IFNT* genes appear to be under different regulatory control than other type I IFN genes, despite a high degree of superficial similarity in nucleotide sequences across all members of this gene family.

3.2 Type II IFN

3.2.1 IFN-γ

IFN-γ is produced mainly by antigen- or mitogen-stimulated mature, T lymphocytes and natural killer (NK) cells. Some T-cell lymphoblastoid lines, especially those chronically infected with HLTV-I, also can be stimulated to produce IFNγ. Like IFN-τ, IFN-γ does not appear to be virus-inducible. The gene structure of *IFNG* is quite apart from the intron-less type I IFN genes and resembles more the four exon–three intron arrangement found in cytokine genes (e.g. IL-2, IL-4, and GM-CSF). There are also similarities in the 5′ flanking region, upstream from the initiation site, of the *IFNG* gene and the 5′ flanking regions of such cytokine genes. *IFNG* gene transcription is probably controlled by binding of nuclear transcription factors to regulatory sequences in the 5′ flanking region. Since phorbol esters can act as (co)-stimulators of IFN-γ induction, it is probable that activation of NFκB is involved in gene derepression.

3.3 Type III IFNs

3.3.1 IFN-λs

Transcription of IFN-λ genes is stimulated by the same inducers of IFN-α, -β, and -ω genes, that is, several viruses, dsRNA (e.g. poly I.C.), in a variety of cell lines and dendritic cells. Virus-infected cells produce IFN-λ activity. The regulation of mRNA expression of IFN-λ genes is likely to involve a positive feedback mechanism, similar to that operating for IFN-α/β genes, but details are not yet available.

4 Regulation of Cellular Gene Expression by IFNs

4.1 IFN Receptors

4.1.1 Molecular Characteristics

IFNs exercise their actions in cells via IFN-specific cell surface receptors. These receptors bind IFNs with high affinity and transduce the signal occasioned by ligand (IFN)-binding across the cell membrane into the cytoplasm. All type I IFNs appear to share a common receptor, whereas the sole type II IFN, IFN-γ, has a distinct receptor. This division of receptors has been corroborated by the cloning of both type I and type II IFN cell surface binding proteins, which revealed little apparent relatedness of their respective amino acid sequences. However, these IFN binding proteins, two for type I IFN and one for type II IFN, share structural features that are frequently found in cytokine receptors; each has a large N-terminal extracellular domain, which is glycosylated, and which forms the binding site for IFN, a comparatively small transmembrane region and an intracellular domain of variable size (Fig. 4). The genes for the type I IFN binding proteins are located on human chromosome 21 and that for the type II IFN binding protein on human chromosome 6. It seems probable that the type I IFN binding proteins are intimately associated and together form high-affinity receptors. The type II IFN binding protein also appears to require a second component or accessory factor (AF), coded for by a gene located on chromosome 21, to form a functional receptor. One group has deduced that possibly the two types of receptor are evolutionarily connected and in their extracellular domains resemble the structures of cytokine receptors of the hematopoietin family (Fig. 4). It is now widely accepted that IFN receptors together with the individual receptors for IL-10 and its paralogs constitute a distinct subclass of hematopoietin receptors, currently referred to as *type II cytokine receptor family* (CRF2).

Comparison of protein sequences of the IFN receptors of different species has indicated that these have evolved with their cognate IFNs in a concerted fashion, and this has resulted in some degree of species specificity for most IFNs. For example, most HuIFN-α subtypes, HuIFN-ß and HuIFN-γ are poorly bound by mouse IFN receptors and vice versa. However, in some instances some IFNs are able to act across species; for example, HuIFN-α subtypes bind as well or better to bovine type I IFN receptors and can trigger antiviral activity in bovine cells.

It has recently been shown that the receptors for IFN-λs are contained within the CRF2 family. All IFN-λs bind to a unique receptor chain known as IL-28Rα (CRF2-12), which forms a functional heterodimeric receptor by combining with the accessory receptor chain of IL-10,

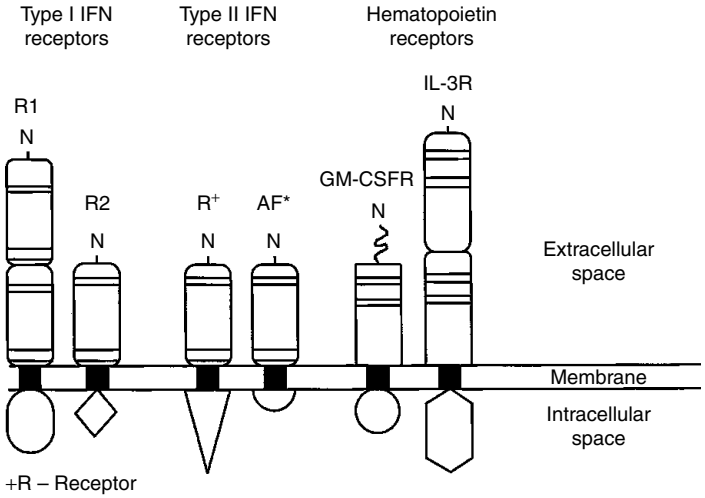

Fig. 4 Schematic drawing of the domain organization of the human type I IFN and type II IFNγ receptors and representative, analogous hematopoietin receptors. The extracellular segments of the granulocyte-macrophage colony-stimulating factor receptor (GM-CSFR) and interleukin-3 receptor (IL-3R) are drawn to linear scale, and conserved cysteines are marked by black bands. Adapted from Bazan, Shared architecture of hormone binding domains in type I and type II interferon receptors, *Cell* (1990) **61**, 753. Copyright Cell Press.

designated IL-10R2. It is not unusual for different cytokine ligands to share receptor components; besides IL-10 and IFN-λs, IL-10R2 is also an accessory receptor chain of the IL-22 and IL-26 receptors.

4.1.2 Receptor Signaling

The intracellular domains of the type I and type II IFN receptors are not predicted to have kinase activity of any sort: many growth factor receptors (e.g. epidermal growth factor receptor) contain integral tyrosine kinase, which is essential for phosphorylation of downstream, intracellular mediators of the signaling pathway. Nevertheless, IFN receptors do associate with intracellular, nonreceptor kinases. The type I IFN-receptor chains are linked with nonreceptor tyrosine kinases, designated TYK2 (R1) and JAK1 (R2), whereas the type II IFN-receptor chains are associated with JAK1 (R1) and JAK2 (R2 or AF). In type I IFN signaling, TYK2 and JAK1 tyrosine kinases further link to what is known as interferon-stimulated gene factor-3 (ISGF-3), a complex of three/four distinct proteins that contains the primary transcriptional activator for IFN-induced genes. ISGF-3 is normally present in an inactive form being composed of inactive ISGF-3α (three related proteins: p84/91, two alternatively spliced transcripts of the same gene, and p113) and a constitutive and IFN-inducible functional component ISGF-3γ (now synonymous with IRF-9) that is associated with p113. The ISGF-3α components have been redesignated as ''Signal Transducers and Activators of Transcription'' (STATs); p84/91 and p113 are thus STAT1 and STAT2, respectively. STAT1 contains a DNA-binding domain

and a nuclear location signal (NLS), which is absent in STAT2; IRF-9 does have an NLS and thus by binding to STAT2 confers ability to be translocated to the nucleus. Following phosphorylation by TYK2 and JAK1, STAT1 and STAT2 dimerize and the ISGF-3 complex (STAT1/STAT2/IRF-9) translocates to the nucleus, where it acts as a transcription factor for the activation of type I IFN-inducible genes (Fig. 5). In contrast, type II IFN (IFN-γ) stimulation leads to phosphorylation of only p91 STAT1: homodimers of STAT1 act as transcription factors for the activation of IFN-γ inducible genes.

For type III IFNs, the IFN-λs, it appears that the same signal transduction pathway operating for type I IFNs is activated, despite the distinct receptors for IFN-λs. This similarity in signaling is probably due to JAK1 and TYK2 association with IL-28Rα and IL-10R2, respectively, the two receptor chains of the IFN-λ (IL-28/-29) receptor complex, and the contingent activation of ISGF3 (see above).

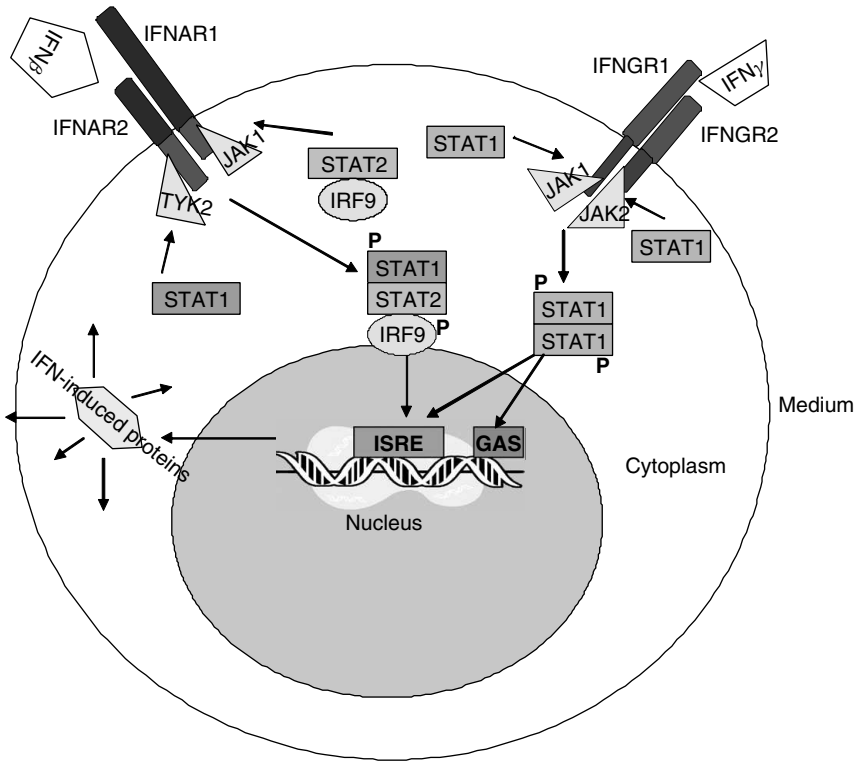

Fig. 5 Schematic drawing depicting signal transduction pathways from type I and type II IFN receptors at the cell membrane to the cell nucleus. ISGF3, interferon-stimulated gene factor-3. The ISGF3α complex contains three structurally related proteins (p84), p91[STAT1] and p113 [STAT2], and the ISGF3γ subunit is composed of a single protein, p48/IRF-9. ISRE, interferon-stimulated response element, present in IFN-inducible genes. GAS, γ-activated sequences, present in IFN-γ-inducible genes. JAK1, JAK2 and TYK2, nonreceptor protein tyrosine kinases involved in the phosphorylation of ISGF3α proteins, p91 [STAT1] and p113 [STAT2].

While the ''JAK-STAT pathway'' is the major intracellular signaling mechanism activated in IFN-treated cells, it may not be the only one. There has been some, albeit somewhat controversial, evidence to implicate protein kinase C (PKC) pathways as well. In particular, the type II IFN receptor appears to trigger PKC translocation from membrane to cytoplasm upon IFN-γ binding. However, possibly other non-PKC serine/threonine kinases are activated and are responsible for further signal amplification and activation of transcription factors. IFN-γ is a known inducer of IRF-9, which is necessary for the translocation of type I IFN-activatable ISGF-3 from cytoplasm to nucleus.

4.2 IFN-response Gene Sequences

Soon after the binding of type I IFNs to their cognate receptors, a number of nuclear genes are activated and transcripts (mRNA) of a variety of proteins are synthesized. The type I IFN-inducible genes have in common a regulatory nucleotide sequence in their 5′ flanking promoter region, and this type of sequence, which resembles the IRE present in IFN genes, has been designated IFN-stimulated response element (ISRE). The resemblance between ISRE and IRE could account for the fact that many IFN-inducible genes are transcriptionally activated by virus infection or dsRNA, which also activate the transcription of IFN genes (but not *IFNT* genes). The ISRE for type II IFN (IFN-γ), are similar, but generally known as γ-activation sequences (GAS). In contrast to the almost consensus ISRE sequences in type I IFN-inducible genes, it appears that GAS are likely to be heterogeneous. It is evident that signaling pathways of both type I and type II IFN systems share common signal transduction components (e.g. STAT1) leading to ''convergent'' transcriptional activation of a common set of IFN-inducible genes (Fig. 5). However, IFN-γ also induces a unique set of protein genes not induced by type I IFNs suggesting the involvement of other transcription factors. For example, IRF-1 (formerly known as ISGF-2) forms complexes with ISRE in both type I and type II IFN-stimulated cells, but is most particularly involved in transcription of type II IFN-inducible genes, for example, class II major histocompatibility (MHC) antigen genes. Current experimental evidence strongly indicates that type III IFNs, the IFN-λs, induce the same genes as type I IFNs, although probably more weakly.

5 Proteins Induced by IFNs

It is well established that the biological activity of IFNs depends on selective protein synthesis. Thus, it is clear that at least some of the set of IFN-inducible proteins must mediate the biological activity of IFN. IFN-inducible proteins, whose number probably runs into the 100s, include both those proteins induced early after IFN stimulation and those proteins that are produced at later times, often in response to the actions of early IFN-inducible proteins. Many IFN-inducible proteins are induced by both type I IFN and type II IFN, although some may be preferentially induced by either type of IFN. Yet other proteins are exclusively induced by either type I or type II IFN. In some cases, IFN-inducible proteins may be completely absent from the cell before IFN stimulation, but in other cases the effect of IFN causes an overall

increase in production of proteins that are already being expressed. Table 1 shows an incomplete list of IFN-inducible proteins together with their likely functions and their relative inducibility by type I and type II IFNs. Note that since IFN-inducible proteins tend also to be cell type specific, not all of the proteins listed will be expressed in all cell types.

6 Biological Activities Associated with IFNs

6.1 Antiviral Activity

6.1.1 Molecular Mechanisms

As mentioned earlier, viruses often induce IFN responsive genes, including type I IFNs, *IFNA, IFNB*, and *IFNW* and type

Tab. 1 IFN-inducible proteins.

Protein	*Function*	*Induction by*	
		Type I IFN	*Type II IFN*
2,5 A-synthetase	dsRNA-dependent synthesis of ppp-(A2p)n-A (2-5A); activator of RNase L	+	+
Protein (p68) kinase (PKR), dsRNA-activatable protein kinase	Phosphorylation of peptide initiation factor eIF-2α	+	+
MHC class I (HLA-A, B, C)	Antigen presentation to CTL	+	+
MHC class II (HLA-DR)	Antigen presentation to Th-lymphocytes	±	+
Indoleamine 2, 3-dioxygenase	Tryptophan catabolism	−	+
Guanylate-binding proteins (GBP; γ67)	GTP, GDP binding	±	+
Mx	Specific inhibition of influenza virus	+	−
IRF1/ISGF2	Transcription factor	±	+
IRF2	Transcription factor	+	−
IP-10	Related to chemotactic IL-8-like cytokines	±	+
Metallothionein	Metal detoxification	+	+
(TNF) receptors	Mediate TNF action	±	+
IL-2 receptors	Mediate IL-2 action	−	+
Intercellular adherence molecule-1 (ICAM-1)	Endothelial cell adhesion protein	−	+
Immunoglobulin Fc-receptor (FcR)	Ig binding by macrophages/neutrophils	±	+
Thymosin ß4	Induction of terminal transferase in lymphocytes	+	?
ß2-microglobulin	Immune function	+	+
Nitric oxide synthetase	Production of nitric oxide from arginine. Increased microbicidal activity in macrophages	−	+
200 family	From cluster of 6 genes; p204 is located in nucleolus	+	−
6–16	Unknown; extracellular	+	±
1–8/9–27	Cell surface proteins	+	+

III IFNs. The corresponding IFNs probably act in a paracrine manner on adjacent cells to induce antiviral mechanisms. The vast number of viruses with different replication strategies notwithstanding, it appears that these agents can be countered by relatively few IFN-inducible ''antiviral'' proteins. One of the best characterized of these proteins is an enzyme known as 2-5A synthetase which, in the presence of dsRNA (often an intermediate of viral RNA synthesis), catalyzes the formation of an unusual oligonucleotide, ppp (A2′p)nA (2-5A), which in turn activates a latent endonuclease, RNase L. This endonuclease degrades viral (and cellular) mRNA and therefore inhibits viral protein synthesis. Small RNA viruses (*Picornaviridae*), such as Mengo virus or murine encephalomyocarditis virus (EMCV), whose replication is cytoplasmic are most affected by the induction of 2-5A synthetase. A second important antiviral protein is a dsRNA-activatable protein kinase, now designated PKR, which in the active form phosphorylates the peptide initiation factor, eIF2, involved in polyribosomal translation of mRNA. Phosphorylated eIF2 is inactive and thus protein synthesis is inhibited. This inhibition has been associated with the loss of replicating capacity of rhabdoviruses such as vesicular stomatitis virus (VSV). Both type I and type II IFNs have the potential to induce 2-5A synthetase and PKR, but induction occurs more slowly in type II IFN-treated cells. A third ''antiviral'' protein, Mx, is however primarily induced by type I IFNs; type III IFNs probably weakly induce Mx too. The Mx protein inhibits the replication of influenza viruses in rodent cells, specifically by inhibiting the nuclear stage of influenza viral nucleic acid synthesis.

Probably there are other antiviral proteins and mechanisms by which virus replication is inhibited. For instance, some viruses (e.g. herpesvirus and certain retroviruses) appear to be inhibited at the relatively late stage of virus particle maturation and budding. Table 2 summarizes the antiviral mechanisms applying to different virus families.

Tab. 2 Antiviral mechanisms for different virus groups.

Virus family	***Principal antiviral mechanism***
Small RNA viruses (picornaviruses), including rhinoviruses, poliovirus, encephalomyocarditis virus, Coxsackie viruses	2-5A synthetase system, inhibition of viral polypeptide synthesis by RNase L degradation of viral mRNA.
Rhabdoviruses, e.g. vesicular stomatitis virus (VSV)	dsRNA-activatable protein kinase, phosphorylation of initiation factor eIF-2 to inhibit viral polypeptide synthesis
Influenza viruses (orthomyxoviruses)	Mx protein, inhibition of early nuclear phase transcription of viral mRNAs (type I IFN only)
Retroviruses, e.g. Rous sarcoma virus, human immunodeficiency viruses (HIV-1, 2)	Acute infections: early inhibition of proviral DNA synthesis or integration. Chronic infections: late inhibition of virion (virus particle) assembly or maturation
Herpesviruses, e.g. herpes simplex viruses 1 and 2, varicella virus	Possibly early inhibition of viral protein synthesis by 2-5A synthetase system. Late stage inhibition of viral glycoprotein assembly

6.1.2 Defense Mechanisms of Viruses

In the course of evolution, many viruses have developed countermechanisms by which they can disrupt the antiviral mechanisms induced by IFNs. The IFN-inducible, dsRNA-dependent protein kinase PKR is one of the main targets, and different viruses overcome this by various means. For example, adenoviruses and Epstein–Barr virus (a member of the herpesvirus family) produce small RNA molecules, VAI-, and EBER-RNAs, respectively, which bind to PKR and block its activation by dsRNA. Reoviruses and vaccinia virus (a member of the poxvirus family) produce proteins, sigma 3 and SKI respectively, that bind to dsRNA and thus impair the activation of PKR. Interestingly, if IFN-treated VSV-infected cells are coinfected by vaccinia virus, VSV-replication is rescued, presumably by the inhibitory effect of SKI on PKR. Vaccinia also produces a nonfunctional protein analog of eIF2, which competes with eIF2 for phosphorylation by PKR and thus dilutes out the antiviral effect of activated PKR. Other viruses (Table 3) may ''defeat'' the kinase by yet other means.

The 2-5A synthetase-RNase L system can also be attacked. For example, encephalomyocarditis virus (EMCV), a picornavirus, can inactivate RNase L in several cell lines, but this inactivation is usually blocked by IFN treatment. Herpesviruses in contrast appear to impair RNase L activation by producing competing analogs of 2-5A.

Some viruses even have the capability to block the transcription of (normally) IFN-inducible genes. The E1A protein of adenoviruses, for example, which is produced early in viral replication, prevents activation of ISGF3 by IFNα (type I IFN). Hepatitis C virus uses a viral protease to block IRF-3 activation and IFN synthesis, while in hepatitis-B virus-infected cells, the so-called virus-specified ''terminal protein'' inhibits both type I and type II IFN-inducible gene expression.

Tab. 3 Viral defense mechanisms against IFN antiviral effects.

Virus family	*Defense mechanism*
Small RNA viruses, e.g. encephalomyocarditis virus	Inactivation of RNase L of 2-5A synthetase system
Herpesvirus	Viral analogs of 2-5A block 2-5A synthetase
Epstein–Barr virus (a herpesvirus)	Production of small RNA molecules, EBER-DNA, which block activity of dsRNA-dependent protein kinase (PKR)
Adenoviruses	Production of small RNA molecules, VAI-RNA, which block activity of dsRNA-dependent protein kinase (PKR). Early adenoviral E1a protein blocks activation of ISGF-3 by type I IFN
Reoviruses and poxviruses, in particular vaccinia virus	Production of viral proteins that bind dsRNA and therefore inhibit activation of PKR. Vaccinia also produces a nonfunctional analog of the initiation factor eIF-2, which competes for PKR-mediated phosphorylation with the cellular PKR
Influenza viruses	Activate preexisting inhibitor of PKR
Human immunodeficiency virus-1 (HIV-1)	HIV-1 TAT gene mediated inhibition of PKR synthesis. HIV-1 TAR RNA may also inhibit PKR activity

Finally, members of the poxvirus family, including vaccinia, encode IFN binding proteins, which are soluble and thus able to act as decoy receptors for either type I or type II IFNs. These viral decoy IFN receptors competitively bind IFNs and therefore reduce their antiviral activity.

6.2 Antiproliferative Activity

The antiviral actions wrought by IFNs are mediated by enzymes whose mechanisms have broad implications for cell growth and proliferation. Virus replication may be regarded as a form of pathological growth of a foreign, cell-like, entity at the cell's expense. In the presence of IFN, enzymes that generally curtail protein synthesis are activated, but because viral protein synthesis is normally rapid, the inhibitory effect on virus replication appears more dramatic than on the slower and more complex cellular growth. Possibly, the type I IFN system was evolved as part of a complex, interactive network of intercellular mediators that regulate cell growth and proliferation.

The dsRNA-dependent protein kinase, PKR, is constitutively produced in low amounts in a variety of cell types and is made in larger amounts following IFN induction. If a mutant form of this enzyme, which is unable to phosphorylate eIF2, is introduced into cells they undergo neoplastic transformation. This result suggests that normal PKR acts as a tumor-suppressor gene product whose activity is abrogated in the presence of dominant-negative (catalytically inactive) PKR mutants. The 2-5A synthetase-RNase L system could also have tumor-suppressor activity. For example, the levels of these two enzymes are high in growth-arrested cells. Introduction of 2-5A-like oligoadenylates into proliferating cells causes growth impairment, probably through activation of RNase L.

The foregoing observations indicate that enzymes such as PKR, 2-5A synthetase, and RNase L are involved in negative growth control mechanisms. That these enzymes are increased and activated in IFN-treated cells correlates well with IFN's antiproliferative activity. The increase in synthesis of these enzymes is however dependent on IFN-inducible transcription factors. Two of these transcription factors, IRF-1 and IRF-2, behave antagonistically; IRF-1 is a transcriptional activator while IRF-2 is a transcriptional inhibitor of the same set of IFN-inducible genes. IRF-1 has a short half-life and thus transcription of IFN-inducible genes is normally inhibited by the longer lasting IRF-2. After IFN induction, IRF-1 is transiently increased and leads to derepression of IFN-inducible genes. If IRF-2 is overexpressed, cells become transformed, probably because even low-level constitutive production of IFN-inducible gene products, such as PKR and 2-5A synthetase, is blocked. This transformation can be reversed by overexpressing IRF-1.

6.3 Antimicrobial Activity

A variety of microorganisms, including bacteria, mycoplasma, rickettsiae, chlamydia, protozoa, and fungi, have been cited as IFN inducers. Since, however, they lack IFN receptors, they are not directly susceptible to IFN actions. Nevertheless, IFNs tend to inhibit the growth of many of these microorganisms, particularly those that are intracellular parasites. It is unlikely, though, that the actions of the enzymes (e.g. 2-5A synthetase, PKR) that

inhibit viral replication will affect the replication of intracellular parasites, since their biosynthetic machinery is protected by their cell membrane. Other indirect mechanisms are therefore implicated. For example, type II IFN induces the enzyme indoleamine 2,3-dioxygenase (IDO), which catalyzes the conversion of tryptophan to N-formyl-kynurenine, resulting in tryptophan starvation, an activity that could also contribute to IFN-mediated antiproliferative effect. The growth of certain intracellular parasites (e.g. the protozoan *Toxoplasma gondii*) is inhibited by type II IFN, and tryptophan deprivation appears to be one of the inhibitory mechanisms involved. In phagocytic cells such as macrophages, which can be invaded by protozoans (e.g. *Leishmania*), IFNs, particularly type II IFN, inhibit parasite growth, probably by the induction of synthesis of reactive oxygen intermediates (ROI) and reactive nitrogen intermediates (RNI, e.g. $NO^{\bullet}$), which are toxic. The production of ROI following type II IFN induction may also contribute to the killing of intraerythrocytic malarial parasites.

There is rather less evidence to support a protective role of IFNs in bacterial and mycobacterial infections. Few bacteria appear to be growth inhibited by IFNs, but one exception is *Legionella pneumophilia*, whose replication inside macrophages is inhibited by type II IFN. Again, the production of ROI appears to be involved. It is noteworthy that patients with chronic granulomatous disease (CGD), who are inherently deficient in the respiratory burst oxidase system required for ROI generation, suffer from repeated severe bacterial infections of the deep tissues. At least some CGD patients benefit from type II IFN therapy.

6.4 Immunoregulatory Activity

Emerging evidence strongly suggests the involvement of IFNs not only in innate defense mechanisms but also in shaping adaptive immune responses to microbial attack. For example, type I IFN production by PDC following viral stimulation probably mediates T and NK cell maturation. However, the most crucial action is the increased expression of MHC antigens in leukocytes and other cell types triggered by IFNs. (The MHC antigens are cell surface glycoproteins essential for recognition of foreign, nonself, antigens). Both type I and type II IFNs induce expression of class I MHC antigens (i.e. HLA-A, B, C), but only type II IFN can induce *de novo* synthesis of class II MHC antigens (i.e. HLA-DR, DP, DQ). Class II MHC antigen expression is critically required for presentation of foreign antigen by macrophages and dendritic cells to T-helper (T_h) ($CD4^+$) lymphocytes leading to their activation. T_h-lymphocytes then secrete a range of cytokines that regulate B-lymphocyte proliferation and immunoglobulin (antibody) synthesis. Class I MHC antigen expression occurs more widely and is required for recognition of foreign antigen by cytotoxic T lymphocytes (CTL, $CD8^+$). For example, recognition of virus-infected cells by CTL depends on class I MHC antigen presentation of viral antigens at the cell membrane. Another category of leukocytes composed of large granular lymphocytes and known as NK cells are also activated by IFN, particularly type I IFN. It is not presently known how type I IFN augments the cytotoxic function of NK cells whose recognition of virus-infected cells or tumor cells appears to be independent of MHC antigen expression.

In the presence of antigen-specific antibodies, macrophages can effect cell-mediated cytotoxicity. Such antibody-dependent cell-mediated cytotoxicity (ADCC) can be enhanced by IFN through augmentation of immunoglobulin G-Fc receptor (IgG-FcR) expression.

Other cell surface proteins whose expression is increased by IFNs include cell adhesion molecules. Intercellular adhesion molecule 1 (ICAM-1) in particular is highly induced by type II IFN, but not by type I IFN, in vascular endothelial cells. The increased expression of ICAM-1 and other cell adhesion molecules leads to lymphocytes and monocytes bearing counterreceptors, for example, those expressing the integrin LFA-1, sticking to the endothelial cell lining of blood vessels from where they can migrate into injured or infected tissues.

Apart from the upregulation of cell surface molecules, IFNs also appear to be involved in the proliferation and functions of B lymphocytes, particularly immunoglobulin (antibody) synthesis. For example, type I IFNs inhibit antibody production when present at high concentrations but may stimulate antibody production at low concentrations. In comparison, type II IFN may act as a costimulant for B-cell proliferation as well as an immunoglobulin isotype switch in antibody-producing cells. Type II IFN (IFN-γ) enhances IgG_{2a} synthesis and inhibits IgG_1 and IgE production, an action that is opposed to that of interleukin-4 (IL-4). Type II IFN may also act by an unknown mechanism as a maturation factor for certain classes of cytotoxic T lymphocytes (CTL). IFNs, in general, are inhibitory for the proliferation of hematopoietic progenitor cells and therefore can depress hematopoiesis and the production of leukocytes.

7
Potential Physiological and Pathophysiological Roles of IFNs

7.1
Do IFNs have Physiological Roles?

All of the biological activities ascribed to IFNs were discovered through *in vitro* experimentation. Here it is possible to pick and choose conditions that favor particular outcomes (e.g. the antiviral response) by adjusting doses of IFN, times of incubation, levels of virus challenge, and so on. Experiments are frequently performed in cell systems where IFNs are the only exogenous, biologically active reagents present. The whole range of IFN-inducible activities is not demonstrable in a single-cell type; thus *in vitro* experimentation, often involving multiple cell ''targets,'' including tumor cell lines, tends to illustrate, and perhaps exaggerate, the potential of IFNs as multifunctional regulators rather than define their ''true'' physiological roles. *In vivo*, IFNs together with other cytokines are often coinduced; therefore, it can be difficult to deduce whether IFN, or rather a particular type of IFN, has a major physiological role or one or more subordinate or accessory roles. Furthermore, although IFNs can be shown to have actions that regulate cell growth and differentiation *in vitro*, it is much harder to show unequivocally that IFNs are involved in physiological processes such as embryogenesis, organ and tissue development, and homeostatic mechanisms. That IFNs have the potential for inducing antiviral, antimicrobial, and antitumor activity suggests that their true physiological worth is as regulators of host defense mechanisms, to prevent pathophysiological events.

7.2 Ways of Studying IFN "Physiology"

Probably the best approach to determine how IFNs work *in vivo* is to investigate animals in which a deficiency of the IFN system exists or can be induced. For the IFN system, however, natural genetic deficiencies, either in the IFN genes or in the IFN-receptor genes, are probably very rare. Nevertheless, it is now possible to knockout the function of particular genes by specific site-directed disruption of the gene, for example, in mice. This approach involves targeting a nonfunctional gene by means of a vector into the mouse embryonic stem (ES) cell genome resulting in disruption of gene expression. Subsequently, ES cell lines are selected for the disrupted gene and injected into blastocysts. A program of breeding of the resulting chimeric animals and selection of offspring carrying the disrupted gene in the germline eventually leads, as long as this is not prenatally lethal, to the generation of viable null or knockout mice, which are homozygous for the disrupted gene.

To date, knockout mice with disrupted IFN, IFN-receptor, IRF, JAK, and other IFN-stimulated genes have been generated. For example, knockout mice with either a disrupted type II IFN gene or a disrupted type II IFN-receptor gene have been produced. Both kinds of mice developed normally and were healthy, but they exhibited a defect in natural resistance when challenged with pathogens (e.g. vaccinia virus or *Listeria monocytogenes* or mycobacteria). Macrophages in these mice showed impaired ROI and nitric oxide production and expression of class II MHC antigen expression; NK cell activity, but not CTL activity, was reduced while splenocytes proliferated in an uncontrolled manner in response to mitogen or alloantigen. Knockout mice deficient in the IFN receptor lacked an antigen-specific IgG_{2a} response. It thus has been clearly demonstrated that type II IFN (IFN-γ) is essential for immune responses to pathogens by several cell types.

Production of macrophage nitric oxide is crucially dependent on type II IFN-inducible nitric oxide synthetase (iNOS), whose gene transcription is regulated by IRF-1, a transcriptional enhancer. Thus, mice deficient in IRF-1 are also deficient in iNOS and susceptible to mycobacterial (e.g. *M. tuberculosis*) infections, which they are unable to clear. IRF-1 knockout mice also share other phenotypic similarities, such as reduced NK activity, with IFN-γR knockout mice.

Although IFN-γR knockout mice were susceptible to vaccinia virus, they were no more susceptible to other viruses (e.g. Semliki Forest virus (SFV), VSV) than their normal littermates. In contrast, knockout mice defective in type I IFN-receptor R1 gene, while displaying no overt phenotypic abnormalities, were unable to counter infection with several different viruses, including SFV and VSV. These findings indicate that type I and type II IFNs exert their antiviral effects through different, partially nonredundant pathways.

Certain mouse strains are more susceptible to infection by viruses or microorganisms, and in some cases this can be attributed to low type I IFN production. In addition, injection of mice with antitype I IFN antibody has been shown to increase their susceptibility to a range of virus infections. Children who suffer repeated rhinovirus (common cold) infections also have been shown to secrete lower than average levels of type I IFNs.

There are many molecularly different species of type I IFN (e.g. IFN-α_1,

α_2, ... α_n, IFN-ß, IFN-κ, IFN-ω, IFN-τ). Except for IFN-τ, which has a special role as an antiluteolytic agent in ruminant pregnancy, there is no good evidence why such a large diversity of type I IFN molecules is necessary. Qualitatively, there are no differences in the *in vitro* biological activities of IFN-α, IFN-ß, and IFN-ω. Quantitative differences among these IFNs can be demonstrated, but these probably reflect their differing affinities for the type I IFN receptor. Possibly, differences in their hydrophobicity causes individual type I IFNs to locate more efficiently to particular tissues or anatomical sites but, as yet, there is little to support this hypothesis.

7.3 IFNs and Pathophysiological Phenomena

IFN genes are normally switched off and only expressed transiently during intervals of acute illness or injury. IFNs are thus induced to contribute to the host's specific and nonspecific defense mechanisms to combat infectious diseases and resolve tissue injuries. They are part of a network of mediators, including many other cytokines, responsible for regulatory immune responses and inflammatory reactions. However, if immunity and inflammation are excessive, pathophysiological phenomena often arise. IFNs are usually secreted locally, but can, if overexpressed, find their way into the circulation and produce symptoms such as fever, malaise, and headache, often associated with such acute viral infections as influenza. Such symptoms can be reproduced in patients receiving therapeutic doses of exogenous IFN-α or IFN-ß for malignancies and so it is clear that it is the IFN molecule itself that has the capacity to induce undesirable "side effects."

IFNs, and particularly type II IFN (IFN-γ), are proinflammatory. By increasing recognition of infected cells through augmentation of MHC antigen expression and enhancing cell adhesion molecules, leukocytes (neutrophils, lymphocytes, and macrophages) are recruited to sites of infected or injured tissues, are activated by antigen and cytokines to become cytotoxic or phagocytic, and synthesize a range of inflammatory and vasoactive mediators. In damaged skin, for instance, this results in local reddening and swelling before healing and resolution of the damaged area occurs. Infection or injury occurring a second time at the same site sometimes leads to a more severe inflammatory reaction as leukocytes are "primed" to infiltrate the site. This phenomenon is known as delayed hypersensitivity (DH). The severe complications (e.g. hemorrhagic shock) observed in children suffering from a second dengue virus infection (normally of a different serotype to the one that caused the primary infection) probably result from DH reactions. In a murine model, DH has been shown to be inhibited by neutralizing antibody against IFN-γ, thus strongly implicating IFN-γ as a proximal mediator of DH.

7.4 IFNs and Pathogenesis

On some occasions, the presence of IFNs correlates well with disease progression. Again, in a murine model, *Plasmodium berghei* induces cerebral malaria, often a severe complication of human infection with *Plasmodium falciparum*. Neutralizing antibodies to IFN-γ injected prior to infection with *P. berghei*, however, prevented the development of cerebral malaria. IFN-γ and other cytokines (e.g. TNF-α) are also partly responsible for the formation

of granulomas, nodular-like tissue masses characteristic of infections caused by some microorganisms, particularly mycobacteria (e.g. *Mycobacterium leprae*, the microbe that causes leprosy). Granulomas prevent spread of the mycobacteria, and since they contain large numbers of macrophages and neutrophils, mycobacteria can be killed by IFN-γ induction of ROI and nitric oxide synthesis. If, for example, ROI production fails to clear the mycobacteria and persists over an extended period, however, this cell-mediated response may lead to chronic inflammation and tissue damage. In such cases, chronic disease might result not from excessive IFN-γ levels, but from continuous, low-level production, which is insufficient to induce resolution of the disease. Other types of acute illnesses (e.g. viral hepatitis) may also become chronic due to a failure of the IFN system to clear the virus or microorganism. In both hepatitis-B and -C virus infections, viral mechanisms actively inhibit type I IFN production and action, and probably contribute to the establishment of chronic virus infection.

IFNs have also been associated with autoimmune diseases, but while levels of certain IFN types may be raised in such diseases, it is difficult to distinguish whether the IFNs are contributing to pathogenesis or whether they are by-products of underlying pathological processes. Autoimmune diseases usually result from a breakdown in immunological tolerance to self-antigens, but the causative agents are mostly unknown. It is, however, widely believed that viruses, bacteria, or mycoplasma, often infecting individuals years prior to the onset of disease, are responsible for lymphocyte sensitization to self-antigens. There are some genetic factors also (e.g. MHC antigen haplotypes) that increase susceptibility to particular autoimmune diseases. The inbred New Zealand Black (NZB) mice, for example, ''spontaneously'' develop autoantibodies and glomerulonephritis; this autoimmune disease progresses more rapidly if the mice are injected with type I or type II murine IFN and less rapidly if the mice are given neutralizing antitype II murine IFN antibody. Type I IFN-receptor deficiency in homozygous IFN-α/βR gene deleted NZB mice also resulted in reduced lupus-like disease. These findings suggest that IFNs have a pathogenic role in this autoimmune disease of NZB mice.

A small number of people suffer from systemic lupus erythematosus (SLE), an autoimmune disease characterized by high titers of autoantibodies of a range of specificities, including nuclear components, DNA, and nucleosomes leading to immune complex induced vasculitis and kidney failure, a feature in common with the NZB mice's autoimmune disease. Circulating IFN-α can be found in some SLE patients, with levels correlating to disease activity. Its role remains enigmatic, but there is increasing evidence of IFN-α being involved on both the initiation and maintenance of the central autoimmune processes of SLE. It is hypothesized that a specific class of dendritic cells is stimulated by viruses to secrete IFN-α in the first phase and by immune complexes in the second phase, thus creating a vicious cycle mechanism driving autoimmune processes. The unabated IFN-α production might contribute to autoimmune disease in a number of ways (e.g. by stimulating B-cell production of autoantibodies, by increasing MHC antigen expression and thus stimulating autoreactive T and B cells. In support of this hypothesis, an IFN-α ''signature'' of many IFN-induced genes has been demonstrated in white blood cells from patients with active SLE.

Tab. 4 IFNs and disease correlations.

Disease	*IFN type*	*Putative pathogenic mechanism(s)*
Systemic lupus erythematosus (SLE)	IFN-α	Stimulation of autoantibodies, autoreactive T and B cells
Insulin-dependent diabetes mellitus (IDDM)	IFN-α/IFN-γ	Upregulation of MHC class I and class II antigens in ß-islet cells, generation of autoreactive cytotoxic T lymphocytes
Behçets disease (eye lesions)	"Acid labile" – IFN-α/IFN-γ	Increased MHC class I and class II antigen expression. Increased autoantibody production
Grave's ophthalmopathy (immunological cytotoxicity against eye muscle cells)	IFN-γ	Increased MHC class II antigen expression. Increased ADCC of eye muscle cells
Multiple sclerosis	IFN-γ	Generation of autoreactive CTL in central nervous system
Sjögren's syndrome (chronic inflammatory disease of exocrine glands)	IFN-γ	Downregulation of type I IFN receptors in NK cells leading to loss of NK cell activity
Aplastic anemia (primary disorder of hematopoietic system)	IFN-α/IFN-γ	Inhibition of hematopoietic precursor proliferation

In tissue-restricted autoimmune diseases, such as insulin-dependent diabetes mellitus (IDDM), localized IFN secretion in a particular tissue or tissues may also be involved. For example, the ß-islet cells in the pancreas of IDDM patients hyperexpress class I and class II MHC antigens suggesting the presence of types I and II IFN, respectively. This has been confirmed by immunohistochemical staining of sections of pancreases. There are several other autoimmune or autoimmune-like diseases for which IFNs have been associated and these are summarized in Table 4.

8 Clinical Uses of IFNs

The potent antiviral activity of IFNs together with their potential antitumor actions provided the spur to the large-scale manufacture of IFNs for the purpose of clinical evaluation in a variety of viral and malignant diseases. In the early 1970s, large-scale production was limited by the quantities of human buffy coats (leukocytes) which could be used to make type I IFN. Later in that decade, human lymphoblastoid cells (e.g. Namalwa cell line), which could be grown to large culture volumes, became available for type I IFN production. By the 1980s, following the cloning of IFN-α subtype genes, some IFN species were mass-produced in *E. coli* or, in some instances, in mammalian cells, leading to abundant availability of certain subtypes (e.g. IFN-α_2). Production of IFN-ß, IFN-ω and IFN-γ by this means followed. Synthesis or construction of consensus sequence IFNA genes and various hybrid IFNA genes (e.g. A1/A2, A1/A8) has led to the production of nonnatural IFN-α molecules with enhanced activities or stability.

As a result of the anecdotal or often uncontrolled clinical studies of the 1970s, there was great enthusiasm in the 1980s, both from manufacturers of IFNs and clinicians, to test the therapeutic potential of interferons. It was only after many controlled or randomized studies had been conducted that it became obvious that IFN administered as a single agent was not beneficial for the treatment of the majority of malignant diseases, including the major cancers, lung, breast, colon. The initial optimism all but vanished and was replaced in the mid-1980s by a more sober and realistic appreciation of the potential therapeutic value of IFNs.

One major problem remains, that is: there is little real understanding of how IFNs were having their antitumor effects. Although IFNs had been shown to have antiproliferative activity in many tumor cell lines *in vitro*, it was also known that other tumor cell lines that were resistant to IFNs *in vitro* were nevertheless destroyed by IFN treatment when grown as transplantable tumors in mice. This indicated that IFNs probably acted on tumors *in vivo* by indirect mechanisms (e.g. augmentation of NK cell activity or enhancement of MHC antigen expression and antitumor immunity). In other words, their antitumor effects had more to do with modifying biological responses than direct antiproliferative actions. IFNs and cytokines in general are sometimes referred to as biological response modifiers (BRMs). However, it is still not clear what biological and pharmacological responses are necessary for IFN-induced tumor regression to occur.

In patients IFNs are administered in high doses, often close to the maximum tolerated dose (MTD): IFN, a ''biological drug'' is thus being used as if it were a chemical drug, a practice that sometimes leads to severe side effects (Table 5) and toxicity. Therefore, it is difficult to establish whether IFN is acting on tumors in the manner of a chemotherapeutic agent (i.e. direct action) or as a BRM (i.e. indirect action) or as both. It has become apparent nonetheless that IFNs administered at low doses are generally less effective in causing tumor regression. In addition, high-dose IFN therapy over a long period causes leukopenia (i.e. reduced numbers of leukocytes that respond to IFN and mediate indirect IFN antitumor effects), relative immunosuppression, and autoimmune phenomena. It is therefore difficult, against a background of generalized toxic effects, to ''harness'' whatever antitumor activity IFNs may have for particular tumor types.

Tab. 5 Side effects of type I IFN therapy.

Observed clinical responses (frequent)
Fever
Chills
Malaise/Fatigue
Myalgia
Headache
Anorexia/weight loss
Pharmacological toxicity (infrequent)
Liver and kidney toxicity
Inhibition of hematopoiesis, leukopenia
Central nervous system toxicity, e.g. confusion, altered mental states
Heart disturbances, e.g. arrhythmia, ischemia
Immunological responses
Depressed natural killer cell activity and ADCC on prolonged therapy schedules
Induction of autoantibodies

So far IFNs have only been partially successful in the treatment of cancers, and only for a very limited number of types of malignancy. Clinical trials have shown that the efficacy of individual IFN-α subtypes, in particular IFN-α_2, is more or

less the same as heterogeneous, multicomponent, type I IFN preparations such as lymphoblastoid and leukocyte IFN, both of which contain mixtures of IFN-α subtypes. IFN-ß is probably as efficacious, but it has not been used as widely as IFN-α preparations in antitumor therapies. IFN-γ, despite its apparent greater immunoregulatory activity, has been found to be rather less potent than IFN-α. All IFNs in high doses cause significant, but readily reversible, side effects (Table 5). The most responsive cancer to IFN-α therapy is a very rare form of leukemia known as hairy cell leukemia (HCL), where up to an 80% response rate has been reported. In HCL patients, the ''hairy cells'' invade the spleen and bone marrow. It has been convincingly shown that IFN-α therapy continued over several months leads to clearance of ''hairy cells'' and in some patients, a long-term remission is achieved. Some patients develop neutralizing antibodies against IFN, particularly IFN-α_2, which may cause resistance to further treatment. In these cases, beneficial responses maybe rescued by switching to a multicomponent IFN-α preparation. On the whole, IFN-α therapy of HCL appears at least as effective and durable as chemotherapy with the drug pentostatin (2-deoxycoformycin).

IFN-α therapy has also been shown to slow down the progression of CML. In this cancer, leukemic cells grow slowly in the initial chronic phase and persist for 2 to 4 years, but there follows a dramatic ''blast crisis,'' producing rapidly proliferating myeloid leukemia cells and a fatal outcome. CML patients can be treated with IFN-α in the chronic phase, and some achieve complete hematological remission (i.e. disappearance of leukemic cells, and often increased survival). Recently, IFN-α therapy of CML has been replaced by the administration of tyrosine kinase inhibitors such as Gleevec®, which block c-abl activity in leukemic cells, and thus their proliferation.

Other malignancies in which IFN-α therapy seems to work, although with a lower percentage of patients responding than in HCL and CML, include low-grade non-Hodgkin's lymphoma, cutaneous T-cell lymphoma, AIDS-related Kaposi's sarcoma, carcinoid tumors, renal cell carcinoma, squamous epithelial tumors of the head and neck, multiple myeloma, and malignant melanoma (Table 6). In most of these cancers, complete responses are low compared to partial responses, but IFN-α may help with maintenance therapy of disease in some cases. In preclinical systems, the combination of IFN therapy and conventional chemotherapy has appeared to offer greater chances of producing effective treatment of many cancers, but in clinical trials this strategy has produced mostly disappointing results, probably because optimal combinations of IFNs with cytotoxic drugs cannot be deduced owing to a lack of understanding of the physiological interaction of these agents.

As mentioned earlier, IFN therapy induces leukopenia and generalized immunosuppression. This effect may be useful for the treatment of diseases in which there is uncontrolled leukocytosis (e.g. thrombocytosis: markedly elevated platelet numbers) associated with various myeloproliferative diseases. Parenteral (subcutaneous or intramuscular) injection of IFN-ß appears to benefit multiple sclerosis (MS) patients in the early stages of this disease by leading to a reduced rate of exacerbations. This, however, could be a result of the relative immunosuppression caused by IFN-ß (e.g. by inhibiting IFN-γ actions and thereby

Tab. 6 Responses seen in human malignancies following IFNα therapy.

		Approximate response rate[a] [%]
Hematological malignancies:	Hairy cell leukemia	80
	Chronic myelogenous leukemia (preblast crisis)	79
	Cutaneous T-cell lymphoma	52
	Non-Hodgkin's lymphoma	46
	Multiple myeloma	20
Solid tumors:	Squamous tumors of head and neck	91%
	Carcinoid tumors	55
	Bladder cancer	65
	Cervical cancer	43
	Kaposi's sarcoma (AIDS-related)	30
	Ovarian cancer	19
	Renal cell carcinoma	17

Notes: Intermediate and high-grade lymphomas, Hodgkin's disease, and chronic lymphocytic leukemia, all less than 20%. Malignant melanoma, breast cancer, colorectal carcinoma, lung cancer, osteogenic sarcoma, all around 10% or less.
[a]Response rate includes complete, partial, and minor responses.

suppressing the growth and activity of autoreactive T lymphocytes in the central nervous system.

Type II IFN, IFN-γ, has been rather less successful in the treatment of cancers, but uniquely it has been found to benefit some chronic granulomatous disease (CGD) patients, probably by boosting and thus correcting the impaired ROI producing capacity of macrophages and neutrophils. IFN-γ may also be useful in the adjunctive treatment of leishmaniasis and mycobacterial diseases.

In the treatment of viral diseases, IFNs, despite having proven antiviral activity *in vitro*, have not proved to be the panacea for most common viral infections of man. IFNs prevent the replication of rhinoviruses in cell cultures when administered to volunteers in the form of a nasal spray, but IFNs cannot ''cure'' colds once established. IFNs are only partially effective in preventing influenza infection. Topical applications of IFN in the form of creams or ointments to herpesvirus lesions (e.g. in herpes zoster) and genital warts caused by papilloma viruses have been tried but have given limited beneficial effects. It has been found that parenteral administration (i.e. intramuscular or intravenous injection) has greater beneficial effects of IFN-α on virus-caused lesions and warts, although not to the extent that IFN therapy has become the treatment of choice. Another wartlike disease, juvenile laryngeal papilloma (JLP), which can severely obstruct the airways of young children, also has been found to respond beneficially to IFN-α therapy. Nevertheless, it appears neither curative nor of substantial value as an adjunctive agent in the long-term management of JLP.

Probably, the most successful application of IFN-α therapy in virus-mediated

diseases is in the treatment of chronic active hepatitis, caused by either hepatitis-B or -C viruses. A certain proportion of chronic active hepatitis-B patients respond positively to IFN-α treatment. For instance, viral infectivity markers disappear and seroconversion and cure follows. It is interesting that in the case of hepatitis-B virus, viral activity is probably responsible for inhibiting the endogenous IFN system, and therefore the administration of exogenous IFN-α constitutes a replacement therapy. In hepatitis C virus infection, the most common cause of transfusion-linked hepatitis, IFN-α is the treatment of choice. Recent improvements in combination therapies using ''pegylated'' IFN-α_2 (the pegylation markedly increases the half-life of IFN in the circulation) and the antiviral drug ribovarin have resulted in cure rates approaching 70%. However, some strains of the virus, in particular genotype 1, which is the most prevalent worldwide, are strongly resistant to IFN therapy. This resistance has been recently demonstrated to be associated with the capacity of the virus to block IRF-3 activation, which is essential for antiviral activity.

Type I IFN, both IFN-α and IFN-ß, has been shown to inhibit HIV-1 replication *in vitro*. However, *in vivo* there is little evidence showing IFN-α has any long-term beneficial effect in HIV-1 positive individuals. IFN-α can cause tumor regression in some AIDS patients with Kaposi's sarcoma, but this possibly has more to do with IFNs antitumor or antiangiogenic activity than with its antiviral one. Combination therapies for HIV-1 infections involving IFN-α, antiviral drugs such as 3′-azido-2′,3′-dideoxythymidine (AZT) and cytokines, such as granulocyte-macrophage colony-stimulating factor (GM-CSF), appeared promising, but have not been followed up.

9 Final Remarks

Since their discovery over four decades ago, IFNs have ceased to be poorly characterized antiviral factors; both at the molecular and cell biological levels; they are now among the best defined and better understood biologically active intercellular mediators. However, despite the large body of information concerning IFNs and their actions, there are still many issues to be resolved. Why, for example, is the type I IFN family so heterogeneous? There is a need to find more ways to translate the potent antiviral, antimicrobial, and antitumor activities of IFNs into the means for combating human disease. Future progress will depend on further understanding not only of IFN-mediated actions at the molecular and cellular level but also of the numerous ways IFNs can interact with other biologically active mediators, including cytokines, hormones, and chemical drugs.

Keywords

Attachment Factor
Cell surface molecule that permits virus binding without triggering conformational rearrangements in the viral envelope, and without permitting viral entry.

Innate Immunity
Immediate cellular response without previous exposure of the host cell to an infectious agent.

Interferons
Large family of multifunctional secreted proteins involved in antiviral defense, cell growth regulation, and immune activation.

Intracellular Trafficking
Translocation of cellular and viral macromolecules within a cell. A phenomenon that occurs at both early and late stages of viral replication.

Receptor
Cellular surface molecule that binds virus and permits viral entry.

Ribonucleoprotein
A complex that is composed of both RNA and protein.

Viral Restriction
A block to virus replication due to the presence of constitutively-expressed genes, or to the absence of a required component in the infected cell.

Abbreviations

AAV:	adeno-associated virus
ACE2:	angiotensin converting enzyme 2
ADAR:	adenosine deaminase
Ag:	antigen
AIDS:	acquired immunodeficiency syndrome
ALV:	avian leukosis virus
APOBEC:	apolipoprotein B mRNA-editing enzyme-catalytic polypeptide-like
ASLV:	avian sarcoma and leukosis virus
ASV:	avian sarcoma virus
ATF:	activating transcription factor
BAF:	barrier-to-autointegration factor
BDV:	Borna disease virus
CAT:	cationic amino acid transporter
CBP:	cAMP Binding Protein
ccc:	covalently closed circle
CD4:	cluster differentiation 4
CDK:	cyclin dependent kinase
CIITA:	MHC class II transcription factor
CK2:	calcium kinase 2
CMV:	cytomegalovirus
c-onc:	cellular proto-oncogenes
c-PKA:	cAMP-dependent protein kinase
CPSF:	cleavage and polyadenylation specificity factor
CREB:	cyclic-AMP response element binding
CRM-1:	chromosome maintenance region 1
CTD:	carboxy terminal domain
CTE:	constitutive transport RNA elements
CTL:	cytotoxic T lymphocytes
DC:	dendritic cells
DC-SIGN:	dendritic cell-specific ICAM-3 grabbing nonintegrin
dsRNA:	double-stranded RNA
EBV:	Epstein–Barr virus
eEF1α:	eukaryotic elongation factor-1 alpha
EGF:	epidermal growth factor
EIAV:	equine infectious anaemia virus

eIF:	eukaryotic initiation factor
EMCV:	encephalomyocarditis virus
eRF1:	eukaryotic release factor 1
ESCRT:	endosomal sorting complex required for transport
FADD:	Fas associated death domain
FIV:	feline immunodeficiency virus
FMDV:	foot-and-mouth disease virus
FV:	foamy virus
Fv-1:	Friend virus susceptibility factor-1
Gag:	group specific antigen
gD:	glycoprotein D
GLUT:	glucose transporter
GM-CSF:	granulocyte-macrophage colony-stimulating factor
HAT:	histone acetyl transferase
HBV:	hepatitis B virus
HCMV:	human cytomegalovirus
HCV:	hepatitis C virus
HDAC:	histone deacetylases
HDM2:	human double minute 2 protein
HDV:	hepatitis delta virus
HHV8/KSHV:	human herpes virus 8/Kaposi's sarcoma-associated herpesvirus
HIV:	human immunodeficiency virus
HIVD:	HIV-associated dementia
HLA:	human leukocyte antigen
HMG:	high-mobility group protein
HNF:	hepatocyte nuclear factors
hnRNP:	heterogeneous nuclear ribonucleoprotein
hnRNP A2:	heterogeneous nuclear ribonucleoprotein A2
HPV:	human papillomavirus
HSPG:	heparan sulfate proteoglycans
HSV:	herpes simplex virus
HTLV-I:	human T-cell leukemia virus
IFN:	interferon
IFNAR:	IFN-α Receptor
IFNGR:	IFN-γ Receptor
IKK:	IκB kinase
IL:	interleukin
IN:	integrase
INI1 or hSNF5:	integrase interactor 1
iNOS:	inducible nitric oxide synthase
IRES:	internal ribosome entry site
IRF:	IFN regulatory factor
IRS-1:	insulin receptor substrate 1
IS:	immunological synapse

ISG:	IFN-stimulated gene
ISGF3:	IFN-stimulated gene factor 3
ISRE:	IFN-stimulated response elements
IκB:	inhibitory factor κB
Jak:	Janus kinase
kDa:	kiloDaltons
LEDGF/p75:	lens epithelium-derived growth factor
LT:	large T antigen
LTR:	long terminal repeat
MA:	matrix
MAP:	mitogen-activated protein
MCP-1:	monocyte chemoattractant protein 1
MCV:	molluscum contagiosum virus
MHC:	major histocompatibility complex
MIP-1:	macrophage inflammatory protein 1
MKKK:	MAP 3 kinase
ML:	major late
MLV:	murine leukemia virus
MPSV:	Mason-Pfizer simian virus
MTOC:	microtubule organizing center
MVB:	multivesicular body
NC:	nucleocapsid
NES:	nuclear export signal
NF-κB:	nuclear factor-κB
NK:	natural killer
NLS:	nuclear localization signal
NP:	nucleoprotein
OAS:	2′–5′ oligoadenylate synthetases
P/CAF:	P300/CBP-associated factor
PA:	polymerase subunit A
PABP:	polyA binding protein
PACT:	PKR activator
PDI:	protein disulfide isomerase
PIC:	preintegration complex
PKC:	protein kinase C
PKR:	dsRNA-activated protein kinase
PML:	promyelocytic leukemia protein
pRb:	retinoblastoma susceptibility protein
PyV:	polyomavirus
RANTES:	regulated upon activation, normal T-cell expressed and secreted
RdRp:	RNA-dependent RNA polymerase
Ref1:	restriction factor 1
RISC:	RNA-induced silencing complex
RLI:	RNAse L Inhibitor

RNAi:	RNA interference
RNAP:	RNA polymerase
RNAse L:	endoribonuclease L
RNP:	ribonucleoprotein
RRE:	Rev responsive element
RsSV:	Rous sarcoma virus
RSV:	respiratory syncytial virus
RT:	reverse transcriptase
RVFV:	Rift Valley fever virus
RxRE:	Rex responsive element
Sam68:	Src-associated during mitosis 68 kDa protein
SARS-CoV:	coronavirus that causes severe acute respiratory syndrome
SFV:	Semliki Forest virus
siRNA:	small-interfering RNA
SIV:	simian immunodeficiency virus
SOCS3:	suppressor of cytokine signaling-3
ST:	small T antigen
Stat:	signal transducer and activator of transcription
SU:	envelope surface unit
SV40:	simian virus 40
TAP:	transporter associated with antigen processing
TAR:	trans-activation response element
TBEV:	tick-borne encephalitis virus
TBP:	TATA–binding protein
TGFβ:	transforming growth factor β
TLR:	toll-like receptor
TM:	envelope transmembrane unit
TNFR:	tumor necrosis factor receptor
TNFα:	tumor necrosis factor α
TORC3:	transducer of regulated CREB protein 3
TRAIL:	TNF-related apoptosis-inducing ligand
TRBP:	TAR RNA binding protein
TRIM:	tripartite repeat motif protein
Tsg101:	tumor susceptibility gene 101 protein
UNG2:	uracil-DNA glycosylase 2
vhs:	virion host shut-off
Vif:	viral infectivity factor
v-onc:	viral oncogenes
Vpr:	viral protein R
VS:	virological synapse
VV:	vaccinia virus
VZV:	varicella zoster virus
WNV:	West Nile virus
X-PBP:	X-promoter binding protein

Viruses are obligatory parasites of their host cells. During the viral replication cycle, many host-cell components are co-opted or hijacked to favor viral replication and virus production. The interactions between the virus and the host induce multiple cellular responses that modify normal cell function and can lead either to clearing of the virus or to enhanced virus replication and pathogenesis. Most, if not all steps of the viral replication cycle are characterized by critical virus–host interactions. These begin with the earliest steps of the replication cycle (e.g. viral entry into the target cell) to later steps including mRNA synthesis, genome replication, and protein and viral genome trafficking within the nucleus and cytoplasm to sites of viral assembly. The understanding of the molecular details of these virus-cell interactions will ultimately help in the design of new and specific therapies against viral infection. The purpose of this review is to highlight various virus–cell interactions. Because of the extensive nature of this topic, we will be presenting general themes and specific examples of virus–cell interactions where appropriate rather than a comprehensive catalog of every virus–cell interaction that has been uncovered.

1 Virus Entry

Virus entry designates the process that ultimately permits delivery of the viral content into the target cell cytoplasm, to be replicated by viral and cellular proteins. This process can be grossly divided into two distinct major processes: recognition of the surface of a suitable target cell by the virus and the translocation process itself, that is, for enveloped viruses, fusion between the viral and cellular lipid membranes. These functions, receptor binding and virus-cell fusion, are mediated by the viral envelope proteins. The first step, the recognition of suitable target cells itself comprises several distinct, though partly overlapping, functions that are interactions with defined structures on the cell surface.

Nonenveloped viruses, such as small DNA-containing viruses and the RNA-containing viruses of the Picornaviridae and Reoviridae families, are devoid of a viral lipid bilayer and thus have to break the host-cell membrane instead of merging with it. Their entry mechanism into target cells is therefore fundamentally different from that of enveloped viruses, on which we will concentrate in this review. However, the principles guiding entry remain the same: nonenveloped viruses use cellular receptors to recognize and attach to target cells and receptor binding is followed by the activation of a viral fusion protein.

1.1 Virus Attachment to Target Cells

Attachment is defined as a low affinity, but high avidity interaction that permits velcro-like virus–cell association. These interactions facilitate the following entry steps, especially the interaction of the viral envelope with specific protein receptors, but alone do not lead to major conformational rearrangements in the viral proteins and the cellular attachment factor. Most attachment factors are repetitive carbohydrate structures, such as heparan sulfate

proteoglycans (HSPG) and glycolipids, but some lipids may also be involved in attachment. The nonexhaustive list of viruses binding to cell surface HSPG comprises viruses as different as papillomaviruses, parvoviruses, dengue virus, hepatitis C virus (HCV), herpesviruses, and human immunodeficiency virus (HIV). Herpes simplex viruses (HSV) are somewhat more selective in that they require the activity of specific sulphotransferases to generate HSV glycoprotein D (gD) binding sites. The importance of the contribution of the virus–HSPG interaction to viral entry is illustrated by the finding that treatment of target cells with heparitinase drastically reduces infectivity. Similarly, a role for phosphatidylserine in vesicular stomatitis virus (VSV) entry has been described, but the interaction of the viral envelope protein with the lipid does not actually fulfill the criteria for a viral receptor (see the following), but rather those of an attachment factor.

Another virus–carbohydrate interaction occurs between the glycosylated viral envelope proteins and C-type lectins such as dendritic cell-specific ICAM-3 grabbing nonintegrin (DC-SIGN), L-SIGN or hMGL. Virus binding to lectins seems, as interaction with HSPG, neither to induce major conformational changes in the envelope, nor to trigger membrane fusion and thus entry. Virus binding to DC-SIGN, which was first identified with HIV, nevertheless has dramatic consequences, as it increases the half-life of infectious virions and facilitates transmission to susceptible target cells. The lectin-bound virus may be internalized in intracellular vesicles, travels with the dendritic cell, and is presented to susceptible target cells at distant sites such as the lymph node. Virus–lectin interactions therefore enhance viral spread, and are far from being unique to HIV. As yet, DC-SIGN has been shown to interact with HCV, Ebola virus, Marburg virus, and coronavirus that causes severe acute respiratory syndrome (SARS-CoV).

A third mechanism by which viruses can enhance the efficiency of virus–cell contacts is the incorporation of cellular receptors in the viral envelop during egress. For example, incorporation of ICAM-1 and other cellular adhesion molecules into HIV-1 virions clearly affects the viral replication cycle and enhances the efficiency of infection (Table 1). Although not yet systematically studied in other viruses, it is possible that this mechanism has evolved as a general mechanism for enveloped viruses to optimize viral entry.

1.2 Viral Receptors

Viral receptors in the strict sense of the term are transmembrane proteins that are sufficient to permit viral fusion with any given cell type. Unlike attachment factors, they lead to conformational rearrangements in the envelope protein(s), and unfolding cascades of events that ultimately permit viral entry. Therefore, *in vivo* cell tropism directly relates to the capacity of viruses to infect targets via the expressed viral receptor. Of note, for many viruses there are multiple receptors that form either a receptor complex (e.g. receptor and coreceptor), or are alternatively used to gain entry into different types of target cells. A good example for this interplay between obligatory and/or alternative viral receptors are those permitting HIV-1 entry into target cells. All known HIV-1 strains depend on the single transmembrane domain receptor cluster differentiation 4 (CD4). Interaction between the viral envelope surface unit (SU) and CD4 is followed by envelope-binding

Tab. 1 Examples of virion-incorporated cellular proteins.

Gene	*Virus*	*Putative function*	*Incorporation*[a]
AIP1/Vps28	Retroviruses	Assembly/budding	Via Gag
APOBEC3G	Retroviruses	Deamination; infectivity	Via viral RNP and Gag
β-actin	HHV8/KHSV, HIV-1	Structural	Associated with tegument-capsid
c-PKA	HIV-1	Infectivity	Via Gag
CK2	VSV	Kinase activity on L, P and M proteins	Via viral RNP
CK2	Influenza virus	Kinase activity on NP, PA	Inside virion
Cyclophilin A	HIV-1	Uncoating; infectivity	Via Gag
DC-SIGN	Retroviruses	cell-to-cell transmission	In envelope
ERK2/MAPK	HIV-1, HTLV-I	Kinase activity on CA, MA	Via MA and CA
HBV-associated kinase	HBV	Infectivity	Via core
HP68	Retroviruses	Capsid/Gag assembly	Via Gag
HSV-associated kinase	HSV	Infectivity	Via tegument proteins
ICAMs	Retroviruses	Infectivity; cell-to-cell transmission; host-cell attachment	Via Gag
INI1	Retroviruses	Assembly, PIC import and integration	Via Gag/Pol
Myosin	HHV8/KHSV	Unknown	Associated with tegument-capsid
Nucleolin	MLV	Virion assembly	Via NC
PKC	Sendai virus	Kinase	Inside virion
Ribonucleotide reductase	HSV	Serine/threonine kinase	Via NC
Ribosome-associated protein	HBV	Infectivity	Via core
Staufen	Retroviruses, reovirus, other RNA viruses	Gene expression, RNA encapsidation, infectivity	Via retroviral RNP and genomic RNA
Tal1	Retroviruses	Virion budding	Via Tsg101
tRNA synthetases	Retroviruses	Virion assembly, reverse transcription	Via Gag/Pol
Tsg101	HIV-1	Assembly/budding	Via Gag
Uracil-DNA glycosylase (UNG2)	Retroviruses	PIC import and integration	Via Gag/Pol and/or Vpr
Virion-associated matrix-interacting protein, VAN	HIV-1	RNA localization; acts with HIV-1 MAp17	Via MA p17 domain of Gag
Vps4b	Retroviruses	Assembly/budding	Via Gag

[a] Location or mediator of incorporation is indicated.

to one of two alternative chemokine receptors: CCR5, which is used by all viral strains in the initial phase of infection, or CXCR4, which is mainly used by strains isolated in advanced stages of HIV disease. These chemokine receptors contain seven transmembrane domains and their extracellular regions are far closer to the cellular membrane than the envelope-binding domains of CD4. Consequently, a two-step mechanism for this virus–receptor interaction has been proposed: the first interaction permitting "capture" of the virion and induction of conformational changes in the envelope that expose a structure that will interact with the chemokine coreceptor. This second interaction triggers, by a still not well-understood mechanism, the activation of the fusion peptide in the envelope transmembrane unit (TM), which will lead eventually to membrane fusion (see the following). In the case of HIV, both receptor and coreceptor restrict viral tropism, and the switch from CCR5-usage to CXCR4-usage permits the virus to gain access to immature and naïve $CD4^+$-T cells. However, anecdotal reports also describe the occasional usage of CD8 as a primary receptor of some HIV strains. The identification of CD134, but not CD4, as a primary receptor for the closely related feline immunodeficiency virus (FIV), which also depends on CXCR4, further illustrates that there is, in principle, some evolutionary plasticity for receptor usage by viruses, as long as the new target cells permit efficient viral replication downstream of virus entry.

For many viruses, only one receptor has been identified as yet. These include one transmembrane domain receptor with several globular extracellular domains, such as the epidermal growth factor (EGF) receptor, which permits entry of the human cytomegalovirus (HCMV) into target cells, or the angiotensin converting enzyme 2 (ACE2) that is a receptor for the SARS-CoV. Receptors containing multiple membrane spanning domains can also function alone as viral receptors. One example is the human serotonin receptor 5HT2AR that mediates entry of the human polyoma virus JCV. Moreover, most retroviruses depend on multiple transmembrane domain containing transporter proteins, such as the glucose transporter (GLUT)-1 for the human T-cell leukemia virus (HTLV-I), the cationic amino acid transporter (CAT)1 for ecotropic murine leukemia virus (MLV), and many other similar transporters for the gamma (γ)-retroviruses.

There is an increasing number of viruses for which a complex interplay between several cell surface receptors, coreceptors, and attachment factors is reported, such as HSV, HCV, HIV, and adeno-associated virus 2 (AAV-2), and it is not always easy to determine which role is played by which molecule. Additional complexity comes from entry factors that are not mandatory but alternative, and determine entry in different target cells, that is viral tropism. Therefore, viral entry may be expected to remain a dynamic research field with many surprises in store.

1.3 Virus Fusion

Fusion between the viral and cellular lipid bilayers is ultimately achieved by the action of the fusion peptide. The action of this peptide is irreversible as it inserts into the host's cell membrane. This is triggered by events that differ between viruses, and is in many cases not well understood. Interestingly, there is increasing evidence that, at least in the case of HIV-1, the envelope-coreceptor interaction alone is insufficient to trigger efficient fusion

peptide activation, but requires the activity of extracellular enzymes of the host, such as protein disulfide isomerase (PDI).

There are some differences in the fusogenic structures of different viruses, and these can be classified as N-terminal (class I) fusion peptides or internal (class II) fusion peptides. Some viruses, such as influenza virus, are efficiently endocytosed by the host cell after receptor binding, and the decrease of the pH in endosomes triggers activation of the fusion peptide. For HIV-1, fusion is pH-independent and can occur at the plasma membrane, although endocytic HIV-1 uptake cannot categorically be ruled out. The event that triggers the activation of the HIV-1 TM fusion peptide remains elusive, but depends on SU interaction with chemokine receptors. Intriguingly, the fusion events downstream from fusion peptide activation seem similar between HIV-1 and influenza virus, despite their distance in evolutionary terms. Indeed, in both cases, intramolecular interactions between proximal and distal helices within the triple-stranded helical fusion protein bundles lead to rapprochement of the viral and cellular bilayers.

2 Innate Cellular Response to Virus Infection

2.1 Immediate Cell Response to Virus Infection

2.1.1 Cytokine and Chemokine Induction upon Virus Infection

As an immediate response to virus attachment or entry, the host cell will produce a large number of cytokines and chemokines. This induction has been well documented for herpesviruses, poxviruses, paramyxoviruses, influenza virus, adenovirus, VSV, hepatitis B virus (HBV), HIV-1, and HTLV-I, but probably occurs for most viruses. The triggering event is either the virus–receptor interaction, the early release of viral glycoproteins, nucleocapsid, or double-stranded (ds)RNA. The cytokines produced vary with the inducer and include tumor necrosis factor (TNF) α, various interleukins (IL)1–18, granulocyte-macrophage colony-stimulating factor (GM-CSF), macrophage inflammatory protein (MIP)-1α/β, transforming growth factor (TGF)β, monocyte chemoattractant protein (MCP)-1, regulated upon activation normal T-cell expressed and secreted (RANTES), and interferon (IFN)-α/β, and γ. Interestingly, infection with Lassa, Ebola, and Marburg viruses, three viruses that cause hemorrhagic fevers with high mortality rates, do not induce cytokine production when they cause death, emphasizing the protective role of the innate cell response.

2.1.2 Interferon α/β Production

One of the most important cell responses is the production of IFNα/β proteins (Fig. 1). Virus attachment to toll-like receptor (TLR) family proteins, viral nucleocapsid (NC), viral glycoproteins, and double-stranded RNA (dsRNA) will trigger the activation of multiple signal transduction cascades. One such cascade is the activation of the IκB kinase (IKK)-α, -β, and -γ complex that will lead to the activation of the inhibitory factor κB (IκBα) and the liberation of nuclear factor-κB (NF-κB). Another cascade is the IKK-related complex composed of TANK/I-TRAF, IKK-ε, and TBK1 that will lead to the activation of the IFN regulatory factor (IRF)3. Activating transcription factor (ATF) -2/cJun dimers will also be produced from the mitogen-activated protein (MAP) 3 kinase (MKKK) pathway.

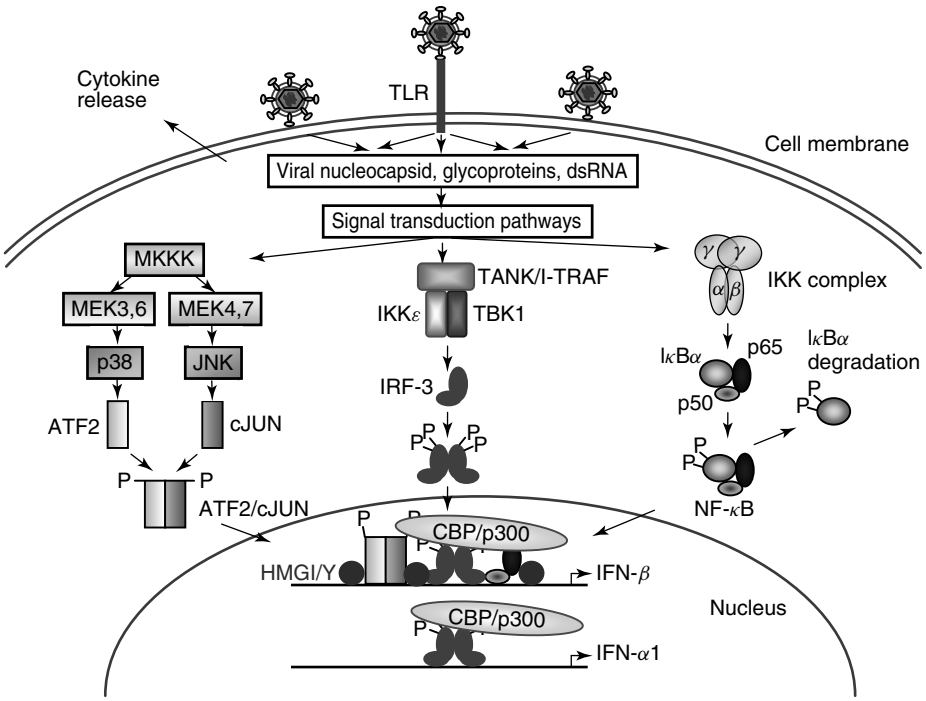

Fig. 1 Early events of the innate immune response after virus infection leading to IFN production and cytokine release.

These factors will be activated by phosphorylation and will translocate to the nucleus and bind to the IFN-α and -β promoters. IRF3 homodimers will transcriptionally induce the production of IFNα1, whereas ATF2/cJun, IRF3/IRF3, and NF-κB with the chromatin associated high-mobility group protein (HMG)I/Y will recruit the histone acetyl transferase (HAT) cAMP binding protein (CBP)/p300 and the chromatin remodeling protein SWI/SNF leading to the activation of IFN-β promoter. IRF1, IRF5, and IRF7 are also involved in the early production of IFN-α/β as shown for HIV-1 and paramyxoviridae.

2.1.3 IFN-γ Production

IFN-α/β are produced in most cells in response to a large number of viruses, whereas IFN-γ is produced mostly in T cells, macrophages, natural killer (NK) cells, and polymorphonuclear neutrophils. Although IFN-γ is mainly induced by antigens (Ags), mitogens, and cytokines, human papillomavirus (HPV), HSV, encephalomyocarditis virus (EMCV), influenza, respiratory syncytial virus (RSV), cytomegalovirus (CMV), and HBV induce its production. Its induction pathways are not fully elucidated, but likely involve IL-12, IL-18, and MIP-1α-mediated signaling.

2.2 The Interferon Pathway

The IFN-α/β produced in response to viral infection are secreted and bind to their receptor composed of IFN-α Receptor (AR)-1

and IFNAR-2 chains, which are associated with the Janus kinases Tyk2 and Jak1, respectively (Fig. 2). IFN-γ binds to the receptor IFN-γ Receptor (GR)1 and IFNGR2 chains associated with Jak1 and Jak2. Both will activate the Jak/Stat signal transduction pathway. The Jaks will phosphorylate Stat1 and Stat2 leading to the formation of Stat1-Stat2 heterodimers and Stat1 homodimers. Stat1-Stat2 heterodimers, mainly induced by IFN-α/β, will associate with IRF9 (p48) and the trimer, called ISGF3, will translocate to the nucleus and bind to the IFN stimulation response element (ISRE), a DNA element in the promoter of IRF7 and IFN-stimulated genes (ISGs). IRF7 will become phosphorylated, will associate with IRF-3, and will further contribute to an increased activation of IFN-α and -β promoters during the delayed events. Following activation by IFN-γ, Jak1 and Jak2 will induce Stat1 phosphorylation and dimerization. The Stat1 dimer will translocate to the nucleus and will bind to the IFN-γ-activated site (GAS) element. Stat1 bound to the GAS motifs will activate or inhibit IFN-γ regulated genes.

2.3 Activation of Host Genes in Response to Interferon

IFNs induce the synthesis of more than 300 ISGs. Some of them have been studied extensively for their antiviral activities, and the activity of many others are likely to be elucidated in the near future.

2.3.1 2′–5′ A Synthetase and RNAse L

2′–5′ Oligoadenylate synthetases (OAS) are a family of enzymes activated by dsRNA that catalyze the synthesis from

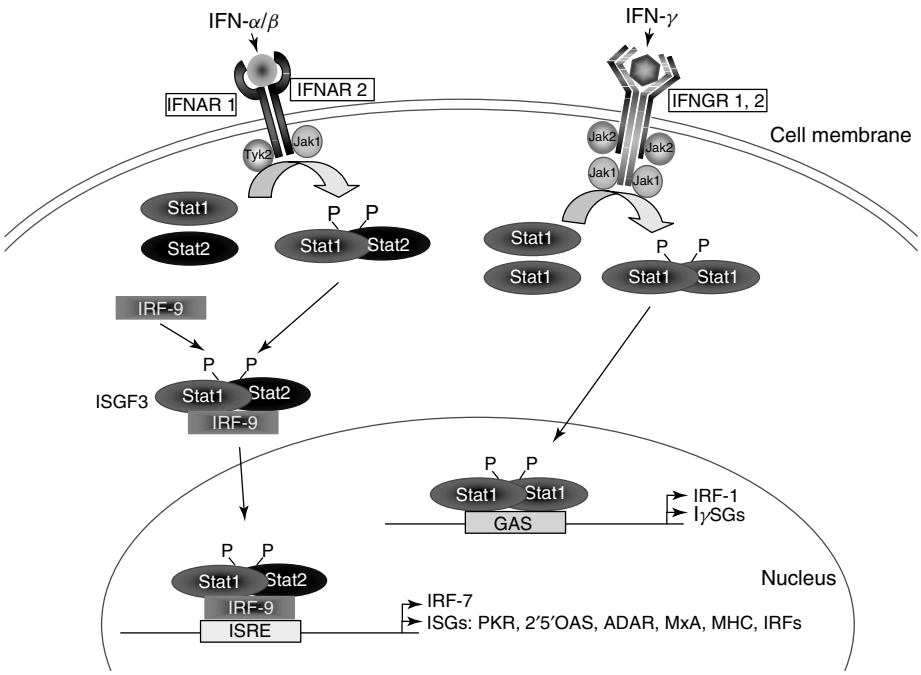

Fig. 2 Interferon pathways mediated by the binding of IFN-α/β and IFN-γ to their receptors.

ATP of oligomers of adenosine linked by 2′ 5′ phosphodiester bonds. The 2′–5′A oligoadenylates bind to endoribonuclease L (RNAse L) with high affinity. They induce its dimerization and endonuclease activity on viral and cellular RNA. In the context of virus infection, HIV-1 transactivation response (TAR), HTLV-I Rex responsive element (RxRE), Epstein–Barr virus (EBV), EBER-1, and adenovirus VAI RNAs are very good activators. In Picornaviridae, the activation of the OAS pathway correlates very well with the inhibition of viral replication. This system also plays a role in the antiviral effects of IFN-α/β against vaccinia virus (VV), EMCV, and reovirus.

2.3.2 Mx GTPase

The IFN-α/β-induced Mx proteins were first identified in the infection by influenza and Thogoto viruses, two members of the Orthomyxoviridae family. They belong to the dynamin-like GTPase family and exert their activity either by blocking the transport of viral nucleocapsid to the cytoplasm or by inhibiting viral RNA synthesis in the nucleus. MxA shows antiviral activities on several RNA virus members of the Orthomyxo-, Bunya-, Paramyxo-, Rhabdo-, and Togaviridae, but not Picornaviridae.

2.3.3 RNA-Specific Adenosine Deaminase, ADAR1

IFN-α and IFN-γ induce adenosine deaminase (ADAR1), that converts adenosine to inosine in viral RNA and cellular mRNA. A-to-I editing modifies RNA polymerase and ribosome recognition of the RNA and alters the sequence of replicated RNA and its translation. Extensive RNA editing leading to hypermutation occurs in measles virus, parainfluenza virus 3, VSV, Borna disease virus (BDV), avian leukosis virus (ALV), and polyomavirus (PyV), whereas limited selective editing is essential for hepatitis delta virus (HDV) protein synthesis.

2.3.4 Protein Kinase PKR

The IFN-inducible serine/threonine protein kinase PKR is activated by autophosphorylation, dsRNA, and homodimerization. Its best-characterized substrates are the α-subunit of the translation initiation factor 2 (eIF2α) and IκBα. The phosphorylation of eIF2α leads to inhibition of translation of viral and cellular mRNA, which strongly contributes to an antiviral state. All dsRNAs more than 30 nt in length can potentially activate PKR. Specifically, highly structured RNA such as HIV TAR, reovirus S1, and HDV RNAs are very good PKR activators. The antiviral activity of PKR has been demonstrated in cell culture for EMCV, influenza, HIV-1, VV, and VSV. This activity is certainly very broad and its intensity varies with the presence or absence of PKR antagonists in the viral genome.

2.3.5 ISG56

ISG56 is very strongly induced by virus infections including VSV, EMCV, Sendai, and influenza viruses as well as IFN, IRF3, and dsRNA. The gene encodes the P56 protein that interacts with the p48 subunit of the translation initiation factor eIF3 and blocks initiation of protein synthesis. Overexpression of the protein does not block VSV or EMCV replication in cell culture, but it contributes, with PKR, to the inhibition of HCV translation by IFN treatment.

2.3.6 Major Histocompatibility Complex Proteins

The major histocompatibility complex (MHC)/human leukocyte antigen (HLA)

class I and II molecules present the antigenic peptides derived from viral protein antigens to cytotoxic T cells. MHC-I and MHC-II are both activated during viral infection. MHC-I is induced by both IFN-α/β and IFN-γ, whereas only IFN-γ induces MHC-II proteins. Stat1 and IRF1 are involved in the IFN-induced expression of MHC class I antigens. The MHC-II transcription factor (CIITA) activates MHC-II protein expression and is the key mediator of IFN-γ activity. MHC-restricted recognition and killing of infected cells by lymphocytic T cells is a key component of the host response to viral infection.

2.3.7 Other Genes Induced by Virus Infection

Recent studies have used DNA microarrays to analyze the RNA profile of cells either treated by IFN or overexpressing IRF3. Similar studies have used virus-infected cells including CMV, papillomavirus, HCV, HSV, enterovirus, HBV, HDV, varicella zoster virus (VZV), adenovirus, and HIV-1. They all show the induction or suppression of known genes but also reveal unknown genes that may have a functional importance in the cell response to viral infection. Among them, the induction of ISG15, a ubiquitin-like protein, the inducible nitric oxide synthase (iNOS), and the P200 family involved in inhibition of gene transcription, cell growth, and differentiation show an increasing functional importance in viral replication.

2.4 Viral Antagonists to the IFN Response

A functional innate immune response to viral infection can lead to the suppression of viral replication. To complete their life cycle, viruses have evolved several mechanisms that involve virus–cell interactions to counter the cellular responses to viral infection. These include the inhibition of IFN synthesis, blocking IFN signaling and ISG function (Table 2). An additional mechanism to counter these cellular responses is to interfere with normal immune response.

2.4.1 Inhibitors of IFN Synthesis

The first mechanism to inhibit the IFN response is to prevent its synthesis either during the early events or during the late events of viral replication. To overcome the cellular IFN response, several viruses encode inhibitors of IRF3. HCMV pp65 suppresses the activation of IRF3. Ebola VP35, influenza NS1, HPV16 E6 bind to IRF3 and inhibit its activation and transduction pathways. Influenza NS1 and the V proteins of some paramyxoviruses block the activation of IRF3, IRF7, NFκB, and ATF2/cJun transduction pathways by dsRNA or viral products. Poxvirus protein N1L inhibits NF-κB and IRF3 signaling by TLR by association with the components of the IKK complexes. HCV NS3/4A protease blocks IRF3 activation by blocking more than one step upstream of the IKKε/TBK1 activity. In addition, E7 of HPV16 binds IRF1 and human herpes virus 8/Kaposi's sarcoma-associated herpesvirus (HHV8/KSHV) encodes a viral (v)IRF1 protein and a vIRF3 that prevent IRF1 and IRF3 activities by binding to CBP/p300.

ORF-C of HBV, the ML protein of Thogotovirus, the matrix protein of VSV, and NSs proteins of bunyaviruses inhibit IFN α/β synthesis, but the mechanism is not well characterized. A stronger inhibition of IFN synthesis by wild type measles virus compared to the vaccine strain may correlate with the expression of C and V virulence factors.

Tab. 2 Viral antagonists of the IFN response.

Virus	*Viral protein*	*Mechanism of inhibition*
1. Inhibition of IFN synthesis		
HCMV	pp65	Inhibits IRF3
Ebola	VP35	Binds to and inhibits IRF3
HCV	NS3/4A	Blocks IRF3 phosphorylation
HPV16	E6	Binds to and inhibits IRF3
	E7	Binds IRF1
Influenza	NS1	Blocks the activation of IRF3, IRF7, NFκB and ATF2/cJun
Paramyxoviruses	V	Blocks the activation of IRF3, IRF7, NFκB and ATF2/cJun
HHV8	vIRF1 and vIRF3	Binds CBP/p300, prevents IRF1, IRF3 activity
Adenovirus	E1A	Binds CBP/p300, prevents IRF3 activity
HBV	ORF-C	Unknown
Thogotovirus	ML	Unknown
VSV	Matrix	Unknown
Bunyaviruses	NSs	Unknown
2. Inhibition of IFN signaling		
Myxoma virus	MT-7	Decoy receptor, binds IFN-γ
Vaccinia virus	B8R	Decoy receptor, binds IFN-γ
	B18R	Decoy receptor, binds IFN-α/β
	VH1	Dephosphorylates Stat1
Adenovirus	Unknown	Downregulates IFN-γ-R2 receptor chain
	E1A	Decreases Stat1 and IRF9
		Interferes with Stat1-CBP and Stat1-IRF1
HCMV	Unknown	Decreases Jak1 and IRF9
Murine polyomavirus	LT	Binds to Jak1
Sendai virus	C	Interacts with Stat1, inhibits Tyk2, Stat1 phosphorylation
hPIV-2, SV5, MUV	V	Degrades or inhibits Stat1 or 2
HPV18	E6	Binds to Tyk2
HPV 16 and 31	E6	Downregulates Stat1
	E7	Binds to IRF9
VSV	Matrix	Blocks Stat3 phosphorylation
HSV-1	ICP0	Inhibits ISGs transcription
	UL41, UL13	Induces SOCS, a host Jak–Stat inhibitor
HCV	Core	Induces SOCS, a host Jak–Stat inhibitor

2.4.2 Inhibitors of IFN Signaling

IFN signaling is initiated by association of IFN with its cognate receptor. This step is inhibited in poxviruses that synthesize viral mimics of both IFN-α/β and IFN-γ receptors. Myxoma virus MT-7 and VV B8R are decoy receptors that bind IFN-γ, whereas B18R from VV and B18R-like from other orthopoxviruses bind IFN-α/β. They prevent IFNs binding to their native receptors and the subsequent signaling pathways. Interference with signal initiation also occurs with adenoviruses that downregulate the expression of IFNγ-R2 receptor chain.

Another major target of viral interference is the Jak–Stat signaling pathway. Although some proteins like HBx of HBV, or HTLV-I Tax activate the Jak–Stat pathways, many viruses encode inhibitors to shut down the IFN response. HCMV decreases the levels of Jak1 and IRF9,

whereas the large T (LT) antigen of murine PyV binds to Jak1, inhibiting IFN-α/β and -γ pathways. The C proteins of Sendai virus physically interact with Stat1 and mediate Tyk2, Stat1 phosphorylation inhibition and Stat1 degradation. Other members of the paramyxoviridae have a V protein that interacts with Stats and either degrade or inhibit Stat1 or 2. HPV18 E6 protein binds to Tyk2, prevents its binding to IFNAR1 and inhibits the Jak–Stat pathway of IFN-α/β. HPV16 and HPV31 E6 downregulate Stat1, whereas the E7 protein blocks ISGF3 formation by competitively binding to IRF9. Similarly, adenovirus E1A protein decreases the levels of Stat1 and IRF9, which blocks ISGF3 formation. E1A also interferes with Stat-CBP/P300 and Stat1-IRF1 interactions, resulting in a block in transcriptional activation of Stat1. VSV matrix protein blocks Stat phosphorylation via the IL-6 signal transducer gp130, and VV virion phosphatase VH1 dephosphorylates Stat1. HSV-1 ICP0 blocks the transcription of ISGs by a process that involves the host proteasome–mediated degradation.

HSV-1 and HCV infection lead to a marked suppression of IFN-induced phosphorylation of Jak1, Tyk2, Stat1, and Stat2 indicating an inhibition that precedes the Jak phosphorylation step. Indeed, these two viruses transcriptionally induce the suppressor of cytokine signaling-3 (SOCS3), a host Jak/Stat inhibitor, at an early step of infection. This activity is mediated by the UL41 RNAse, and UL13 protein kinase of HSV1, and by the core protein of HCV.

2.4.3 Inhibitors of ISGs

A very common way for viruses to counteract the IFN response is to inhibit the function of ISGs that inhibit virus replication. One of the best-known mechanisms is the inhibition of PKR by viruses. The OAS/RNAse L pathway and ADAR activity are also targeted by viral components. Interestingly, viruses have evolved mechanisms to counteract the activity of ISGs by several mechanisms (Table 3).

The best-studied poxvirus, VV, encodes for two proteins, E3L and K3L, which inhibit the activity of PKR and RNAse L. E3L is a dsRNA binding protein (dsRBP) that directly binds to PKR and sequesters dsRNA to prevent PKR activity. E3L also inhibits OAS activity by dsRNA competition and ADAR1 deaminase function. In contrast, K3L is an eIF2α homolog that acts as a pseudosubstrate of PKR to competitively inhibit eIF2α phosphorylation and restore viral translation. Several other poxviruses express or are predicted to encode homologs of E3L and/or K3L, but not molluscum contagiosum virus (MCV). In addition, Myxoma virus encodes a protein, M156R, which is a structural mimic of eIF2α.

HSV1 is the best-studied virus of the Herpes family. The virus encodes a protein, Us11, which is sufficient to prevent PKR activation. Us11 binds dsRNA; it has no known RNA binding domain but an RXP motif that mediates the binding. It could act either by sequestering dsRNA or by direct binding to PKR. Us11 also inhibits PKR activation by the cellular PKR activator (PACT), by protein–protein interactions. HSV-1 has a second mechanism to increase viral translation. The virus encodes $\gamma_1$34.5 protein, which associates with phosphatase 1α to dephosphorylate eIF2α. Us11 homologs can be found in several other α-herpesviruses like HSV-2 and simian B virus, whereas the γ-herpes virus EBV

Tab. 3 Viral inhibition of IFN-induced enzymes.

Virus	*Viral factor*	*Mechanism of inhibition*
1. PKR inhibitors		
Vaccinia virus	E3L	Binds dsRNA and PKR
	K3L	eIF2α homolog, pseudosubstrate for PKR
HSV1	Us11	Binds dsRNA, PKR and PACT
	$\gamma_1$34.5	Dephosphorylates eIF2α
EBV	SM	Unknown
	EBER RNA	Binds to PKR with no activation
Adenovirus	VA RNA	Binds to PKR with no activation
HIV-1	Short TAR RNA	Binds to PKR with no activation Recruits TRBP to inhibit PKR
	Tat	eIF2α homolog, pseudosubstrate for PKR
HCV	NS5A, E2	Binds to PKR
Influenza	NS1	Binds dsRNA and PKR Induces p58^{IPK} that inhibits PKR
Reovirus	σ3	Binds dsRNA and PKR
Rotavirus	NSP3	Binds dsRNA and PKR
SV40	LT	Unknown but after PKR phosphorylation
2. OAS/RNAse L inhibitors		
Vaccinia virus	E3L	Sequesters dsRNA
Influenza	NS1	Sequesters dsRNA
HSV1	Us11	Sequesters dsRNA Synthesizes 2′5′A antagonists
Reovirus	σ3	Sequesters dsRNA
Rotavirus	NSP3	Sequesters dsRNA
EMCV		Induces RNAse L inhibitor, RLI
HIV-1		Induces RNAse L inhibitor, RLI

encodes for the SM protein with RXP motifs that mediate PKR inhibition. HSV1 and HSV2 also induce the synthesis of 2′5′A derivatives that antagonize the OAS system.

Other mechanisms to inhibit PKR include the synthesis of large amounts of viral RNA that prevent PKR activation. This has been shown to be the case with the accumulation of EBV EBER, adenovirus VAI, and HIV-1 TAR RNAs. Viral dsRBPs like influenza NS1, rotavirus NSP3, and reovirus σ3 bind to PKR and prevent its activation, whereas HCV NS5A and E2 also bind to PKR and may participate in the IFN responsiveness in patients. HIV-1 Tat acts as a pseudosubstrate for PKR by mimicking eIF2α. Finally, simian virus 40 (SV40) LT acts after the phosphorylation step, all contributing to the inhibition of PKR activity.

Some viruses use the cellular machinery to inhibit PKR. Influenza NS1 induces the cellular inhibitor of PKR p58^{IPK} by promoting its dissociation with its negative regulator hsp40, whereas HIV-1 TAR RNA recruits the TAR RNA binding protein (TRBP), a potent cellular PKR inhibitor in close proximity to PKR. Finally, while proteins that sequester dsRNA can inhibit the OAS/RNAse L system, EMCV and HIV-1 downregulate RNase L activity through the increased expression of RNAse L Inhibitor (RLI).

3
Early Events in Virus Replication

3.1
Uncoating

Several types of enveloped viruses enter cells via a fusogenic route such that the lipid bilayer that envelopes the virus fuses with the plasma membrane. This is followed by the penetration of the genetic material and auxiliary factors of the capsid into the cytosol. The viral capsid must first pass through the dense cortical actin network located immediately beneath the plasma membrane. The cytoplasm represents a tightly packed, and somewhat organized environment, indicating that this early event of the replication cycle must be tightly regulated. While viral proteins such as HIV-1 Nef have been proposed to aid in this first assault on the cell, few details are known about this. Subsequent to this fusion, a capsid uncoating event (decapsidation) occurs. The movement of these large macromolecular complexes has been shown to be along cytoskeletal elements such as microtubules (Fig. 3). For HSV-1, adenovirus and HIV-1 for example, directed vectorial transport has been visualized microscopically (see next section) to direct the capsids containing the genetic material toward the nucleus. Few other details about this process are known because this subject of entry inhibition has been difficult to address experimentally. However, recent evidence and the creation of *in vitro* virus fusion and decapsidation system have allowed further insight into this process. This system allows for reconstitution of proteins and cellular environments to study this for MLV, equine infectious anaemia virus (EIAV), Rous sarcoma virus (RsSV), and avian sarcoma and leukosis virus (ASLV). The substrates used in this system are viral particles that are trapped before completing membrane fusion. These virions are induced to fuse out of endosomes and the viral cores are released into solution where they are amenable to biochemical manipulation. This system revealed that membrane fusion is not sufficient to stimulate the formation of a reverse transcription complex. Instead, ATP hydrolysis and cellular factors that are >5 kiloDaltons (kDa) in size are required. One salient observation is the necessity for an energy source, ATP, reciprocating this requirement *in vivo*. These *in vitro* systems however will require improvement and greater flexibility to recapitulate the *in vivo* setting. The identification of host-cell proteins in this process is essential and it will also be important to study other types of viruses in order to gain insight into and to fully appreciate the process of decapsidation.

3.2
Decapsidation and the TRIMs

The interest in this event has come to the forefront of HIV-1 research through the discovery of restriction factors that prevent decapsidation of retroviral capsids following viral entry. This viral restriction was noted in very early studies that showed restricted replication of MLV in mouse cells of different genetic backgrounds. Expression of distinct alleles of the mouse Friend virus susceptibility factor-1 (Fv-1) locus dictated susceptibility to infection by B- or N-tropic MLV. Fv-1, it turns out, bears a striking similarity to MLV coat proteins. Restriction factor 1 (Ref1) was also characterized to be a restriction factor for MLV infection of human cells, but this restriction can be overcome by infecting the cells with MLV, suggesting that

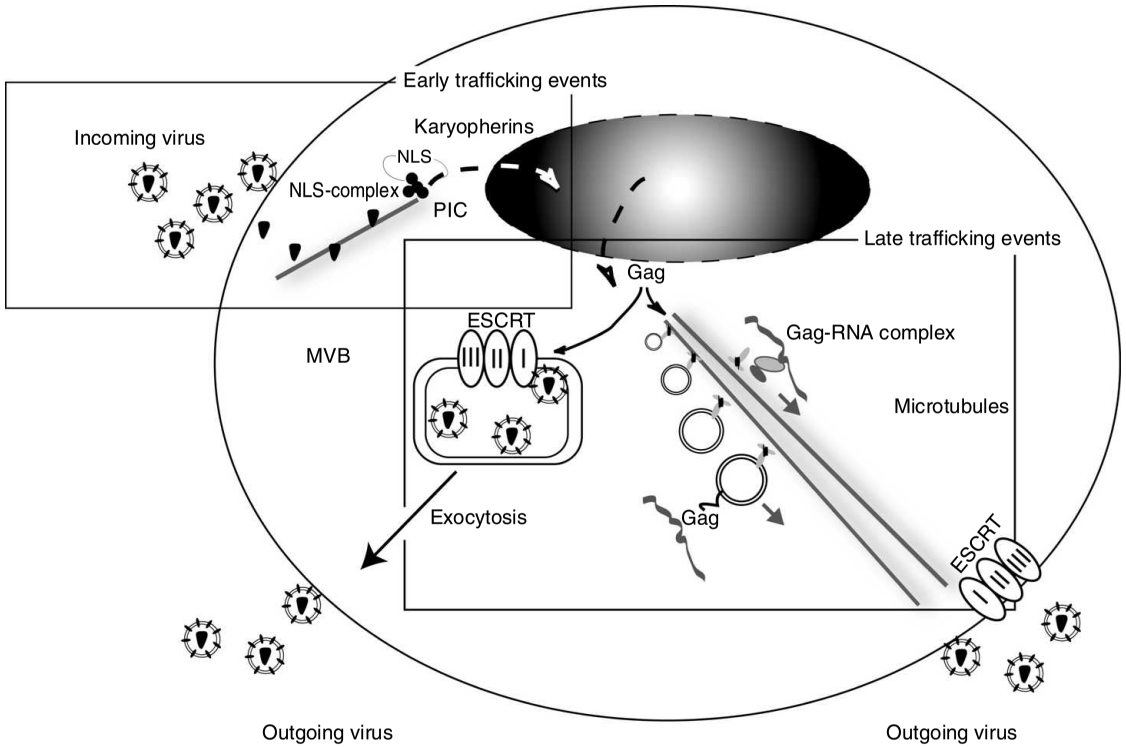

Fig. 3 The early trafficking events following entry of viruses into the cell, enveloped viruses are uncoated and the RNA–protein complex is trafficked along microtubules toward the nucleus (in HIV-1, this RNA–protein complex is translocated to the pericentriolar region or MTOC). Viral proteins that contain NLS interact with karyopherin proteins in the nuclear pore and form NLS-complexes that are imported into the nucleus. For viruses that require mitosis for entry (e.g. MLV), the nuclear membrane must be broken down during cell division before the NLS-complex can be exposed to the nuclear milieu. Following nuclear export, Gag is synthesized and associates to membranes via an amino-terminal myristoylation signal. Gag can be brought to MVB by direct interaction with class E type proteins for viral budding. This is reportedly the principal means of Gag trafficking in HIV-1 host cells like macrophages. The other scenario pertains to $CD4^{+}$ T cells budding mechanisms. Gag can traffic along microtubules attached to vesicular membranes to reach the cell plasma membrane, where it can bud using the same budding machinery involving class E proteins and the engagement of the ESCRT complexes. Viral RNA (blue squiggle) can be trafficked accordingly as a naked Gag-RNA complex or associated to vesicles (See color plate p. xxxii).

Ref1 can be saturated to allow infection by noncognate viruses like HIV-1. Infection of monkey cells by HIV-1 was not possible for reasons that have now become increasingly clear. New and Old World monkey cells express a protein that restricted HIV-1 infection and the block was shown to be at the level of decapsidation. While the restriction was linked to the HIV-1 capsid (CA) protein domain Lv-1, the tripartite repeat motif protein (TRIM) 5α was identified as the dominant cellular restriction factor that restricts HIV-1 infection of monkey cells. TRIM5α inhibits decapsidation of incoming HIV-1 capsids, thereby preventing subsequent steps in infection. Interestingly, a single amino acid substitution found in the TRIM5α protein from monkeys blocks HIV-1 decapsidation and reversion can restore decapsidation to salvage infection. Additional details of this process will undoubtedly reveal mechanistic information as well as identify other host factors that are involved in this process. Attention to this early step of infection could be the basis of future anti-retroviral compounds.

3.3 Reverse Transcription and the APOBECs

The reverse transcription process has been the focus of recent efforts to understand the reasons behind host factor-induced restriction to HIV-1 infection. Recent work points to restriction factors that are incorporated in virions from virus-producing cells that restrict early steps of virus replication. In the case that will be presented below, the acquisition of host-cell proteins is important for the generation of infectious virus particles. In the so-called ''viral infectivity factor (Vif) permissive cells,'' HIV-1 infectious particles are generated regardless of whether Vif is expressed in producer cells. However, in cell lines that were found to be nonpermissive, infectious virus can only be produced when the HIV-1 auxiliary factor, Vif, is expressed in virus-producing cells.

Apolipoprotein B mRNA-editing enzyme-catalytic polypeptide-like (APOBEC) proteins have been shown to be important for restricting retroviral replication by triggering massive deamination of deoxycytidine within the retroviral minus (first)-strand complementary (c)DNA during a postentry step of the retroviral replication cycle. The impact on viral replication is evidenced by high frequencies of retroviral genomic strand G-to-A transition mutations. Recent work also points to the activity of ribonucleotide deamination, capable of mediating ribocytidine-to-deoxythymidine changes in genomes of RNA viruses, indicating that this may actually occur prior to reverse transcription. This added level of complexity may be a larger part of the innate defense mechanism to viral infection, as described above for TRIM5α. In HIV-1, the auxiliary protein Vif was shown to be key to overcoming this antiviral (or innate) response to infection by binding to and interfering with APOBEC's incorporation when it was expressed. This is achieved, at least in part, by impairing APOBEC3G translational efficiency and by targeting the APOBEC3G for proteasomal destruction prior to virion incorporation. Vif associates with APOBEC3G and directs it to the Cul5-elonginB-elonginC-RBx1 ubiquitin ligase complex and, as a consequence, APOBEC3G becomes polyubiquitinated and degraded by proteasomes. However, expression of Vif-defective HIV-1 was followed by massive deamination as shown by A->G mutations in sequence analyses to result in a catastrophic defect in infectivity. APOBEC proteins have now been shown to interact with a few viral proteins

to mediate incorporation and subsequent editing activity: APOBEC3G can also associate to the Gag NC domain. It will be interesting to determine whether Vif and NC coordinate to promote APOBEC interaction.

Interesting new data have revealed the negative replicative activity of APOBEC proteins in several viruses in addition to HIV-1, including HIV-2, simian immunodeficiency virus (SIV), MLV, EIAV, and HCV. The biochemical consequence of deamination appears to be identical even if most of these viruses (such as in the latter three viruses) do not naturally express Vif. This suggests that a Vif-like activity may exist in the cognate hosts of these viruses, or alternatively, these viruses have evolved to replicate in APOBEC-negative tissues. This perhaps reflects the narrow and restricted expression pattern for several of the APOBEC genes.

The relevance for APOBEC function lies in APOBECs' ability to restrict several viruses and this appears to occur across species. MLV replication for instance is inhibited by APOBEC action through cytidine deamidation of the *de novo* synthesized DNA. In SIVs, however, Vif's interaction with either APOBEC3G or APOBEC3F does not restrict strains of SIV in human cells. Thus, we do not have the entire picture of what is turning out to be a more complex picture of APOBEC function in retroviruses. APOBECs may interact with each other suggesting additive antiviral activities of multiple APOBEC proteins for a single virus. There are at least 11 APOBEC proteins expressed in vertebrates that can be coordinately expressed, and this is evidence for this added level of complexity. A multimodal mechanism of action for APOBEC proteins is suggested in viral replication, but this model must await identification of functional relationships between these proteins. Implicating multiple APOBEC proteins with temporal and activated functions timed by the viral replication cycle could reveal new details about the mechanisms of viral pathogenesis. The determination of the cellular and viral composition of the APOBEC complexes will likely be the subject of intense research in the upcoming year.

3.4 Intracellular Replication and Trafficking

Once inside the cell, virus capsids must make their way to the nucleus or other intracellular sites for reverse transcription, RNA or DNA replication. A formidable task must be undertaken by the virus to transport its genetic material to the nuclear membrane. Active transport along a microtubule-based cytoskeletal network appears to be the case for many viruses including adenoviruses, HSV, VV, and retroviruses following decapsidation, and for endocytosed viruses from the parvovirus family. This hijacking of vesicular transport mechanisms might be easier to visualize; nevertheless, viruses that unload their capsids into the host cells will likely require additional virus–cell interactions to traffic. The co-opting of the microtubule network and molecular motor proteins appears to be the mechanism of choice. Adenovirus-activated host cell–signaling cascades based on protein kinase A and MAP kinases require a *bona fide* extracellular virus–cell interaction to mediate entry, or this virus remains inert in the cytosol when entering the cytoplasm. HIV-1, and likely other retroviral capsids, are unloaded and track along microtubules to the microtubule organizing center (MTOC) region before entering the nucleus (Fig. 3). Some evidence demonstrates that viruses

can mediate the restructuring of the microtubule network early and late in their replication cycle by activated signaling cascades as mentioned above or by the specific action of regulatory proteins, for example, Rev in the case of HIV-1. A recent example of this is the significant restructuring of microtubules during HSV1 infection, in order to facilitate the nuclear localization of the major virion tegument protein, VP22.

3.5 Trafficking to the Nucleus

Viral genomes of viruses that replicate via a nuclear step or a DNA intermediate, such as retroviruses, hepadnaviruses, HSV1, influenza virus, and adenovirus, must bypass the nuclear envelope and enter the nucleus. Most viruses enter the nucleus via nuclear pores. However, these cellular structures have a pore size estimated to be 25 to 39 nm in diameter, which is too small for most viral capsids to penetrate, except hepadnavirus capsids. This suggests therefore that there is a requirement for an active transport mechanism to achieve this critical step of the viral life cycle. This is supported by the identification of MLV mutants that cannot bring their PICs into the nucleus in dividing cells and suggests an active transport process to bypass the nuclear barrier. Active transport is now known to be regulated by both viral and host proteins in both mitotic and nondividing cells.

To achieve nuclear import of the viral genome in HIV-1 for example, a preintegration complex or PIC is formed. This is composed of double-stranded linear DNA, viral proteins Matrix (MA), RT, integrase (IN), and the auxiliary protein, viral protein R (VpR). This PIC has an estimated Stokes diameter of 56 nm. Except for lentiviruses such as HIV-1, PICs from most retroviruses are unable to enter intact nuclei and must therefore ''wait'' for the breakdown of the nuclear membrane occurring during mitosis. Consequently, these retroviruses, such as MLV, are dependent in part on the cell cycle and cannot replicate in nondividing cells. In contrast, lentiviruses are able to productively infect nondividing cells such as macrophages or quiescent T lymphocytes, indicating that PICs are able to actively cross the nuclear membrane even if the cells are not cycling. Some other retroviruses seem to have an intermediate capacity to enter the nucleus, since the PICs of RsSV and foamy viruses (FV) are able to penetrate intact nuclei with a low efficiency, but their replication is dramatically increased in dividing cells.

3.6 Cellular Proteins and Nuclear Import

The karyopherin receptor complex is a heterodimer of an α-subunit, which recognizes nuclear localization signal (NLS) found within karyophilic proteins (both viral and cellular) and a β-subunit which docks the complex at nucleoporins that scaffold the nuclear pore. Several nucleophilic viral and host-cell factors that harbor NLSs have been shown to play key roles in this process. For HIV-1, multiple redundant functions for viral proteins might serve as the signal to route the PIC to the nucleus and through the nuclear pore, and host cell–protein factors associated with PICs might supply NLS activity. Indeed, several viral and host factors have been identified as components of the HIV-1 PIC. These include, for example Vpr, MA, IN, HMGI(Y), Ku, and barrier-to-autointegration factor (BAF). Several reports indicate a possible role for direct

interactions between karyopherin α and β with HIV-1 IN in the nuclear import of HIV-1 PIC. HIV-1 MA also possesses multiple NLSs and this is believed to be a primary determinant for nuclear import of the HIV-1 PICs via karyopherin α and β. The HIV-1 auxiliary protein, Vpr, colocalizes with karyopherin β and regulates karyopherin β-mediated docking of the HIV-1 PIC at the nuclear envelope, but this evidence remains to be substantiated.

Before migrating to the nucleus, HIV-1 PICs, containing IN, induce the cytoplasmic recruitment of integrase interactor 1 (INI1 or hSNF5) and promyelocytic leukemia protein (PML, or TRIM19, a member of the TRIM family of proteins), a protein found in nuclear bodies. Other viruses encode NLS-containing proteins that direct nuclear import such as nucleoprotein of influenza A virus. HPV16 L2 protein interacts with several karyopherins by its NLSs to promote nuclear entry via these import pathways (Fig. 3). Thus, to be determined are the fine molecular details on how particular host proteins associated with the PICs might supply an NLS activity to PIC. A recent example of this is the newly discovered involvement of importin-7 in HIV-1 PIC transport. Importin-7 is mildly hydrophobic, belongs to the importin-β superfamily, and is involved in nuclear import and chaperoning of basic nucleic acid–binding proteins, such as ribosomal proteins and histone H1. Via direct interaction with IN, importin-7 contributes to nuclear import of PIC in HIV-1. Importin-7 has also been demonstrated to have a principal role in nuclear import of adenovirus type 2 DNA, suggesting that importin-7 could have a more general role in mediating nuclear import of viral nucleic acids and complexes.

3.7 Cellular Proteins and Integration

As a suitable target for antiviral therapeutics, the process of proviral DNA integration by retroviruses and in particular HIV-1 has been a subject of intense research. This process involves the introduction of proviral DNA into the host chromosome by a series of biochemical reactions involving primarily the IN protein. The discovery of the roles of viral and cellular proteins in this process has led to a better understanding of this complex process. We will briefly mention some of the virus–cell interactions involved in this process. At least two of these proteins (i.e. INI1 and Uracil-DNA glycosylase 2 or UNG2) are acquired by the virus during assembly for later function in integration (Table 1).

Viruses ensure their survival by packaging some of the required cellular and viral components during assembly for postentry replicative events. This can have either a positive (in this case) or negative impact on viral replication (see Sect. 3.3 and Table 1). For integration, several cellular proteins have been found to interact with structural and polymerase proteins to achieve virion incorporation. INI1 was found to play a role in both virus assembly and earlier events in PIC nuclear import and integration. INI1 is incorporated into HIV-1 virions, presumably through its interaction with HIV-1 integrase (Table 1). Interaction between these proteins has been mapped to amino acids 183–243 of INI1 and the central domain of HIV-1 IN (amino acids 48–188). INI1 is part of a complex that relieves repressive chromatin structures, allowing the transcriptional machinery to access its targets more effectively. The encoded nuclear protein may also bind to and enhance the

DNA joining activity of HIV-1 IN. UNG2 is a glycosylase that removes uracil from both double- and single-stranded DNA in nuclear chromatin, thus contributing to base excision repair in the integration reaction. It is believed to be incorporated into virions via IN in the context of the precursor Gag/Pol protein since a virus that harbors two single point mutations in IN (L172A/K173A) is deficient for UNG2. Alternatively, it may be brought into the virus by a specific interaction with the auxiliary protein Vpr. In this case, this virus–host interaction was shown to influence HIV-1 mutation rate during reverse transcription. Other, not so well studied host proteins are involved in this process through characterized interactions with IN such as lens epithelium-derived growth factor (LEDGF/p75) considered to be the main lentiviral IN-to-chromatin tethering factor in several lentiviruses, but not in oncoretroviruses like MLV and HTLV-1. The IN/LEDGF/p75 interaction can also target the PIC to chromosomes and stimulate IN strand transfer activity at the same time. Finally, the HMG I(Y) protein mentioned above as a component of the HIV-1 PIC has been identified in a variety of PICs from several retroviruses and are active in integration assays for HIV-1, avian sarcoma virus (ASV), and MLV.

4
Viral Gene Expression

4.1
Synthesis of Viral mRNA

4.1.1 Transcription of DNA Virus Genomes

DNA viruses synthesize their mRNA from their DNA genome. The family with the largest genomes, the poxviruses, replicate entirely in the cytoplasm of the host cell. They show a high level of independence from the host cell, but borrow several host proteins to synthesize their mRNA. Poxviruses have similar transcription mechanisms, and VV is the model for this family. VV transcription can be separated into three phases: early, intermediate, and late gene transcription. The RNA polymerase and transcription factors are included in the virion, which allows the virus to synthesize all early class genes without any cellular factors. These include proteins participating in DNA replication, nucleotide synthesis, and intermediate gene transcription. Whereas early transcription occurs within the virus core particle, intermediate transcription starts after DNA replication in a more open environment. Key functions for both initiation and termination of intermediate and late transcription appear to be borrowed from the cell. Several host factors, including a nuclear DNA binding protein, have been characterized within the transcription complex formed around the viral RNA polymerase.

Herpesviruses have a nuclear step in their replication cycle. The prototype of the α-herpes viruses is HSV-1. The transcriptional control of its immediate early promoter by viral and cellular factors determines a latency stage or a lytic cycle. The virion protein VP16 is a key regulator of this mechanism through its association with two host-cell factors, Oct1 and HCF-1. All three proteins form a multiprotein complex that binds to the immediate early promoter through the Oct1 DNA binding domain. The precise interaction with Oct1 and HCF-1 mediates the activation and triggers the lytic cycle, whereas the binding of Oct2 or the association of VP16 with HCF-2 leads to promoter inactivation and

a latent mode of infection. Zta, a bZIP protein of the γ-herpesvirus EBV, is a trans-activator that acts by interactions with DNA, TFIIA-D transcription factors and other transcriptional activators. Like VP16 on HSV1, it triggers the lytic cycle of EBV.

Small nuclear DNA viruses including polyoma-, parvo-, papilloma-, and adenoviruses do not code for DNA or RNA polymerases and therefore rely entirely on the cellular enzymes to complete their replication and transcription. The ability of the cellular DNA polymerases to replicate the viral DNA, and the presence or absence of various transcription factors will therefore restrict the replication and the expression of these viruses to specific species and cell types. The early promoter of HPVs is recognized by cellular transcription factors. The first viral proteins to be expressed are the replication factors E1 and E2. They form a complex at the viral origin to recruit cellular polymerases and accessory proteins to mediate replication. Binding of low concentrations of E2 at sites adjacent to cellular transcription factors activates the early promoter, whereas at high concentrations, it induces a repression by blocking the binding of cellular factors.

The transcription of adenovirus requires complex interactions between cellular and viral factors. It starts with the recognition of the E1A transcription unit by cellular proteins alone. As the two forms of E1A proteins lack a DNA binding activity, they associate with transcription factors, proteins of the general transcription machinery, coactivators and chromatin-modifying enzymes to activate transcription of viral early genes. They also release cellular repression of the viral E2 promoter. The E2 late promoter is then activated by a joint coordination between the viral E1B and the host-cell factor YB-1 to produce the E2 viral replication proteins. The expression of E2 genes triggers DNA replication. The IVa2 promoter is bound by a cellular repressor and this promoter inhibition is released when viral DNA synthesis increases and binds the repressor. The IV2a protein, a DNA binding protein, is then produced and stimulates the major late (ML) promoter. The complete interplay between viral and cellular factors leads to the formation of viral particles.

HBV has a partially double-stranded DNA, which is converted to covalently closed circle (ccc) in the nucleus by the host cell. This ccc DNA is the major transcriptional template for the virus, and its efficient regulation is the result of a complex interplay between trans-acting factors and their corresponding cis motifs. HBV transcription is mediated by four different promoters and two enhancer elements. The precore promoter is regulated by a number of cellular transcription factors including nuclear receptors. These are ubiquitous nuclear receptors or hepatocyte nuclear factors (HNF) 3 and HNF4. They have activating or repressing activity leading to the synthesis of either the precore or the core RNA with different biological activities. Whereas the basal preS1 promoter is regulated by the TATA-binding protein (TBP) and HNF-1 binding sites, its activity is enhanced by SP1, NF1, and HNF-3 to produce the large surface antigen. The TATA-less promoter S2 is regulated by a CCAAT motif bound by NF-Y/CBF transcription factors. It directs the production of the middle and major surface antigen transcript. The S2 promoter is also indirectly activated by the accumulation of the large surface antigen to the endoplasmic reticulum, which likely releases transcription factors that bind to the S2 promoter. The X promoter regulates the synthesis of

the mRNA coding for HBx, the viral trans-activator. The X promoter is regulated by ubiquitous and liver-specific transcription factors such as the X-promoter binding protein (X-PBP). HBx does not bind DNA directly but binds to and modifies the function of transcription factors to increase the activity of all the other HBV promoters.

4.1.2 Transcription of Viruses Integrated into the Host Chromosome

Retroviruses are RNA viruses that convert their RNA into DNA by reverse transcription. This DNA is then transported to the nucleus and integrated into the host genome. Basal transcription is regulated by cellular transcription factors and activators. Some retroviruses also encode viral trans-activators whose function requires a tight interaction with host factors. Two typical examples, the HTLV-I Tax and the HIV-1 Tat proteins, have a similar function but important mechanistic differences (Fig. 4). The HTLV-I long terminal repeat (LTR) contains three 21-bp repeats required for Tax activation. Each of these Tax-responsive sequences (TxRE) contains cyclic-AMP response element binding (CREB)/ATF binding sites flanked by GC-rich sequences. In the nucleus of the host cell, Tax dimerizes and interacts with CREB, CBP, and P/CAF cofactors. The formation of a ternary complex, Tax/CREB/TxRE, mediates a specific HTLV-I Tax trans-activation, as Tax is not able to activate transcription at other CREB/ATF sites on cellular promoters. Three Tax-interacting factors are involved in this specificity. P/CAF binds to the C-terminal activation domain of Tax, and the binding correlates with the trans-activation ability of Tax. The SR-related protein TAXREB803/SRL300 is a DNA binding protein that binds Tax and the 3′ GC-rich sequence of TxRE. It functions as a Tax coactivator in the expression of HTLV-I genes. The transducer of regulated CREB protein 3 (TORC3), a coactivator of CREB, also binds Tax and increases transcriptional activation at the HTLV-I LTR. Although the exact coordination of all these host and viral factors remains to be fully determined, their requirement in Tax trans-activation suggests the formation of a large multiprotein complex on the TxRE site that will contact factors of the general transcriptional machinery.

The HIV-1 LTR is controlled by a large number of transcription factors with SP1 and NFκ-B as the most proximal from the transcription start site. Cellular components control the basal level of HIV-1 LTR expression, whereas the activated level is regulated by the viral trans-activator Tat. In contrast to all other known trans-activators, Tat has an RNA target, the TAR element, located at the 5′ end of all HIV-1 mRNAs. *In vivo* trans-activation by Tat occurs by a multistep mechanism that requires a coordinated activity of cellular and

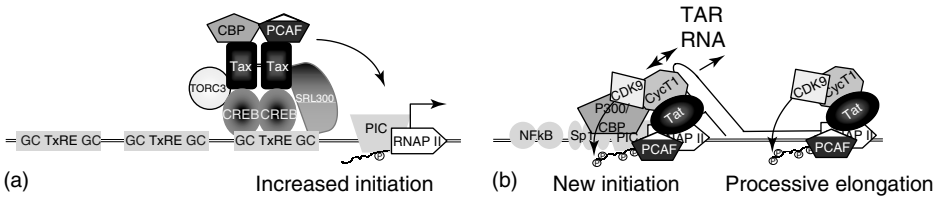

Fig. 4 Comparison of the trans-activation mechanisms mediated by HTLV-I Tax and HIV-1 Tat with their associated host factors.

viral factors. As a first step, Tat is acetylated by P/CAF at K28 and the Ac28-Tat has a very high affinity for the positive transcriptional elongation factor (P-TEF)b, composed of Cyclin T1 (CycT) and the cyclin dependent kinase (CDK) 9. Indeed, Tat binds directly to CycT, which itself binds to CDK9. The Tat-CycT-CDK9 complex has a very high affinity for TAR RNA and forms a ribonucleoprotein complex. This complex recruits p300/CBP, which acetylates Tat at K50. As a result, Ac50Tat-CycT-CDK9 has a decreased affinity for TAR and will be transferred to the next preinitiation complex paused after the carboxy terminal domain (CTD) of the RNA polymerase (RNAP) II has been hypophosphorylated by CDK7. The association of p300/CBP-Ac50Tat-CycT-CDK9 with the preinitiation complex forms an efficient transcription elongation complex in which CDK9 hyperphosphorylates the RNAP II CTD and maintains this phosphorylation during the elongation of HIV-1 mRNAs. These complex interactions between cellular and viral factors provide a very efficient trans-activation mechanism of HIV-1.

4.1.3 Synthesis of Coding mRNA by RNA Viruses

RNA viruses that do not use a DNA intermediate for their replication synthesize their mRNA and replicate using a viral RNA-dependent RNA polymerase (RdRp). This viral enzyme or complex of enzymes renders the synthesis of mRNAs largely independent from the cell and limits virus–cell interactions to a few necessary exchanges. Plus-strand RNA viruses, including Picorna-, Flavi-, Corona-, and Togaviridae, copy the genomic RNA to form a complementary minus-strand RNA using a virus-encoded RdRp. This new RNA in turn serves as a template for the synthesis of new genomic RNA. The sites of viral RNA synthesis are exclusively in the cytoplasm and have been localized to structures derived from diverse intracellular membranes, including the lysosomes, endoplasmic reticulum (ER), Golgi apparatus, and endosomes. Although most RdRps function *in vitro*, their activity remains low, and template specificity is a property of the viral polymerase complexes found in infected cells. Membrane-associated replication complexes, composed of viral proteins, replicating RNA, and altered host-cell membranes, represent a common feature of all plus-strand RNA viruses investigated thus far.

Most negative-strand RNA viruses replicate in the cytoplasm of infected cells. Their RdRp carries out two types of RNA synthesis using the same RNA template associated with the nucleocapsid N protein: (1) mRNA synthesis, called *transcription*, in which the RdRp synthesizes each mRNA successively, and stalls to allow polyadenylation and new start; (2) *replication*, corresponding to RNA synthesis of full-length antigenomic RNA. In the first case the RdRp pauses frequently, whereas it is highly processive in the second, likely due to the coupling of replication and viral assembly. Cellular proteins participate in the formation of either the transcriptase or the replicase complex and likely govern RdRp processivity.

All the dsRNA viruses also encode their own enzymes necessary for transcription and replication. The best-studied ones are the rotaviruses in the Reoviridae family, in which a core particle is released in the cell cytoplasm after the removal of the outer membrane. The transcription from the dsRNA occurs within the core particle and the exchange with the cell is limited to pores that allow the entry of nucleotides, *S*-adenosyl methionine, and ions, as well as the exit of mRNA molecules to the

cytoplasm. Translation takes place in the cytoplasm, whereas genome replication occurs in viral inclusions called *viroplasms*.

4.1.4 Virus-induced Cell Transcription Shut-off

One dramatic result of a virus–cell interaction is the inhibition of nuclear transcription, a phenomenon referred to as *transcription shut-off*. This mechanism has been described with cytopathic RNA viruses, which replicate exclusively in the cytoplasm and encode their own RdRp. The best-studied example of this phenomenon occurs following poliovirus infection. Once the viral RNA is in the cell cytoplasm, it is translated by the host-cell translational machinery into a polyprotein that is then cleaved into three precursor proteins (P1-P3) by virus-encoded proteases. The P3 precursor will then give rise to 3CD, a precursor protease that contains an NLS in the additional region. The self-cleavage of this precursor will generate the viral protease $3C^{pro}$ in the nucleus. $3C^{pro}$ contributes to the shut-off of all three transcription systems by the degradation of transcription factors including TBP. Among the same family, the foot-and-mouth disease virus (FMDV) also induces transcription shut-off by the degradation of histone 3 by its $3C^{pro}$.

Among the negative-strand RNA viruses, the M protein of VSV also induces transcription shut-off by targeting TBP, but the mechanism is not degradation. The Rift Valley fever virus (RVFV) has evolved a different mechanism by targeting TFIIH. The NSs protein of RVFV interacts with the p44 component of TFIIH to form nuclear filamentous structures that also contain the XPB subunit of TFIIH. Therefore, NSs sequesters p44 and XPB subunits and prevents TFIIH formation. TFIIH has a function in RNAP II, and RNAP I transcription, as well as in nucleotide excision repair (Table 4). Viruses take advantage of transcription shut-off to favor their own synthesis, and this activity is certainly correlated to pathogenesis, although not always proven. For some viruses like HDV, the target factor remains unknown and it is likely that other viruses and other mechanisms will be discovered in the future.

4.2 Nuclear Export

4.2.1 Export of Viral RNA

Viruses that synthesize their mRNA in the nucleus need to export it to the cytoplasm using the cellular export machinery. Two well-described examples are HIV-1 Rev and HTLV-I/II Rex, two viral proteins with similar function and mechanism (Fig. 5). Their function is to export unspliced and singly spliced viral RNAs through the binding to a specific RNA sequence, the Rev/Rex responsive element RRE or RxRE. Following HIV genome integration in the host chromosome, transcription is initiated. mRNA from the entire genome is generated and then fully spliced by the host splicing machinery. In the early phase, only the multiply spliced mRNAs are exported to the cytoplasm to translate Tat and Rev and Nef proteins (HIV), or Tax and Rex (HTLV), whereas longer, intron-containing mRNAs are retained in the nucleus. Tat and Rev, Tax and Rex are translocated to the nucleus where Tat and Tax increase transcription, and Rev and Rex bind to RRE and RxRE respectively, to mediate the export of unspliced and singly spliced mRNAs. This starts the late phase of viral expression. RRE is not present on multiply spliced HIV RNAs but all HTLV transcripts contain RxRE. Rev and Rex bind to their RNA

Tab. 4 Mechanisms of virus-induced cell expression shut-off.

Virus	*Viral protein*	*Mechanism of shut-offion*
1. Transcription shut-off		
Poliovirus	3C protease	Degrades TBP, CREB, Oct-1, P53, TFIIICα, SL1
FMDV	3C protease	Degrades Histone 3
VSV	M	Inhibits TBP
HSV	ICP22 and UL13	Alters RNAPII hyperphosphorylation
	ICP4, ICP27 and ICP8	Displaces TFIIE from RNAP II
RVFV	NSs	Prevents TFIIH formation
2. Nuclear export shut-off		
Polio and rhinovirus	Protease	Degrades Nup153 and p62 in the NPC
VSV	M	Interacts with and inhibits Nup98
Parvovirus	NS2	Sequesters CRM-1
HBV	X	Sequesters CRM-1
Influenza	NS1	Interacts with and inhibits CPSF and PABP
HSV	ICP27	Binds to splicing factors
3. Translation shut-off		
HSV	UL41 (*vhs*)	Degrades cellular and viral mRNA
Picornaviruses	2A-protease	Cleaves the N-terminus of eIF4G Impairs all cap-dependent mRNA translation
Adenovirus	100 kDa	Dephosphorylates eIF4E
Rotavirus	NSP3	Binds to eIF4G and excludes PABP

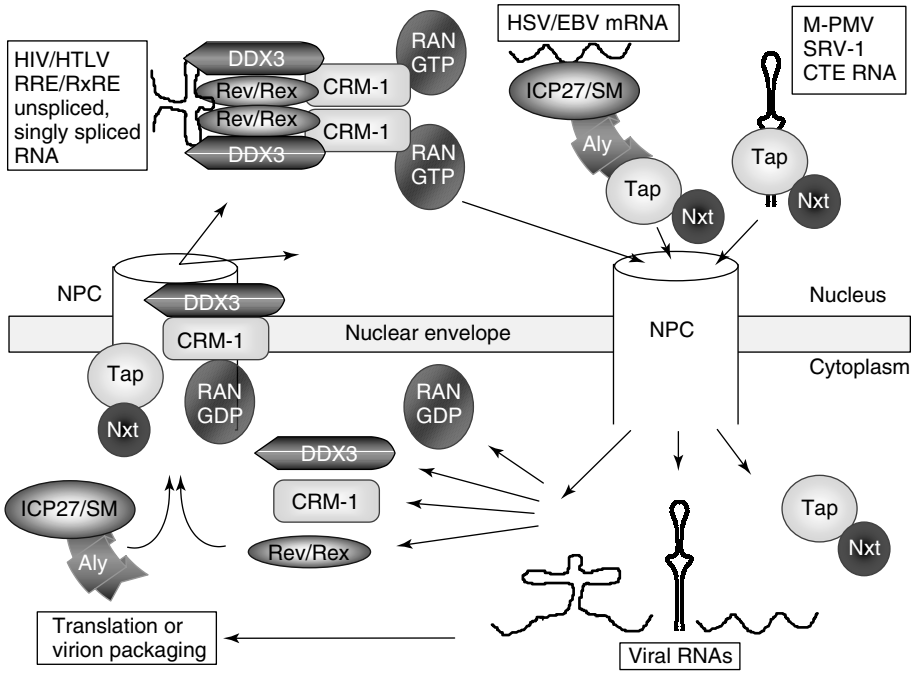

Fig. 5 Mechanisms of viral nuclear mRNA export and their cellular cofactors.

targets through an arginine-rich motif and to the chromosome maintenance region 1 (CRM-1) through their nuclear export signal (NES). Rev (and maybe Rex) also binds to an RNA helicase, DDX3, required for its function and to CRM-1. CRM-1 binds to RAN-GTP, and this ribonucleoprotein complex binds to nucleoporins localized in the nuclear pore complex (NPC) to deliver the RNA in the cytoplasm for translation and virion packaging. Singly spliced and unspliced mRNAs encode Gag, Gag-pol, Env, and other accessory proteins. Many other cellular proteins help the nuclear mRNA export by different mechanisms. For example, Src-associated during mitosis 68 kDa protein (Sam68) and human Rev-interacting protein (hRIP) are cofactors for Rev function, whereas heterogeneous nuclear ribonucleoprotein A2 (hnRNPA2) promotes HIV RNA export through a different pathway. In contrast, hnRNPA1 competes with Rex for RxRE binding.

Other RNA export mechanisms have been described. Retroviruses like the Mason–Pfizer simian virus (MPSV) and simian retrovirus type-1 have constitutive transport RNA elements (CTE) that are recognized by the cellular protein Tap to mediate constitutive transport of their RNA. Tap forms a heterodimer with a small cofactor Nxt, and the CTE-Tap-Nxt complex mediates a high affinity association with components of the NPC to mediate mRNA nuclear export. Herpesviruses also use the Tap-Nxt pathway for nuclear export. The HSV protein ICP27 and its EBV homolog SM, selectively bind to their viral mRNAs and to a cellular factor Aly that itself binds to the Tap-Nxt complex, to direct the mRNA to the NPC. The mechanisms used by other DNA viruses are not so well known, but some studies suggest that adenovirus use several pathways, whereas HBV has a posttranscriptional regulatory element (PRE) with some functional analogies with the CTE mechanism.

Most RNA viruses replicate in the cytoplasm, but influenza, Thogoto, and BDV negative-strand viruses replicate their RNA in the nucleus and then need to export it to the cytoplasm. The influenza M1 protein promotes termination of RNA replication and binds to vRNPs. This complex then recruits the NS2/NEP protein with an NES that interacts with CRM-1. Therefore, influenza and also probably BDV use the CRM-1/RAN-GTP pathway, but no such evidence has been found for Thogoto virus.

4.2.2 Virus-induced Cellular Nuclear Export Shut-off

Whereas viruses that synthesize their RNA in the nucleus subvert the functional cellular import–export machineries for their benefit, some viruses affect this pathway and mediate a general inhibition of nuclear-cytoplasmic trafficking. In poliovirus and rhinovirus infections, the analysis of the NPC revealed that at least two proteins, Nup153 and p62, were proteolyzed shortly after infection, likely due to the activity of a viral protease. As a consequence, several shuttling cellular proteins were found mainly in the cytoplasm. VSV M protein interacts with nucleoporin Nup98 to mediate inhibition of nuclear mRNA transport. IFN treatment increases the level of Nup98 and Nup96, reversing the effect of M, suggesting that the host has evolved mechanisms to counteract the IFN-antagonist properties of VSV M. The parvovirus NS2 and the HBV X proteins use a different mechanism, which is the cytoplasmic sequestration of CRM-1, therefore affecting important cellular processes. The influenza virus NS1 protein inhibits pre-mRNA splicing and

polyadenylation by interaction with the cleavage and polyadenylation specificity factor (CPSF) and the polyA binding protein (PABP), leading to the accumulation of pre-mRNA in the nucleus (Table 4). The investigation of more mechanisms will certainly determine more export pathways affected during viral infection.

4.3 Translation

4.3.1 Initiation of Translation of Viral mRNA

The early steps of virus replication result from an equilibrium between viral and cellular factors. Some viruses, however, have evolved toward a large autonomy from the cell. In contrast, no virus encodes the components necessary for autonomous translation of viral RNA. Therefore, all viruses have to compete with cellular protein synthesis to ensure that their RNAs are translated efficiently. As a consequence, viruses use the full variety of mechanisms available for cellular mRNA translation. The main mechanism is the classical scanning mechanism, whereby the 40S ribosome binds at the 5′ cap structure on the mRNA, and scans toward the translation initiation codon. Variations of this mechanism include ribosome reinitiation, leaky scanning, non-AUG start codons, frameshifting, termination suppression, and ribosome shunting; all are used to different extents by viruses. Several viruses, mainly from the Picornaviridae and Flaviviridae families, have uncapped mRNAs and use an internal ribosome entry site (IRES) to initiate their translation.

The scanning mechanism of translation starts with the recognition of the m7G cap nucleotide structure by the eukaryotic initiation factor (eIF) 4E (cap binding protein) and eIF4G associated with the RNA helicase eIF4A. EIF4G binds to eIF3, which is linked to the 40S ribosome, and to the PABP, which is bound to the 3′ polyA tail. PABP links the 3′ and 5′ ends of the mRNA to ensure efficient translation. Translation initiation requires the loading of the 40S ribosomal subunit linked to eIF2-GTP and the initiator Met-tRNA. Some viruses encode factors that can substitute for cellular factors in the translation scanning process. Rotavirus mRNAs released in the cytoplasm are capped but not polyadenylated. To replace the PABP and its link to eIF4G, rotaviruses encode NSP3, a dsRBP that binds the 3′ end of the mRNA and eIF4G with greater affinity than PABP. Thus, NSP3 subverts the host translation machinery to enhance the translation of virus-encoded mRNAs. Influenza virus may use a similar mechanism because its NS1 protein binds to viral mRNA and eIF4G, but the mechanism is not so well understood (Fig. 6).

The IRES mechanism has been described for several viruses but seems to be the sole translation mechanism used by Picornaviridae, of which poliovirus has been the best studied. Its mRNA is uncapped and its structured 5′ end directly recruits the 40S ribosomal subunit without the requirement for eIF4E, PABP, or the N-terminus of eIF4G. Its 3′ mRNA end is polyadenylated and binds PABP, but it is not clear if this protein is involved in mediating 5′->3′ mRNA association at some step. The flavivirus HCV IRES is also well studied. It does not require eIF4G and its 3′ mRNA end is not polyadenylated. Its translation is initiated by direct binding of the 40S ribosomal subunit and its associated eIF1A, 2 and 3 factors to the RNA.

4.3.2 Translational Regulation by Cellular Factors

In addition to the activity of factors from the general translation machinery, other

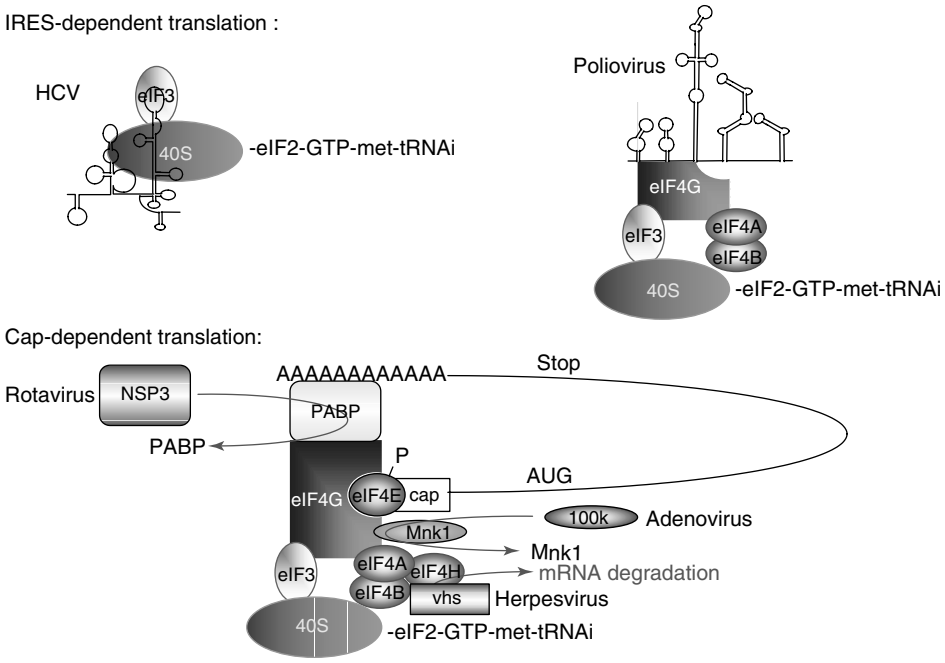

Fig. 6 Subversion of the host cell–protein synthesis by viral proteins.

cellular factors influence translation efficiency of either cap-dependent or cap-independent mechanisms. One general translation inhibition factor is PKR (as described earlier), which is induced by IFN and activated by dsRNA, heparin, or PACT. Its activity results in a general viral and cellular translation shut-off, but cellular and viral factors counteract its activity. One factor that acts both on PKR and on a PKR-independent pathway is the cellular protein TRBP that increases translation from transcripts containing HIV-1, TAR, and other structured RNAs. Similarly, but probably by a different mechanism, the lupus autoantigen, La, increases translation from HIV-1 TAR, but also binds to IRESs. Indeed, La and the polypyrimidine tract binding protein (PTB) seem to be required for efficient translation from poliovirus and HCV IRESs. Retroviruses provide another example of exploiting host translation factors. The production of Gag-Pol protein of MLV occurs by misreading a stop codon in 5% of the translation. This codon is normally recognized by the eukaryotic release factor 1 (eRF1) bound to eRF3 to produce the Gag protein, but the binding of the MLV RT with eRF1 inhibits eRF1 action and enhances the efficiency of readthrough. Other examples of alternate mechanisms can be found in a large variety of viruses as the result of cell-adapted virus mechanisms.

4.3.3 Virus-induced Cell Translation Shut-off

As a consequence of using the cell's translation machinery, all viruses limit the

availability of cellular translation factors for cellular protein synthesis. In addition, some viruses have evolved specific pathways to induce a rapid shut-off of host cell–protein synthesis to favor their own translation. One well-described example is HSV. Upon viral entry, a rapid shut-off of host cell–protein synthesis can be observed by the disruption of preexisting polyribosomes and degradation of host mRNA in the absence of *de novo* viral gene expression. This mechanism is triggered by the virion host shut-off (*vhs*) protein, an mRNA-specific Rnase encoded by HSV UL41. This protein, located in the virion tegument, degrades directly or indirectly cellular mRNA in the cytoplasm through interactions with one or more cellular translation initiation factor (Table 4).

Other mechanisms involve the subversion of translation factors. Picornaviruses encode a protease (2A-pro) that cleaves the N-terminus of eIF4G, therefore preventing eIF4E and PABP binding and impairing all cap-dependent mRNA translation. Among this family, EMCV does not cleave eIF4G but activates an eIF4E repressor. During adenovirus translation shut-off, eIF4E is strongly dephosphorylated, which inhibits cap-dependent translation. Adenoviruses encode a 100-kDa protein that replaces the Mnk1 kinase (which normally phosphorylates the eIF4E cap binding protein) to mediate the dephosphorylation of eIF4E. To selectively continue to translate viral cap-dependent mRNAs, adenovirus uses ribosome shunting, which involves loading of the 40S ribosome onto the mRNA in a cap-dependent manner, followed by direct translocation to the initiation codon without scanning the mRNA. Several other viruses clearly induce a translation shut-off, and more information about these mechanisms remains to be discovered.

5
Virus–Host Interactions Involved in Viral Egress

5.1
Ribonucleoprotein Transport

Interesting new data reveal a role for cellular proteins and major cellular machineries in late viral trafficking events. The assembly of viral particles requires the coordinated movement of all of the viral components to sites of assembly. It has been known for some time that the cytoskeletal network is used as a scaffold for the movement of viral proteins and capsids (or assembly complexes) toward the periphery of cell for release during viral egress (Fig. 3). This is the case for several retroviruses and HSV1. MPSV, a type B retrovirus, not only accumulates at a pericentriolar region but its spherical capsids are also formed there and are transported to the plasma membrane on microtubules to acquire an envelope during the budding process. Many studies have employed host cell–microtubule-destabilizing reagents such as nocodazole to disassemble the microtubule cytoskeleton. This has provided evidence for a directed movement along microtubules and the activity of host-cell kinesin and adaptor proteins to propel the viral components and assembly complexes. HSV1 capsids also require directed transport to the periphery for budding and utilize the cytoskeletal machinery to achieve this. HSV1, however engages dynein, and not one of the conventional kinesin molecules, as the motor protein to propel it essentially out of the cell. HIV-1 trafficking is achieved by microtubule-dependent machinery and it can be stopped by nocodazole treatment. HIV-1 and MLV Gag's association to the molecular motor protein, kinesin KIF4A,

likely aids in propelling HIV-1 and MLV Gag assembly complexes through the cytosol toward the plasma membrane to sites of virus budding. To be propelled, VV mimics signaling and phosphorylation events to promote polymerization of actin filaments likely to provide a scaffold for viral exit from the cell. This has been visualized in cells by identifying actin-rich cytosolic extensions that trail VV particles in cells and in tubular cellular protrusions (or pseudopods). VV (especially the enveloped form of this virus) also utilizes the microtubule network for virus exit from the cell. Similar types of pseudopod structures have also been identified during HIV-1 production in CD4+ T lymphocytes. The actin-based cytoskeleton has also been shown to be important for retroviral morphogenesis, budding, and production, indicating that the two cytoskeletal machineries based on tubulin and actin are both important for viral translocation in the cell.

Nuclear proteins that are involved in transcription and RNA posttranscriptional processing, for example, play downstream roles in replication, and could potentially influence how the virus interacts with host factors in subsequent steps. For instance, nuclear RNA binding proteins initially interact with genomes of retroviruses, mediate its transport, but also potentially influence how the genomes are translated and metabolized. This could be due to multiple functions for a protein, its spatial distribution, or it could serve as a signal for the engagement of some proteins, and a corresponding disengagement of others. The impact of these interactions can have dramatic effects on viral gene expression and as a consequence on pathogenesis. This has been shown in studies examining RNA export, and host proteins such as several hnRNP proteins (A1, A2), and RNA helicases (DDX3, RNA helicase A), proteins that have both nuclear and cytosolic functions during viral replication. The pathway by which retroviral RNA exits the nucleus, via different transportin/exportin proteins, or by CRM-1, influences viral gene expression patterns likely to impact on the spatial segregation of critical virus–host interactions with proteins and limiting membranes required for viral morphogenesis. RNA viruses have the tendency to attract many types of RNA binding proteins and this can impact on host protein acquisition, for instance, of proteins that are involved later in viral assembly or proteins that have function in the encapsidation of viral genomes into virions. Cellular proteins such as nucleolin, hRIP, eukaryotic elongation factor-1α (eEF1α), hnRNP proteins, and Staufen interact with retroviral genomic RNA during some of the major gene expression events (transcription, splicing, translation). Many of these proteins are also found in highly purified viral particles (Table 1). In many ways this would be expected because viral RNAs are trafficked intracellularly like most cellular RNAs. Interestingly, Staufen is found in a complex containing the RNA helicase proteins RHA, DDX1, and DDX3, proteins that are involved in nucleocytoplasmic RNA trafficking. It is part of the cytosolic Gag–ribonucleoprotein (RNP) complex and it is also found in purified virus (Table 3). Staufen's association with influenza virus NS1 in the nucleus, indicates that this RNA trafficking protein plays roles in and out of the nucleus during viral replication in several viruses. Furthermore, this work may indicate a more widespread function of these RNA trafficking proteins during the viral gene expression stages of a variety

of viruses from HIV-1, HSV, adenovirus, and influenza virus in their respective host cells. Live cell imaging of MLV RNA trafficking reveals tight apposition of the viral RNP complex that contains RNA and Gag, to recycling endosomal membranes and a dependence on the microtubule cytoskeleton. It is clear from this recent work that viral RNA translocation requires critical associations between host-cell proteins and the cell's vesicular sorting machinery during viral assembly.

5.2 Viral Protein Egress Mediated Through Vesicular Trafficking Mechanisms

While the process of viral egress is becoming the focus of intense investigation, nowhere have we investigated this process more intensely than in retroviruses. As one of the least understood frontiers in viral replication, research in this area has underscored the importance of the vesicular trafficking machinery in viral protein and RNA egress. A multitude of proteins involved in vesicular sorting mechanisms have been closely associated with viral proteins in several cell types. We will discuss some of these and the cellular compartments to which they belong and the implications for viral replication.

Virion assembly, a phenomenon that was once thought to have been mediated merely by diffusion of components to the plasma membrane to initiate assembly and aggregation, is shaping up to be a highly regulated process requiring the activity of a multitude of cellular proteins and cellular machineries. HIV-1 infection in macrophages plays a determinant role in the establishment, persistence, and pathogenesis of infection. In macrophages, however, it has been appreciated for many years that virus accumulates in intracellular, vacuole-like compartments. Ultrastructural analyses have shown that this intracellular compartment is the late endosome/multivesicular body (MVB). Virus-like structures and several organellar markers of the MVB compartment such as CD63, Lamp-1, and Lamp-2 have been identified ultrastructurally. Many of these proteins are also found in purified virus preparations (Table 1). Gag targeting and assembly in this compartment can occur in macrophages and $CD4^+$ T cells and other epithelial cells (HeLa).

5.3 Virion Assembly: Morphogenesis and Budding

The Gag proteins of several retroviruses harbor late domains that drive viral budding at the MVB. They were so named because virus assembly was arrested at late stages when they were mutated. Several late domain motifs (P(T/S)AP, PPXY, and YP(X)nL) have been identified in enveloped retroviruses such as in EIAV, MLV, MPSV, RsSV, and HTLV-I and they have also been found in ortho- and paramyxoviruses and in Ebola virus. In HIV-1 and SIV, viral budding is mediated by a conserved stretch of proline-rich amino acids with the motif P-T/S-A-P with their p6 domain. These data reveal that these different families of enveloped viruses likely bud using a common mechanism in their respective host cells.

Deletion or mutagenesis of the late domain resulted in a dramatic decrease in viral release and morphologically detectable budding defects. Because viral budding is a phenomenon that occurs on cellular membranes, these morphological data suggested that late domains might interact with the machinery involved in

membrane and vesicle formation. Molecular biology analyses revealed that late domains interacted with cellular class E proteins. The HIV-1 p6 domain for instance is bound by the tumor susceptibility gene 101 protein (Tsg101). This protein is classified as ''class E'' because its deletion gives rise to abnormally enlarged endosomal membrane compartments that fail to mature to MVB. Tsg101 protein's normal function is to help sort proteins into the MVBs. The HIV-1 Gag-Tsg101 interaction essentially hijacks the host's MVB vesicle formation machinery. This in turn recruits proteins of the 350 kDa endosomal sorting complex required for transport (ESCRT) -1, which regulate MVB biogenesis and cellular vacuolar sorting pathways to membranes of the late endosome (Fig. 3). ESCRT-1 is transiently recruited to limiting membranes of endosomes where it recruits two other complexes (ESCRT-2 and -3) to initiate MVB formation. Other cellular components have been identified to play a role in HIV-1 budding, for instance AIP1, another class E protein, but this host-cell protein binds adjacent LRSLF and YPDL motifs in HIV-1 and EIAV, respectively. It is likely that the over 22 candidate human class E proteins play a role in virus budding but most might impact MVB biogenesis in general rather than directly interacting with viral components.

There are fundamental differences in the site of budding of retroviruses depending on cell type, but these processes are topologically identical in that the membranes must curve and bud away from the cytoplasm. Both $CD4^+$ T cell (plasma membrane) and macrophage (MVB) (Fig. 3) virion budding membranes should contain all the machinery needed for this process. Emphasis is now focused on identifying class E and other cellular factors that may induce curvature in these membranes to influence budding (AIP1 could be one of them). The influence of viral budding could impact on pathogenesis since MVB budding pathway used principally by macrophages could promote directional release of virions. The impact on pathogenesis could also be substantial especially since the tropism of HIV-1 changes with time (from macrophage to T-tropic) and the budding pathway changes as a consequence. Recent work has elucidated the nature of viral protein egress in different cell types.

5.4 Gag–Host Interactions: The Gag Interactome

Group specific antigen or Gag is the major viral structural protein and plays a central role in many aspects of the viral replication cycle. It is generally presented as a polyprotein that is cleaved upon maturation of virions during assembly and viral morphogenesis to give rise to multiple smaller proteins. In retroviruses, these proteins have multiple functions throughout the life cycle. As listed above, these proteins interact with cellular proteins for function. Recent work has focused on late events of retroviral replication, a less well-characterized mesh of virus–cell interactions (see the following). Documenting these interactions is crucial to understanding the process of HIV-1 replication and pathogenesis, and it provides the foundation for the development of new therapeutic and prevention strategies to combat the acquired immunodeficiency syndrome (AIDS). The importance of Gag and the central role of this protein in viral replication were the initiative to create the *HIV-1, Human Protein Interaction Database* (www.ncbi.nlm.nih.gov/RefSeq/HIVInteractions/) by the National Institute

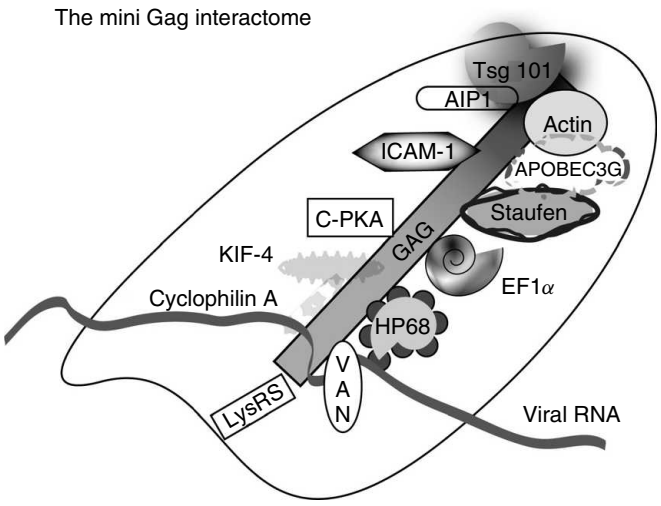

Fig. 7 Some of the host-cell proteins that interact with retroviral Gag protein. This cartoon depicts that Gag interacts with multiple host proteins in addition to the genomic RNA (blue squiggle) throughout the viral life cycle. These interactions can impact on viral egress and assembly (motor protein KIF4A, Actin; HP68, lysyl-tRNA synthetase (LysRS), cyclophilin A), gene expression (EF1α), viral budding (Tsg101, AIP1), early events to influence cell-to-cell transmission and infectivity (ICAM-1), cell restriction to viral infection (APOBEC3G, Cyclophilin A) and signaling, and posttranslational modifications of Gag (catalytic subunit of cAMP-dependent protein kinase, c-PKA). Location of host-cell protein does not indicate region of Gag to which it binds (See color plate p. xxix).

of Allergy and Infectious Diseases of the National Institutes of Health (USA), in which we find an up-to-date and curated list of documented HIV-1-host cell protein interactions. Some of the most recent interactions with Gag have been highlighted earlier and Fig. 7 shows some of these in a cartoon. Table 1 lists a few of these interactions and their possible role in the replication cycle.

5.5 Cellular Proteins Incorporated in the Virion

A partial list of virion-associated host-cell proteins (studied extensively in HIV-1) is provided in Table 1. A few examples of virion-associated host-cell proteins have already been described in the sections earlier (ICAMs, Sect. 1.1), APOBEC3G (Sect. 3.3) INI1 and UNG2 (Sect. 3.7), eEF1α and Staufen (Sect. 5.1), and class E proteins (Sect. 5.3) and their impact on viral replication steps described. These proteins are acquired at various steps of the viral assembly pathway, between the nucleus and the budding membranes. Function can be ascribed to many of these on the basis of biochemical data and genetic data (using RNA interference, RNAi or antisense RNA approaches), and in most cases, the virion association can be explained by specific interactions that occur between viral protein and RNA (or the

viral RNP) components and these host proteins. Earlier reports demonstrate that virion incorporation of host proteins found in the virus envelope may merely reflect the levels of expression at the cell surface in a particular cell type. The expression of several adhesion molecules on the virus envelope (LFA-3, ICAM-1, and MHC-I and II) was studied, and the adhesion molecule profile present on the envelope of primary isolates of HIV-1 was shown to be cell-type dependent. Nevertheless, very recent information on ICAM-1 in HIV-1 demonstrates that its virion incorporation is mediated by a specific interaction with Gag. One of the first proteins to be identified in retroviruses was Cyclophilin A, a peptidyl-prolyl *cis*-isomerase that interacts directly with CA protein of HIV-1 Gag. Its role in viral replication appeared significant since blocking its incorporation by mutagenesis or with the use of cyclosporine A resulted in compromised infectivity. This virus–cell interaction continues to gain attention. It has been shown to impact on viral replication in virus-producing and target cells. These roles include regulation of assembly, decapsidation, reverse transcription and most recently, postentry viral restriction to infection.

While it would seem evident that there would be a limit to the number of proteins that can be packaged into a virion, recent work demonstrates that host protein packaging can be regulated in the virus-producing cells, especially when the host protein is detrimental to virus replication. In cells that are nonpermissive to Vif for example, Vif expression can sequester or bind APOBEC3G, to prevent incorporation into virions and the catastrophic effect on replication as described above (see Sect. 3.3). This example demonstrates the fact that during virus assembly there are additional levels of regulation to influence host-cell protein incorporation that may rely on either viral or host-cell proteins. Both APOBEC3G and Staufen for example are packaged in a Gag-independent manner, but may require the inclusion of viral RNA and a functional RNP assembly complex to take them into the virus. Other documented examples of virion-associated proteins include HO3, a putative histidyl-tRNA synthetase in HIV-1, but not MLV, lysyl-tRNA synthetase in HIV-1, and the nucleolar protein, nucleolin, in MLV. Future work will uncover the impact of host-cell protein packaging in HIV-1 and in other viruses, but it is clear that selective virion incorporation within the viral envelope or inside the virus has a significant impact on viral infectivity and pathogenesis.

6 Cell-to-Cell Viral Transmission

The propagation of viruses within a host organism is known to occur via three main mechanisms. The first and classical mode of entry is by cell-free virions that infect cells via a receptor-mediated mechanism followed by entry into the cytoplasm (see Sect. 1). This might be the least efficient mechanism in that free-floating virions must seek out permissive host cells. The second is via effector cells that engulf or trap virions usually via a receptor-mediated mechanism on C-type lectins and other host cell surface receptors such as DC-SIGN. These cells do not become productively infected but have this capacity to entrap virus particles and mediate the transfer of virus at other sites in the body. This mechanism is believed to contribute to virus spread and to be important for transferring virus to cellular

compartments other than the primary site of contact. The third mechanism of virus propagation is characterized by cell-to-cell transmission of virions. This transmission route likely represents the most efficient means of infection, but is probably the least well characterized. This mechanism has been recently studied in good detail for HTLV-I and HIV-1 and there is some evidence to suggest that the SARS-CoV can also be transmitted via this route of transmission. There are several advantages for the virus to be transmitted this way and these pertain to immunological escape, creation of viral reservoirs, and dissemination of virus throughout the body, to areas, for example, that might be impervious to antiviral therapies.

6.1 The Virological Synapse

Cell-to-cell transmission occurs via the so-called virological synapse (VS) that is formed between virus-harboring or infected cells and an uninfected cell. It is important first to draw on its similarities with the immunological synapse (IS), a well-characterized structure that is formed between T cells, cytotoxic T lymphocytes (CTL), NK T cells, and target cells. The main similarity is the interaction between adhesion molecules (such as ICAM-1) and Talin/LFA-1 between cells. Noteworthy is that immune cells will continually sample each other, infected or not, or in the case of the IS, antigen presenting or not. So the bombardment might appear to be haphazard, suggesting that additional membrane signals derived from a virus-expressing cell (i.e. its envelope) will be important to engage a cell and to initiate cell-to-cell transfer of virus components. Evidence for the involvement of Env comes from very early work, which demonstrated that the addition of recombinant HIV-1 envelope protein to uninfected cells in culture caused a dramatic reorganization of its cognate receptor and coreceptor molecules and the cytoskeleton (actin). Other similarities are the dramatic reorganization of the cytoskeletal machinery, as well as the nature of the cell-to-cell interactions that appear to be transient in nature, as shown by live cell microscopy studies (although this has not been accurately timed in the case for the VS).

Immunofluorescence imaging studies reveal a tight membrane apposition between infected and uninfected T cells. Electron microscopy also reveals the presence of mature virions in this extracellular compartment, suggesting that virions bud out and are concentrated in the VS to favor immediate uptake by the target cell. Recruitment to the site of cell-to-cell contact of many receptors in the uninfected cells such as CD4, and CXCR4/CCR5 coreceptors ensues. Once engaged, a series of cellular events occur. Imaging data suggest that a reorganization of cytoskeletal networks based on actin and tubulin occurs in both the infected and uninfected or target cell. The actin coactivator, Talin, is observed at the site of cell-to-cell contact. The remarkable observation was also made showing that the microtubule network also redistributes to this area. The principal cellular organizing center for RNA, protein, and vesicular trafficking, the MTOC or pericentriole, migrates to the vicinity of the VS. This surprising response, perhaps mediated either by the cell–cell apposition, viral expression, or cellular signaling cascades in the cell, might provide efficient targeting of Gag, viral RNA, and other components to these sites of virion budding. This may be in part an effective strategy to propagate viral

genomes, but also represents a viral transmission route that masks viral antigens from an immune response that can clearly be detrimental to viral replication. While this mode of transmission appears to be the only mode of transmission for HTLV-1, other types of viruses such as HIV-1, HSV1, and maybe SARS-CoV use this transmission route. Cell-to-cell contact of an HSV1-infected cell induces a significant restructuring of cell surface receptors and the engagement of immunoglobulin-like receptors, nectin1 (PRR1/HveC/HIgR), nectin2 (PRR2/HveB), and the mannose-6-phosphate receptors. Because HTLV-I succumbs to a block in cell-free virus infection, it will be interesting to determine the virus–cell interactions that are overcome when HTLV-I cell-to-cell transmission occurs. Cell-to-cell contact and what ensues clearly subvert the normal cellular processes to allow efficient spread of viral particles to many cell types and cellular compartments.

6.2 Dendritic Cell to T-cell Transmission

As the primary site of infection, the epithelial cells that line the vagina are usually the sites of initial HIV-1 virus exposure. This milieu is rich in immature dendritic cells (DC) and upon encountering viral antigens, as they would do following a sexual encounter with a virus-infected individual, virus is trapped within DC. This is mediated via the same DC-SIGN molecules on the surface of the DC and likely, its receptor that is expressed on the surface of virus particles (ICAM). Virions are engulfed in the DCs and these cells migrate to secondary lymphoid tissues, where they have the potential to transmit virus via cell-to-cell transmission to other immune cells. The DC cells have been shown to mediate cell-to-cell transmission to T cells (likely in these secondary tissues), without becoming infected themselves and this would necessarily result in the first steps in infection. Immunofluorescence imaging reveals the formation of a VS at the site of contact between DC and T cells, a similar redistribution of cytoskeletal proteins and receptor molecules described above. Importantly, DC-SIGN represents the means for other pathogens including bacteria, parasites, and emerging viruses such as SARS-CoV to usurp the primary immune defense mechanisms and to disseminate in the body.

6.3 Nanotubes and Viral Transmission

Long protrusions have been demonstrated to form between immune cells following cell-to-cell contact. These have been termed *nanotubes*, and have been visualized by both light and electron microscopy. These are very narrow membrane channels. Complexes have been shown to move by saltatory and directed transport between cells via this tunnel (via channeled microtubules and cellular kinesin motors). Complexes and even cellular organelles up to several microns in diameter are capable of trafficking through these channels. While only shown to occur following IS formation to date, these types of structures can form between immune cells and any other cell type in coculture. This structure could potentially be formed between uninfected and infected cells and could provide an efficient means to transfer viral genetic material and proteins to many uninfected cells at the same time. This could be a means once again for viruses to avoid the immune system. Whether viral transmission occurs via nanotubes as

a consequence of specific virus–cell interactions will be the subject of further experimentation.

7 Pathogenesis Induced by Virus–Cell Interactions

7.1 Virus–Cell Interactions Leading to Oncogenicity

Many viruses induce cancers in animals including humans. The first group of viruses is the DNA tumor viruses of the Adeno-, Polyoma-, and Papillomaviridae families. HPV infection represents a major risk for the development of human cervical carcinomas. Adenoviruses have not been associated with human tumors, but some serotypes transform cells in tissue culture and induce tumors in rodents. PyV have a host restriction. In permissive cells, they induce a lytic cycle, whereas in nonpermissive cells, viral entry results in abortive infection or cell transformation. Although the exact origin of SV40 in some human tumors is still under investigation, JC and BK polyomaviruses are human pathogens with an oncogenic potential, but their association with human cancers may be the result of a combination with other factors. Members of the Herpesviridae, EBV and HHV8 can also induce tumors in specific conditions. Retroviruses constitute a large group of RNA tumor viruses, although not all retroviruses cause cancers. Several retroviruses induce different types of cancers in animals, and HTLV is the first discovered human retrovirus that induces cancer. The mechanisms used by these viruses are quite complex, involving specific genes that contribute to cell-cycle deregulation by different mechanisms.

7.1.1 Cellular Genes Targeted by Viral Oncoproteins

The cellular retinoblastoma susceptibility protein (pRb) and the human tumor suppressor p53 play major roles in the cell cycle and are the target of viral oncoproteins. The Rb family ''pocket proteins'' negatively regulate progression from G0 to G1 and progression to S phase, thus controlling cell-cycle progression. pRb sequesters the E2F family of transcription factors, therefore preventing E2F-dependent genes like c-fos and c-myc to be activated. In addition, pRb recruits chromatin remodeling factors, histone deacetylases (HDAC) and Grg1/Brm1 to further repress E2F-dependent transcription. p53 protein is a tumor suppressor encoded by a gene whose disruption causes 50 to 55% of all human cancers. p53 has a key role in cell-cycle arrest and apoptosis induction when DNA becomes extensively damaged. In normal cells, p53 is a short-lived protein maintained at very low levels bound to its inhibitor human double minute 2 protein (HDM2). p53 production is activated in response to various stimuli including DNA damage, oncogene expression, or viral expression. It translocates to the nucleus upon activation and stimulates the expression of genes implicated in cell-cycle arrest, DNA repair, or apoptosis. These two mechanisms overlap when p53 production increases and stimulates transcription of CDK inhibitors, resulting in decreased pRb phosphorylation and inactive E2F that remains bound to pRb. pRb and p53 constitute major targets of oncoproteins of DNA viruses, but also contribute to oncogenesis induced by retroviruses.

7.1.2 Viral Oncoproteins

SV40, JC, and BK polyomaviruses all encode two proteins that contribute to oncogenicity, the LT and the small T (ST)

Ag; LT is sufficient to transform cells. LT stimulates the cell cycle by binding to several proteins that control cell-cycle progression and apoptosis. LT binds to pRb and p53, and these interactions are major factors of the oncogenic transformation. LT disrupts pRb-E2F interactions, allowing E2F activation of c-fos and c-myc that promote G1/S phase transition. LT binds to and inactivates p53, thus preventing inhibition of cell cycle and apoptosis. Another interaction of LT is with the insulin receptor substrate (IRS-1), which causes its translocation to the nucleus and may affect DNA repair and chromosomal stability. LT also binds to β-catenin and enhances expression of c-myc and Cyclin D1. ST cooperates with LT, but also binds to protein phosphatase 2A and inhibits its activity. This inhibition results in an increased transcription of Cyclins D and A, and in the downregulation of the cyclin kinase inhibitor, p27, to contribute to cell transformation.

Adenovirus E1A, E1B, and E4 gene products contribute to cell-cycle deregulation. The two forms of E1A protein inactivate the pRb checkpoint, allowing S phase progression. E1A also interacts with chromatin remodeling factors, including the HAT CBP/p300 and HDACs. These interactions affect transcription of several cellular and viral genes that contribute to cell-cycle regulation, and also increase p53 production and stabilization. To counteract its activity, the E1B and E4 gene products inactivate p53 to further prevent cell-cycle inhibition and apoptosis.

HPV E6 and E7 are oncoproteins that both contribute to the induction, the progression, and the severity of human cancers. E6 binds to p53, and this interaction results in the degradation of p53 via the ubiquitin proteolytic pathway. This activity results in a strong inhibition of apoptosis. E6 also activates the expression of the telomerase enzyme, thereby decreasing the stability of chromosome ends. It also associates with CBP/p300, which reduces the transcriptional trans-activation of p53. E7 associates with Rb and HDAC and thereby releases E2F that increases cell-cycle progression.

Herpes viruses can progress to a lytic or to a latent phase and some members induce cancers. HCMV, HHV-6, EBV, and HHV-8 all encode proteins that inhibit the p53 transcription pathway, promoting oncogenesis. The clear implication of γ-herpesviruses EBV and HHV-8 in human cancers is linked to genetic abnormalities but has additional molecular pathways to induce cell-cycle deregulation. HHV-8, responsible for Kaposi's sarcoma, has at least three latent genes encoding proteins that deregulate cell cycle. The viral cyclin (vCyc) inactivates pRb. LANA-1 interacts with and represses p53 and pRb; it also interacts with H-ras. vFLIP inhibits Fas-induced apoptosis and activates NF-κB. EBV genes involved in oncogenesis are the EBNA1 nuclear antigen, the latent membrane proteins (LMPs 1, 2A, and 2B) and the BamHIA transcripts.

Many retroviruses are oncogenic, inducing mainly sarcomas and hematopoietic tumors. The mechanism of tumor induction by retroviruses involves viral oncogenes (v-onc), which are derived from cellular genes called *proto-oncogenes (c-onc)*. Retroviruses that carry v-onc genes transform cells *in vitro*, but are generally replication-defective because some or all the genes required for viral replication were deleted when the oncogene was captured. Therefore, virus production can only be obtained with a helper virus

that provides the gene products for replication and virion packaging. More than 30 v-onc genes and their cellular proto-oncogenes (c-onc) homologs have been discovered including src, ras, raf, jun, fos, and myc among the best-studied ones. Many tumors are also induced by retroviruses that lack oncogenes. In this case, the oncogenic process is generally long and requires provirus integration in the vicinity of a proto-oncogene, a mechanism called *proviral insertional mutagenesis*. The overexpression of the c-onc promotes cell growth deregulation. v-onc genes have a large variety of activities and are classified in families on the basis of the function of the protein encoded by the corresponding c-onc gene. They include growth factors, growth factor receptors, protein tyrosine kinases, adaptor signaling proteins, G proteins, serine/threonine kinases, and transcription factors. v-onc transcription factors are often modified compared to their cellular counterpart and induce activation or repression of several genes leading to cellular dysfunction. Many of the v-onc genes cooperate, and insertional mutagenesis may target several loci. In some retrovirus infections, tumor suppressor genes may also be involved, indicating that retrovirus-induced tumors are multifactor processes. HTLV-I is different from other retroviruses because its trans-activator Tax is its major oncoprotein, and it lacks a cellular homolog. Tax has numerous effects leading to cell-cycle deregulation. It activates the expression of Cyclin D, cdk2, 4, and 6 and represses most cdk inhibitors, which promotes cell-cycle progression by allowing constitutive activation of cyclin–cdk complexes. Tax also mediates repression of DNA repair by inhibition of DNA polymerase β and p53 and trans-activation of PCNA.

7.2 Viral Proteins Contributing to Cell Death

Viruses and cells use a wide variety of strategies to affect or maintain the balance between growth and death of infected cells. Apoptosis is a programmed cell death for the elimination of unwanted cells, including virus-infected cells. Two main signaling pathways are used by the cell to reach apoptosis. The death receptor pathway, which includes CD95/Fas and the tumor necrosis factor receptor (TNFR)1 and uses the adaptor molecule Fas associated death domain (FADD), leads to the activation of caspase 8 and 10. The mitochondrial pathway leads to the activation of caspase 9, which forms the apoptosome with cytochrome *c* and Apaf-1. Bcl-2, an integral mitochondrial membrane protein, prevents apoptosis, whereas other members of the Bcl-2 family such as Bax have proapoptotic activities. As described in the previous section, p53 induces growth arrest and has apoptotic properties.

7.2.1 Anti-apoptotic Viral Genes

Virus infection induces the expression of IFN and in turn IFN activates genes that play a role in apoptosis. These include TNF-related apoptosis-inducing ligand (TRAIL), PKR, IRF-1, and PML. To maintain host-cell survival and to ensure viral replication, viruses have evolved strategies to prevent cell death. As examples, the herpesvirus vFLIP, the poxvirus CrmA, and the insect baculovirus p35 encode proteins that inhibit caspase 8 and 3 activation. The γ-herpesviruses encode BHRF1 and KSBcl-2 that inhibit the mitochondrial apoptotic process. HSV-1 LANA, adenovirus E1B, HPV E6, and polyomavirus LT inhibit p53-mediated apoptosis. EBV, LMP1, and HTLV-I Tax may also stimulate the expression of

cell survival factors by activating the NF-κB pathway.

7.2.2 Proapoptotic Viral Genes

Some viruses have an advantage to promote cell-cycle arrest for a specific step in their replication cycle or to induce a lytic phase. For these purposes, they encode proteins with proapoptotic properties. γ-herpesviruses are able to arrest or modulate cell-cycle progression during the lytic phase. EBV Zta and the HHV-8 K-bZIP mediate these changes through increased c/EBPα protein production and interaction with this protein production. c/EBPα upregulates the expression of $p21^{WAF1}$, also involved in cell-cycle regulation. Zta and K-bZIP use another route to halt the cell cycle; they both interact with p53. Zta was shown to upregulate p53 and $p27^{KIP1}$, which contributes to cell-cycle arrest and apoptosis, but the mechanism is likely more complex, involving the modulation of several other genes. HIV-1 has evolved several ways to mediate apoptosis. Its Vpr protein induces G2 cell-cycle arrest in proliferating T lymphocytes. HIV-1 protease directly cleaves and activates procaspase 8. HIV-1 envelope gp120 induces apoptotic cell death of lymphocytes, neurons, and myocardiocytes by interaction with surface receptors. The HPV E2 protein not only induces cell-cycle arrest by blocking the transcription of E6 and E7 genes but also induces apoptosis through the caspase 8 pathway. In addition, E2 is cleaved by caspases during apoptosis, which enhances its apoptotic activity.

7.3 Viral Proteins that Affect Host Immunity

To achieve a successful invasion of their host, viruses have developed mechanisms to counteract the cell immune response. In addition to interfering with the innate immune pathways described in Sect. 2, viruses interfere with adaptive immunity by different mechanisms involving B and T lymphocytes. Examples that have been studied at the molecular level include chemokine mimicry and decreasing MHC-I/HLA expression, but viruses subvert many other cellular pathways.

7.3.1 Virus-encoded Cytokine and Cytokine Receptor Homologs

Many viruses, especially those in the herpes- and poxvirus families encode cytokine and chemokine variants, as well as soluble or membrane-bound cytokine and chemokine receptors. Viral (v)IL-6 encoded by HHV8 and vIL-10 encoded by HCMV and EBV modify the host immune response and lead to the activation and growth of infected cells, thereby significantly contributing to pathogenesis. Similarly, soluble cytokine receptor homologs or original viral chemokine binding proteins serve as scavengers that interfere with inflammation, immune activation, and the migration of antiviral immune effector cells. The biological role of virus-encoded chemokine receptors, such as the HHV8-encoded ORF74, remains somewhat enigmatic. Although ORF74 is constitutively active and sufficient for the development of Kaposi's sarcoma-like lesions, other virus-encoded chemokine receptors, such as the syntenic *H. saimiri*-encoded ECRF3, are not, suggesting different functions for different receptors. Moreover, the finding that HHV-8 ORF74 is expressed in the lytic and not the latent phase of HHV-8 replication makes it difficult to conceive that the receptor plays a major role in the transformation of latently HHV-8 infected cells. Like ORF74, the HCMV-encoded US28 is constitutively active, but not transforming, and has been proposed to serve as a

chemokine scavenger. However, the receptor also induces chemokinesis in vascular smooth muscle cells, which is consistent with the epidemiological association of HCMV infection with atherosclerosis. Hence, although the biological function of virus-encoded immune modulators remains still partly elusive, it is clear that they are major determinants for virus pathogenesis.

7.3.2 Inhibitors of MHC/HLA Molecules

The MHC-I/HLA antigen presentation pathway plays a crucial role in immunity to viruses. MHC-I molecules are expressed on the cell surface and present peptides derived from intracellular proteins to CTLs, which then eliminate the infected cells. The MHC-I antigen presentation pathway involves: (1) protein processing in the cytosol by the proteasome; (2) peptide translocation into the ER lumen by the transporter associated with antigen processing (TAP); (3) MHC-I folding and assembling in the ER lumen with ER proteins; (4) association between the MHC-I complex with TAP and peptide binding; and (5) transport of peptide loaded MHC-I through the secretory pathway to the plasma membrane. Many viruses have evolved mechanisms to inhibit the MHC-I pathway, thus enabling virus-infected cells to escape CTL lysis. One first mechanism is to decrease the amount of MHC-I molecules either by inhibiting their synthesis, by sequestration, or by promoting their degradation. Herpes viruses represent a family in which most, if not all, members encode proteins that inhibit MHC-I Ag presentation. In HSV, ICP27 mediated cell shut-off and *vhs*-induced mRNA decay contribute to the loss of MHC-I mRNA and protein. HCMV UL18 and UL40 suppress MHC-I expression. Adenovirus E1A inhibits MHC-I expression, whereas E1B inhibits transport and expression. Bovine papillomavirus and HPV E5 inhibit expression of MHC-I/HLA by retention in the Golgi apparatus, whereas HIV-1 Nef promotes their sequestration in the trans-Golgi network. HCMV US2 and US11 promote ubiquitination of the MHC-I heavy chain and its degradation through the proteasome pathway. HHV7 U21 binds to MHC-I molecules in the ER and targets them to the lysosome for degradation. HHV8 K3 and K5 proteins cause a rapid downregulation of MHC-I molecules from the plasma membrane by clathrin-dependent endocytosis. Another mechanism is to turn off the mechanism of peptide presentation. HSV ICP47 acts as a competitive inhibitor of peptide binding to TAP, whereas HCMV US6 interacts with TAP and inhibits peptide translocation. The adenovirus gene product E3/19K (E19) binds to TAP and prevents TAP/MHC-I association. HCMV US3 and US10 inhibit the export of peptides loaded MHC-I from the ER. These viral mechanisms contribute to viral evasion from the cell immune system, ensure prolonged survival in the infected host and facilitate virus transmission and pathogenesis.

7.3.3 HIV-1 Example: Downregulation of CD4 by Several Mechanisms

HIV induces a severe immunodeficiency due to several mechanisms all of which contribute to this pathogenesis. In addition to decreasing MHC-I expression at the cell surface by its Nef protein, HIV induces the degradation of its receptor CD4. A decline of CD4+ T lymphocytes, which have a helper T-cell function and a cytotoxic capacity, contribute to decreased cellular and humoral immunity. HIV-1 encodes three proteins that contribute to CD4 downregulation. The Nef protein decreases the number of CD4 molecules

at the cell surface by accelerating their clathrin-mediated endocytosis that target them to the lysosome for degradation. The Env gp160 precursor has a high affinity for newly synthesized CD4 molecules and retains them in the ER. The Vpu protein binds to the cytoplasmic tail of CD4 and to β-TRCP/Skp1 that targets the complex to the proteasome degradation pathway. The combination of these mechanisms contributes to increased virus spread and increased viral pathogenicity.

7.4 Viral-induced Neurotoxicity

7.4.1 Viruses Inducing Neurotoxicity

Several viruses induce neurotoxicity and several brain disorders different from brain cancers. The neurotropic polyomavirus JCV is the etiologic agent of the fatal demyelinating disease, progressive multifocal leukoencephalopathy. Whereas its LT induces brain tumors in nonpermissive cells, JVC-infected oligodendrocytes are permissive for viral lytic infection and are destroyed, leading to demyelination. Virus-induced demyelination can also be induced by neurotropic strains of mouse hepatitis virus, Theiler's virus and Semliki Forest virus (SFV). Several flaviviruses, including West Nile virus (WNV), tick-borne encephalitis virus (TBEV) and the Japanese encephalitis also cause neuropathies. Herpes viruses and rabies that infect neurons, poliovirus that infects anterior horn cells have also been implicated in neuropathogenesis. For most viruses, the mechanism of neurotropism and neuropathy is not fully elucidated. HIV-1-associated dementia has been well studied and has the particularity to induce neuronal cell death with no or rare neuronal infection.

7.4.2 Example of HIV-associated Dementia

HIV-1 infects the brain via infected macrophage/microglial cells that cross the blood brain barrier. Although this infection occurs early after HIV infection, HIV-associated dementia (HIVD) occurs late in the disease in about 20% of infected individuals and is characterized by several cellular disorders including macrophage activation and increased death of astrocytes and neurons. Productive infection of microglia leads to the release of HIV virions and soluble Tat protein. When the virion enters a new cell, the envelope may be shed outside and promotes independent toxicity. Viral Tat and envelope have been implicated in the neurotoxic process of HIV. Astrocytes that are also infected by HIV, produce a very limited amount of virus, but release cytokines that participate to the HIVD. Tat stimulates microglia to synthesize neurotoxic molecules including proinflammatory cytokines and free radicals. Envelope proteins retain the ability to interact with the cognate HIV receptors. The interaction of soluble HIV-1 gp120 does not require the presence of CD4, at least on neuronal cells. This interaction leads to CXCR4 signaling, and may result in neuronal apoptosis, in the same was as the natural CXCR4 ligand, the chemokine SDF-1. The gp120 interaction with CXCR4 on other cells of the nervous system such as astrocytes induces signaling that leads to activation of these targets, which, in turn, secrete neurotoxic products. Other lentiviruses like FIV share some functional features in envelope mediated neurological disorders. HIV-1 and FIV env and HIV-1 Tat induce metalloproteinase (MMP)-2 in macrophages, which also participates in neuronal death. Overall, the productive infection of microglial cells, the nonproductive infection

of astrocytes, the secretion of neurotoxic molecules, the viral Tat and Env proteins, all lead to neuronal and astrocytic cell death and contribute to HIVD.

8 Perspectives on Therapies Based on Virus–Cell Interactions

8.1 Virus Entry as an Antiviral Target

Virus entry as an antiviral target holds several specific advantages as well as drawbacks as compared to viral enzyme drug targets. Blocking entry by viral receptor ligands that successfully compete with the envelope for the available binding sites means that a protein of the host, and not the virus, is targeted. This strategy is currently pursued with the development of inhibitors of HIV-1 entry into target cells that block the chemokine entry coreceptors. Being encoded by the host genome, this kind of target is invariable and will therefore not evolve to give rise to drug resistant variants, a mechanism that is the major cause of failure of therapies using HIV-1 RT and PR inhibitors. Other viral strategies to achieve resistance can however not be prevented and may constitute an obstacle for the success of coreceptor-targeting drugs: the virus may bypass the requirement for a given coreceptor by using another, alternative receptor. For example, it will be important to evaluate whether the use of CCR5 antagonists will induce a coreceptor switch in the virus, provoking the emergence of CXCR4-using strains. Another conceptual problem of targeting host molecules rather than viral proteins is that this kind of therapy often interferes with the natural functions of this host protein, thereby inducing intolerable side effects. This point clearly depends on the given target, as illustrated by the HIV-1 chemokine coreceptors. CCR5 is a safe target, since a homozygous functional deletion of the CCR5 gene exists with relatively high frequencies in some human populations without readily detectable phenotype. However, CXCR4 is a housekeeping receptor with fundamental importance. Genetic ablation of either of the genes coding for CXCR4 or its ligand, stromal cell-derived factor 1 (SDF-1) in mice is perinatally lethal. Although the importance of CXCR4 in human adults may be somewhat lower, long-term treatment with CXCR4 ligands seems difficult due to severe side effects. Another approach to interfere with viral entry is an HIV-1 fusion inhibitor that targets the conformational rearrangements of the viral fusion peptide. The first of these compounds, Enfuvirtide, is already used in the clinic. Thus far, no other example of successful pharmacologic inhibition of the entry process of viruses other than HIV is known. Whether entry inhibition may prove an antiviral principle of general interest that is useful for the therapy of different viral infections, remains to be investigated.

8.2 Antiviral Action of Interferons

Various forms of IFNs α and β are currently being used in therapeutic treatment of viral diseases including Hepatitis B and C. HPV diseases are also treated with IFNs α, β, and γ with varied success: from no response to complete effectiveness. IFN treatment has been attempted against HIV infection but multiple clinical trials have shown it to be completely ineffective. Considering the multiple mechanisms and

counter mechanisms of the virus and the host described above, it is clear that the outcome of IFN treatment will be dependent on both of these responses. Cells infected by different strains from the same virus or family of viruses can respond differently to IFN treatment. As an example, in the Poxviruses, a treatment against MCV infection is currently being tested with an immunomodulator that induces IFN production, because MCV does not encode for E3L and K3L homologs and cannot inhibit PKR by this means. The effectiveness of IFNs against hepatitis C infection is about 40%, and correlations have been made with the activity of NS5A against PKR in some studies but not in others. A more complete knowledge of virus–host interactions will help the design of combination therapies using compounds that will prevent the inhibition of the IFN response and thereby will lead to a more effective IFN therapy.

8.3 Inhibition of Viral Gene Expression

The targeting of viral gene expression steps from RNA synthesis to translation has been attempted with various small molecules, some of which are currently being used in therapeutics. Recent improvement in our understanding of virus–cell interactions have allowed rational design of strategies to disrupt vital interactions by competitive peptides, transdominant molecules, or the use of RNA-based technologies to either degrade mRNAs or prevent their translation. Finding molecules to disrupt virus–cell interactions can be first achieved by the search of inactive mimics of cellular factors. These can be small peptides that can bind competitively to a viral target without mediating the cellular function. They can also be transdominant mutant proteins that bind to the viral protein or RNA but have no function. Examples have been developed for HIV-1 with peptides that can block the TAR RNA to prevent trans-activation, and with the use of Rev mutants that have a transdominant activity by a mutation in the NES site. Large-scale screening for inactivating peptides can be achieved by using phage display libraries in assays that target a specific function. Recent examples of viruses that can be inhibited by protein fragments using this technology include hepatitis A virus, HCV, HIV, and rotavirus.

RNA-based technologies include antisense, molecular decoys, ribozymes, and small-interfering (si)RNAs. They all use RNA molecules that target the viral RNA or mRNAs coding for cellular proteins required for viral replication. RNA processing of the RNA duplexes involves cellular functions that are used to cleave the RNA or block its translation. Antisense technology uses exogenous ssRNA (or DNA) that will hybridize to the viral RNA to form duplexes that will then be cleaved by the cellular RNAse H and degraded. Alternative and more potent technology uses the coupling of these antisense RNA molecules to a molecule that sterically inhibits a function. In this case, the RNA targets the 5′ end of the mRNA and the steric block prevents its translation. Antisense nucleic acids, also called *aptamers*, have been used to block HIV, HCV, HBV, RSV, and HPV, but the future of their therapeutic use remains to be evaluated. RNA molecular decoys use structured RNAs that mimic a viral RNA target to sequester viral and cellular factors. They have been developed for the HIV-1 TAR RNA to prevent the Tat-CycT1-CDK9 complex formation and the trans-activation mechanism. Ribozymes (Rz) are catalytic RNA molecules

that combine an antisense RNA to an enzymatic activity that specifically cleaves the targeted RNA. Various forms include hairpin, hammerhead, RNAse P, and HDV (δ) Rz. Their *in vitro* activity indicates that they act independently of any cellular factor, but some variations between *in vitro* and *in vivo* functions, and the very good adaptation of the δRz to the cell environment suggest that cell factors may improve their efficacy in some cases. They have been successfully used to inhibit HBV, HCV, hepatitis E virus, herpesviruses, HIV, HPV, influenza, and rhinovirus.

RNAi allows the targeting of specific genes to explore their function during viral replication. 21–23-bp siRNAs are transfected into mammalian cells to induce the degradation of the homologous mRNA by RNAi. The activity of siRNAs depends on a cellular enzyme, Dicer that associates in an RNA-induced silencing complex (RISC) leading to dsRNA cleavage at the site of hybridization. The list of viruses that have been targeted is growing very rapidly and include HBV, HPV, several herpesviruses, and the polyomavirus JC among the DNA viruses. The targeted RNA viruses include the picornaviruses (poliovirus, rhinovirus, FMDV, HAV, enterovirus), the flaviviruses (HCV, Dengue, WNV), the togavirus, SFV, the SARS-CoV, rotaviruses, the paramyxoviruses RSV, and the orthomyxovirus influenza. Retroviruses HIV-1, HTLV-I, and RsSV have also been successfully targeted. Cellular factors required for viral replication have also been inhibited by RNAi. Decreased HIV replication can be achieved by inhibiting CD4, CCR5, and CXCR4 coreceptors, NFκB, CycT, CDK9, Staufen, Cyclophilin A, Lys-tRNA synthetase, PARP, SPT5, and TRBP. Inhibition of HCV can be obtained by decreasing RNA helicase p68, La, PTB, eIF2Bγ, and hVAP33 levels. A decrease of La can also inhibit HBV and poliovirus replication.

Some of these RNA-based methods, such as siRNAs against influenza and FMDV have been tested successfully in animals, whereas targets against HIV, HCV, and HPV are expressed on viral vectors for gene therapy approaches to treat or prevent infection. *In vivo* assays using RNAi-based strategies, only three years after the discovery of function in mammalian cells, show promise of this therapeutic intervention.

8.4 Inhibition of Assembly

At the forefront of basic research are the efforts placed on the development of new antiviral therapies. Therapies targeting viral enzymes and viral protein function have taken a front seat in the armamentarium against several viruses. Effectiveness is a concern, while escape mutants or viral resistance to drug therapies represent the biggest problem especially for HIV-1. Strategies that include state-of-the-art technologies such as RNAi have met with good success, but again viruses including HIV and poliovirus have managed to elude these site-specific targets by mutagenesis. Targeting of later events such as viral assembly is really an area of intense research with the basic cellular machinery only recently uncovered. One example relied on small molecules to target and block Gag function (i.e. CAP-1, CAP-2 compounds for HIV-1) but have not been touted as inhibitors of specific virus–cell interactions *per se*.

Another emerging and fast-moving field is the cellular mechanisms that HIV and other viruses co-opt to get themselves out of the cell. This includes multiple proteins and interdependent complexes that

bifurcate with other regulatory networks such as limiting membrane compartments and ubiquitination machineries. It would seem that if we were to block the virus from getting out, we would have the key to a successful therapy. Targeting vesicular trafficking machinery, including the cytoskeletal elements on which vesicles track, may create a hostile environment for the cell, but if it's to block viral spread it's worth it!

8.5 Viruses as Therapeutic Agents

Another aspect of virus–host interactions in therapeutics is the use of viruses as delivery vectors or therapeutic agents. Viruses with no pathogenic potential or viruses in which the pathogenic determinants have been removed can be used to deliver therapeutic DNA or RNA into cells by gene therapy. For this purpose, retroviruses, adenoviruses, adeno-associated virus (AAV), vaccinia and herpes-derived vectors have been used or are currently in clinical trials. To improve safety, most modifications of these vectors include reducing the risk of insertional mutagenesis and directing the expression of therapeutic genes to specific tissues. Some of these vectors and other viruses have been developed to replicate in and to specifically kill cancer cells. Because of this property, they have been called *oncolytic viruses*. Adenoviruses in which E1B is deleted replicate only in cells with an inactivated p53 gene and cause cell lysis, but do not replicate in normal cells. HSV deleted for the ICP34.5 gene replicate better in cancer cells than in the adjacent tissue. Reovirus is nonpathogenic in humans but has a distinctive ability to replicate in cancer cells with an activated Ras pathway. Sindbis virus has a natural tropism for tumor cells and modified SFV can stimulate immunity to tumor-associated antigens and induce apoptosis to destroy tumor cells. An attenuated strain of Newcastle disease virus and VSV mutants selectively lyses tumor cells versus normal cells based on tumor-specific defects in the interferon-mediated antiviral response. Several oncolytic viruses have been tested in animal models and are currently assayed in clinical trial against various cancers and hold strong promises as new therapeutic agents.

9 Conclusion

The very low mutation rate of the host genome and the *in vivo* effectiveness demonstrated in some strategies provide strong justification to pursue the study of virus–cell interactions with the principal aim to uncover effective therapeutic targets to cure or treat infectious diseases. It is definite that should a particular virus–cell interaction be interrupted by targeting cellular protein function, rather than viral protein function, the question of resistance will not be a major limitation to the application of this knowledge to a therapy. The use of oncolytic viruses to treat cancers and other disorders has already demonstrated that the study of virus–host interactions will be beneficial to human health.

Acknowledgments

The authors apologize to readers for all the original research articles that could not be cited because of the space limitation and invite them to refer to appropriate reviews. Special thanks go to Drs. Nicholas Acheson (McGill University, Montréal, Canada) and

David Ott (National Cancer Institute, NIH, USA) for their extensive critical analysis and corrections. We also wish to thank the members of our laboratories, Drs. Levon Abrahamyan and Sébastien Lainé for their critical reading. Keywords

Liposomes
Microscopic spherical vesicles that form spontaneously when phospholipids are hydrated. The enclosed aqueous core may be used to transport hydrophilic, the uni- or multilamellar shell to transport lipophilic molecules.

Somatic
Referring to cells of the body, as opposed to sex cells or gametes of the germ line.

Transfection
Insertion of small pieces of DNA into a cell. If the DNA is expressed without integration into the host cell DNA, the transfection is transient. If the DNA integrates into the host cell DNA, it is replicated whenever the host cell divides, and the transfection is stable.

Vectors
Sensu strictu: DNA elements used to amplify and express foreign DNA in a host cell.
Sensu latu: Also used synonymous with ''gene-transfection systems,'' that is, biological, physical, and chemical carriers that augment the entry of pieces of DNA into a cell.

In somatic gene therapy, nucleic acid is transferred into and subsequently expressed in somatic cells (i.e. not in stem cells) in order to alter or substitute gene functions as a means of prophylactic or therapeutic treatment of patients. The nucleic acid itself is the pharmaceutical drug. For transfer of genes, viral (retro, adeno, and adenovirus-associated viruses), physical (electroporation and bioballistics), and chemical systems are utilized. Chemical and physical systems are united as nonviral systems.

1 What is Gene Therapy?

Gene therapy may be defined as the expression of a gene that has been introduced into a target cell or a target tissue in order to alter an existing function or to introduce a new function with the aim of curing or protecting a patient from a specific disease. In many countries, this is restricted by law to somatic cells. In Germany, for example, genetic manipulation of germ cells is forbidden according to §5 Embryoschutz Gesetz (EschG) and is under penalty of up to 5-years imprisonment. German legislation on gene transfection as a form of therapy or medicine is still incomplete. An amendment specifically covering somatic gene therapy has not yet been passed. German Drug Regulation (§2 and §3 Deutsches Arzneimittelgesetz, AMG) defines DNA introduced for therapeutic purposes in a very general manner as a pharmaceutical product. German Gene Technology Regulation (§2 (3) Deutsches Gentechnikgesetz, GenTG) explicitly excludes the regulation

of gene therapy. Interestingly, gene therapy might be indirectly affected: theoretically (*sensu strictu*), a patient undergoing gene therapy becomes a genetically modified organism. Consequently, his release from hospital should be subject to authorization. When discussing DNA as a pharmaceutical, a look at European legislation, for example, at the guidelines of the European Agency for the evaluation of medicinal products (EMEA) is helpful. According to Council Regulations (EEC) No. 2309/93–ANNEX (List A), DNA is considered a pharmaceutical product for gene therapy. The necessary vector is simply defined as an additive.

Most likely, gene therapy will only work for a limited number of "suitable" diseases in a restricted commercial environment. It is very costly and affords a highly complex technology as well as an individually tailored strategy for gene delivery, depending on the relevant circumstances and aims. Monogenetic diseases such as hemophilia, sickle cell anemia, adenosine-deaminase (ADA)-deficit, cystic fibrosis, or Duchenne muscular dystrophy are likely first candidates, as they require the replacement or substitution of only a single gene. Trisomy 21 (Down syndrome), on the other hand, which is also frequently mentioned in this context, is a poor candidate, as it is much more difficult to silence the additional chromosome 21 than to replace nonfunctional genes. Furthermore, the monogenetic origin of Down syndrome is under debate. In different forms of cancer and heart or circulatory failures or of acquired genetic dysfunctions such as hepatitis or AIDS, two or more genes must be substituted or otherwise manipulated. Here, successful gene therapy seems unlikely at the moment due to technical limitations in DNA transport into target cells and in tissue-specific forms of application.

Among the known innate diseases, gene therapy has been most intensively investigated in ADA deficiency and cystic fibrosis. Both reduce mean life expectancy to below 20 years, accompanied by severe symptoms that strongly affect the quality of life.

This review covers nonviral gene-transfection strategies of current interest with special reference to experimental results found *in vivo* and to clinical trials.

2 Strategies in Gene Therapy

Independent of the respective method of gene transfer, two basic strategies for gene therapy may be discriminated (Fig. 1). Following the *ex vivo* strategy, cells or tissue are first removed from the patient, then exposed *in vitro* to the therapeutic genetic construct. If the transfection has been successful, the material is reimplanted in the patient. In the alternative *in vivo* methods, the therapeutic gene or DNA-sequence is integrated into a vector and this construct is injected locally or systemically into the patient. Among other deficits, the latter method is characterized by poor tissue selectivity, rapid extracellular DNA degradation and the danger of inducing oncogenes when using viral vectors.

Further differentiation is possible at the molecular level (Fig. 2): An intact (therapeutic) gene may simply be added to the defect one (Fig. 2A), a missing gene may be substituted (Fig. 2B), or a malfunctioning gene product may be inhibited, for example, during gene translation by giving mRNA-complementary antisense oligonucleotides (Fig. 2C). The first antisense-oligonucleotide drug, Vitravene™ (with

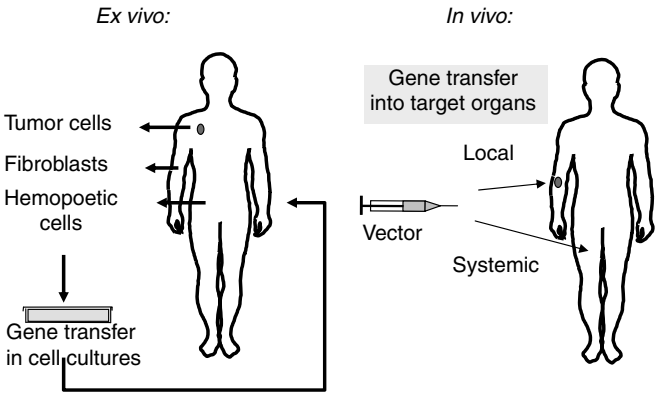

Fig. 1 *Ex vivo* and *in vivo* gene therapy strategies.

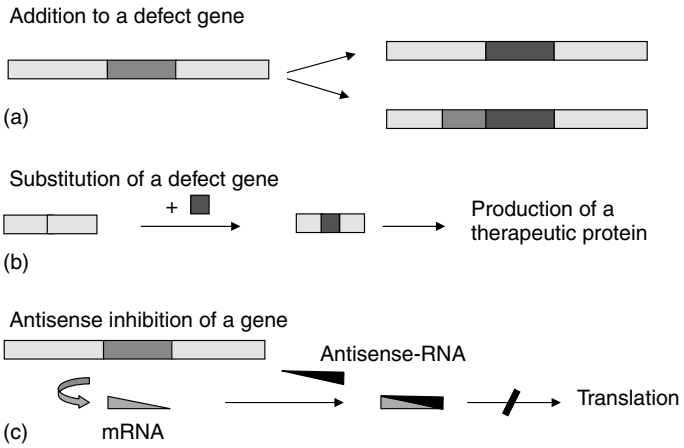

Fig. 2 Therapeutic gene functions.

formivirsen as the active ingredient), has been licensed for treating cytomegalovirus (CMV)-retinitis in AIDS patients.

The description of plasmid vectors, the biotechnology necessary for their production as pharmaceuticals and licensing specifications are not major subjects of this article. These can be studied in comprehensive overviews by Hutchins or Ferreira.

Intensive work is ongoing, both in designing new synthetic vectors and in improving DNA as a therapeutic agent. The transfection efficiency of "naked" DNA is low and it is rapidly degraded in the cytosol. The expression of the therapeutic gene may be enhanced by eukaryotic promoters of viral origin such as CMV or simian virus. The influence of the 5′UTR-site on the translation efficiency of mRNA is also being studied. The insertion of at least one intron into the cDNA may lead to 100-fold enhancement of mRNA. The addition of a suitable terminal poly(A) signal (bovine growth factor) has similar effects. Special attention is given to the development of tissue-specific promoters, restricting transfected gene expression to the necessary therapeutic

sites. A very elegant strategy for controlling the expression of the transfected gene is by turning it on or off with common oral drugs such as tetracycline or progesterone-antagonist. These interact with a mutated receptor acting as a transgene, thus initiating a signal transduction cascade, which finally induces the transcription (or its inhibition) of the respective gene for just as long as the drug is kept at a sufficient level.

3 Gene-transfection Systems

Owing to their rapid degradation in the cytosol, genes or DNA sequences are only rarely transfected as ''naked'' molecules. The commonly used gene transfer methods may be segregated into biological, physical, and chemical systems (Table 1). The biological systems involving viral vectors (retro, adeno, or pox viruses) make up 77% of all gene-transfection studies published to date. However, physical and chemical methods have experienced a relative increase in recent years (12% from 1998 to 2003). This tendency reflects the often highly serious and hardly controllable side effects of viral systems. Despite recent modifications of wild-type vectors, the future of such systems for human application appears limited. One main problem of viral vectors is their strong immunogenicity. Already the first (high-dose) application may initiate an immune reaction against the given proteins, which may lead to all sorts of allergic reactions, even lethal anaphylactic shock, when repeated. Possible reversion of the virus to wild type is another danger. The potential induction of oncogenes by retroviruses must also be mentioned.

With this background, the development of chemical or physical gene transfer systems appears especially interesting, combining simple usage with maximum safety. Further requirements for an ideal gene transfer system are minimal infectivity and immunogenicity, defined

Tab. 1 Gene transfer methods in somatic gene therapy.

	Method	***Application***	***Tissue selectivity***	***Transfection efficiency***	***Expression duration***
Chemical	Liposomes, Ca-phosphate-precipitation	*Ex vivo*/(*in vivo*)	No	Low	Transient/ stabile

chemical and physical characteristics, and the possibility of multiple dosing.

When looking for suitable alternatives to viral vectors, the pharmaceutical industry can offer a broad spectrum of thoroughly investigated and readily available medicinal carrier systems. As far as molecular transport and organ or cell specificity are concerned, the demands on modern drug delivery and gene transfer systems exhibit so much similarity that the latter may profit significantly in the fields of biotechnology and pharmacology. Among the chemical vectors, liposomes, polymer nanoparticles, and polylysine particles deserve special discussion. Physical transfection systems such as electroporation and bioballistics are further examples for an efficient transfer of existing know how in pharmaceutical technology to somatic gene therapy. It might be mentioned that gene transfer in a nonviral system must correctly be addressed as *transfection*, whereas, in biological systems, it should be referred to as *transduction*. Table 1 suggests a systematic arrangement of methods used in gene transfer technology. In the following sections, the most important contemporary nonviral gene transfer systems are described and assessed.

3.1 Physical Gene-transfection Systems

3.1.1 Electroporation

During electroporation, cells or tissues are exposed to an electric field of high voltage (up to 1 kV). Short, rapid pulses cause transient membrane instability and the formation of pores with a mean lifetime of up to minutes. Soluble DNA constructs that have been added to the culture medium or injected into the tissue may thereby enter the cell and ultimately reach the nucleus. The basic principle is also known to pharmacists as iontophoresis and is used for transdermal drug application. This gene-transfection method is so far well accepted by patients and is safe, especially due to the low risk of infection. To date, mainly liver, muscle, and skin cells have been transformed this way, mostly via the transdermal route.

3.1.2 Bioballistics

Bioballistical methods are already widely used in biotechnology, for example as "gene guns" for injecting DNA vaccines (Fig. 3). For this, linear or circular (plasmid-) DNA) is adsorbed to nanometer-sized gold or tungsten particles. These are shot from a cylinder with compressed nitrogen or helium as propellant, thereby reaching speeds of up to 900 m s^{-1}. When applied to skin, the DNA/metal particles pass through dead tissue such as the *Stratum corneum* reaching living cells. Statistically, only one of 10 000 particles reaches the interior of viable cells, thereby loosing its DNA. For the DNA to then enter the nucleus, active transport mechanisms are probably necessary. Bioballistical gene transfer methods are obviously not suitable for systemic application. Further drawbacks are the need for very stable DNA and the high developing costs. Their greatest advantage, on the other hand, is the fact that related technologies are already approved and commercially available such as the Accell® (Powderject) (Fig. 3) or the Helios® (BioRad) systems, which are used for vaccination.

3.2 Chemical Gene-transfection Systems

A multitude of synthetic chemical vectors are being developed. Of these, cationic lipids and cationic polymers are probably

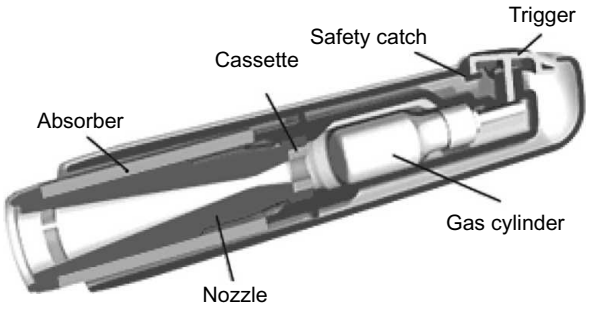

Fig. 3 Accela® gene gun (powderject). From: Burkoth, T.L., Bellhouse, B.J., Hewson, G., Longridge, D.J., Muddle, A.G., Sarphie, D.F. (1999) Transdermal and transmucosal powdered drug delivery, *Crit. Rev. Ther. Drug Carrier Syst.* **16**, 331–384.

the most thoroughly investigated. Already, in 1987, Felgner et al. could demonstrate *in vitro* gene transfection using cationic lipids. Transfer efficiency was systematically improved, leading to the first clinical studies on cystic fibrosis patients.

Irrespective of their highly variant molecular composition and 3D structure, chemical vectors such as liposomes and polymer particles have many biological and physical features in common. Positively charged amine functions are especially important, as these can be loaded with the negatively charged DNA molecules. Optimal interaction between plasmid DNA and cationic additives lead to the development of colloidal, positively charged particles, which may adhere to and be taken up by negatively charged cells a fact that is a cornerstone of chemical vector technology. Type and structure of the amine functions determine the stability of the complex, its cellular uptake in a phagosome, its release from the phagosome into the cytosol and dissociation of the DNA molecule, and even DNA transport to the nucleus.

Nucleic acids as drugs are still rather unusual in pharmaceutics. They are highly negatively charged and range in size from 10^3 kDa (oligonucleotides) to 10^6 kDa (genes). Their targets are invariably intracellular. In contrast to most conventional pharmaceuticals, nucleic acids are too large and too strongly charged to pass cell membranes by simple passive means. Furthermore, free, that is, ''naked'' nucleic acids are rapidly degraded by cellular nucleases. Chemical vectors therefore have the additional job to protect the DNA they carry from enzymatic degradation. In the context of gene transfer, liposomes are also referred to as lipoplex, polymers as polyplex, and combinations as lipopolyplex particles.

3.2.1 Cationic Liposomes (Lipoplex)

Cationic liposomes were developed and already complexed with DNA over 20 years ago. However, it was in the Human Genome Project that their potential as gene transfer vehicles really became apparent to geneticists and pharmacists. Cationic liposomes consist of cationic phospholipids, which may be divided according to their number of tertiary amine functions into monovalent and multivalent cationic lipids. An overview of the most commonly used cationic lipids is given in Fig. 4.

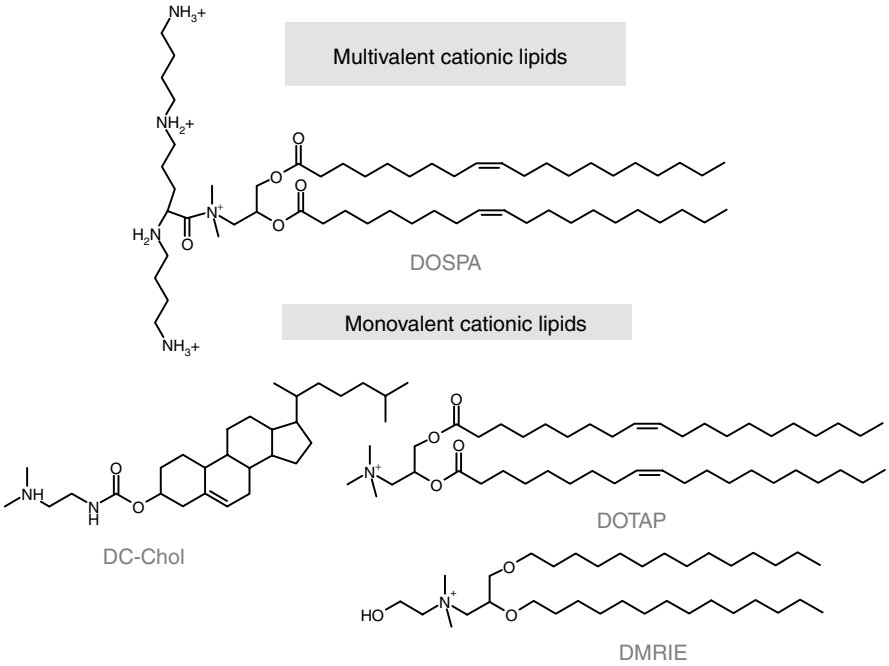

Fig. 4 Cationic lipids: DOSPA: 2,3-Dioleoyloxy-*N*-[2-(spermincarboxyamido)ethyl]-*N*,*N*-dimethyl-1-propanamminiumchloride; DOTAP: 1,2-Dioleoyloxypropyl-3-*N*,*N*,*N*-trimethyl-ammoniumchloride; DC-chol: 3β-[*N*-(*N*′,*N*′-dimethylaminoethane) carbamoyl]-cholesterol; DMRIE: 1,2-Dimyristyloxypropyl-3-*N*,*N*-dimethylhydroxy-ammoniumbromide. From Li, Z., Ma, Z. (2001) Nonviral gene therapy, *Curr. Gene Ther.* **1**, 201–226 and Simoes, S., Pires, P., Düzgünes, N., Pedroso de Lima, M.C. (1999) Cationic liposomes as gene transfer vectors: barriers to successful application in gene therapy, *Curr. Opin. Mol. Ther.* **1**, 147–157.

DOTAP (1,2-Dioleoyloxypropyl-3-*N*,*N*,*N*-trimethyl-ammoniumchloride) and DC-chol (3β-[*N*′,*N*′-dimethylaminoethane)-carbamoyl]-cholesterol are possibly the most important. However, owing to high toxicity, they must be mixed with helper lipids such as DOPE before processing to liposomes. A well-known transfection agent is Lipofectin®, which consists of equal parts DOTMA and DOPE.

The high general toxicity of the first cationic lipids initiated the synthesis of a variety of derivatives. The published *in vitro* data allows a first structure/activity analysis. The presence of a tertiary amine function and of 1 or 2 hydrophobic aliphatic chains are most important for producing stable liposomes and for binding negatively charged DNA. The tertiary amine functions can be combined with the hydrophobic lipid chains by either ester or ether bonds. Ester bonds are split more readily under physiological conditions than ether bonds and the lipoplex particles are consequentially metabolized more rapidly. These different metabolic characteristics are exemplified by DOTMA and DOTAP; the former is synthesized as ester, the latter as ether.

The aliphatic lipid chain may be saturated (DMRI) or contain double bonds (DOTAP, DOSPA). *In vivo*, dialkyl chains, with a length of 12 to 18 carbon atoms each, seem to promote the best gene transfection. A substitution of the alkyl chains with cholesterol, as in DC-chol, shows further advantages in the treatment of cystic fibrosis. Cholesterol structures have strong affinities to bronchoepithelial cells and interact less with plasma proteins.

Positively charged liposomes loaded with negatively charged DNA must maintain an overall positive charge in order to approach and contact target cells that are normally negatively charged. Liposomes that have been overloaded with DNA and have thus received a negative total charge exhibit low endocytosis rates and enhanced metabolic degradation. Proper selection of the cationic lipids and the lipid-to-DNA ratio are decisive for the rate of complexation and the colloidal structure of the product. Finally, conformations may change in time, a process also referred to as ''aging'' of the DNA/lipid complex.

Recent studies show that intracellular stability of the lipid/DNA complex and the necessary dissociation of the DNA molecule from its vector depend both on the pKs of the chosen lipids and on the pH of the product. Safinya et al. describe how not only the main cationic lipid but the helper lipids as well are influenced by the physical characteristics of the resulting lipid phase. For instance, when formulating DOTAP liposomes with DOPC, lamellar structures are achieved. However, when exchanging DOPC for DOPE as helper lipid, inverse hexagonal micelles are produced. One may speculate whether different lipid phase characteristics lead to defined biopharmaceutical variations.

Cationic liposomes have also been intensively investigated *in vivo*. In combination with neutral helper lipids, they appear to be well tolerated even at high concentrations; they are neither immunogenic nor do they induce toxic side effects. This applies to different routes of application such as intravenous, pulmonary, or nasal, none of which have been described as being significantly unpleasant by the recipient patients. Nevertheless, cationic liposomes also pose a number of problems such as high serum protein binding and extremely rapid metabolic degradation in the liver.

Liposomes are generally the most efficient at a diameter ranging from 400 to 500 nm. Larger particles are almost completely removed from the circulation by cells of the mononuclear phagocytes system of liver and lung and therefore do not reach other target areas. Pegylation is one means of improving pharmacokinetics. However, the useful extent of pegylation is restricted as further reduction of the zeta potential at the surface of the liposomes correlates with their reduced cellular uptake.

Low transfection rates are a further problem. Reasons are – among others – insufficient lysosomal release of the therapeutic DNA from its carrier and/or its rapid enzymatic degradation within the lysosome or in the cytosol. The DNA that was integrated in the liposomes must be released to become effective (see Fig. 5). Studies on microinjections of lipid/DNA complexes directly into the nucleus clearly show reduced transfection rates. As the nuclear pores have mean diameters of only 25 to 50 nm and passage for macromolecules is further controlled by the nuclear pore complex, passive diffusion into the karyosol is limited to particle sizes below 45 kDa. Conventional recombinant plasmids normally have a

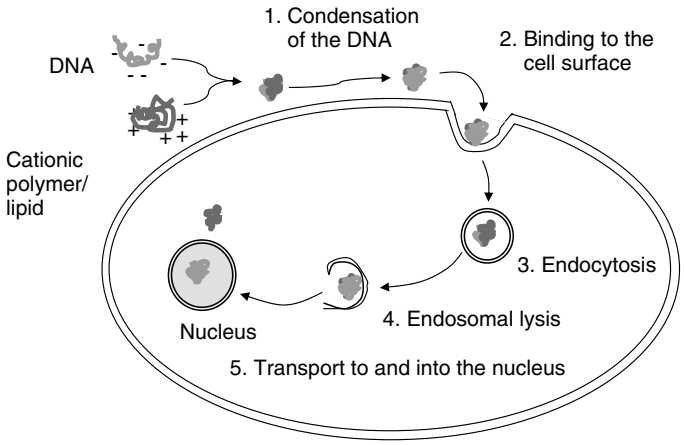

Fig. 5 Uptake, transport, and release of DNA in particulate gene transfer systems.

molecular weight ranging from 50 to 100 kDa and therefore require active transport into the nucleus.

Admission of plasmid DNA into the karyosol is steered by nuclear localization sequences, which are assisted by importin-beta, guanin-nucleotide-binding protein (Ran) and nuclear transport factor (NTF). In the karyosol, the therapeutic DNA is transcribed by RNA polymerases into mRNA, which is transported back into the cytosol where it attaches to ribosomes for translation into protein. In order to improve its transport into the nucleus, the therapeutic DNA may be coupled to such nucleus localizing sequences. The latter can be found naturally in certain viruses, which have developed this strategy for a most efficient nuclear invasion. For example, Rudolph et al. coupled DNA with short TAT sequences taken from the arginine-rich motif of the HIV-1-TAT protein and achieved significant enhancement of transfection. Of the 101 amino acid–long HIV-TAT sequence, they synthesized a 12 amino acid–long oligopeptide, bound it to polyarginine and thus achieved 390-fold enhanced transfection rates.

Unsatisfactory transfection rates and low cell or organ specificity also initiated the development of simple liposomes to virosomes or immunoliposomes. Virosomes are liposomes that contain viral proteins or fusiogenic peptides for enhanced DNA release from the endosome and for generally improved gene-transfection rates. Immunoliposomes are characterized by target-specific monoclonal antibodies bound to their surface. These were first developed in the 1980s for tumor-specific delivery of liposome-entrapped drugs and have since been modified for gene therapy.

3.2.2 Polymer Particles (Polyplex)

A further class of synthetic gene vectors that has received attention in past years is cationic polymers, which condense and package DNA with high efficiency. Polymerized or oligomerized branched or nonbranched amino acid chains composed of lysine or arginine are common. Polyethyleneimine, however, developed in 1995 by Boussif and already used for gene-transfection experiments *in vitro*

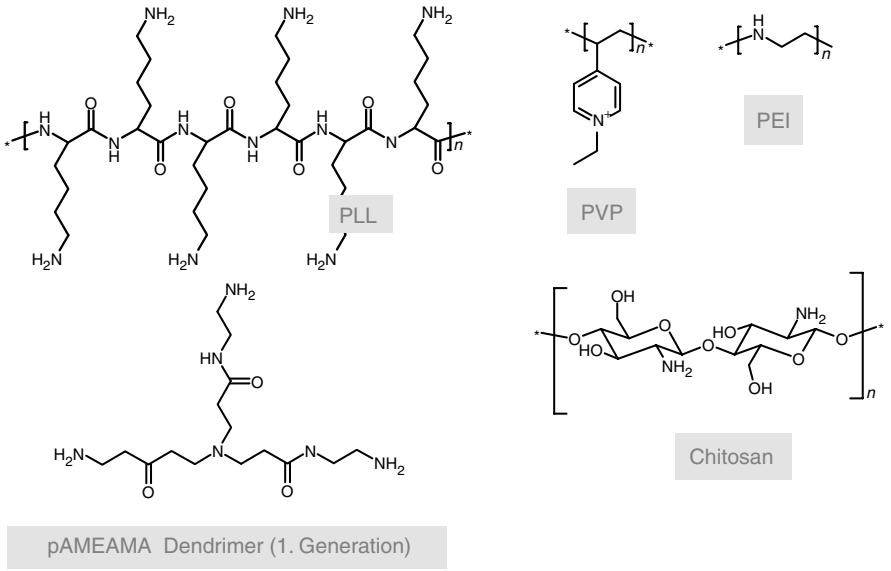

Fig. 6 Chemical structures of cationic polymers.

as well as *in vivo*, appears to be the most promising cationic polymer at the moment (see Fig. 6). Basically, cationic polymer gene transfer systems reveal the same pharmaceutical problems and intracellular barriers as described above for cationic liposomes.

3.2.3 Poly-L-Lysine (PLL) and Poly-L-Arginine (PLA)

Poly-L-lysine (PLL) has already been intensively used as polymeric gene transfer system. It is synthesized by polymerization of the *N*-carboxyanhydrid of lysine. Arginine is polymerized in a similar manner. PLL/DNA complexes are produced by dissolving both components in aqueous media and precipitating the particulate complexes. These particles, which normally range from 400 to 500 nm, are capable of transporting nucleic acids ranging from short molecules to large artificial yeast chromosomes. The first *in vivo* studies, however, revealed substantial toxicity combined with low DNA-transfection efficiency. Different chemical modifications and variations in particle size were then tested. Toxicity is substantially reduced by coating the particles with PEG derivatives, and the transfection rate is enhanced by attaching ligands such as transferrin, folate, or target-specific monoclonal antibodies. Interestingly, pegylation also achieved significant reduction in unwanted hepatic metabolization of the particles.

Apart from lysine, polymers of other cationic amino acids such as arginine and histidine were also investigated. Conjugation of histidine to ε-L-histidine enabled the development of highly interesting PLH/DNA complexes characterized by high transfection rates. One explanation for the elevated transfection efficiency may be that the highly protonated histidine structure that develops in the generally acidic (pH 6) endosomal environment may cause rapid destruction of the endosomal membrane and thus an enhanced

release of the therapeutic DNA into the cytosol.

3.2.4 Polyethyleneimine (PEI)

Linear or branched polyethyleneimines generally range in size from 1.8 to 800 kDa. They are synthesized by cationic polymerization. Starting from 2-substituted-2-oxazoline-monomers, linear polyethyleneimine (PEI) with a mean molecular weight of 22 kDa A, also known as ExGEn 500, are produced by hydrolysis. PEI/DNA complexes have already been used in many *in vivo* studies in animals following iv injection; clinical studies, however, have not been reported to date. PEI/DNA complexes have repeatedly revealed very high transfection efficacy. One advantage of PEI/DNA complexes over lipoplex or PLL particles is their intrinsic buffer capacity at lysosomal pH, leading, as described above for PLL particles, to rapid destruction of the lysosomal membrane and DNA release. This effect, also termed *proton sponge*, is brought about by the chemical structure of PEI. Polymerization produces particles with primary amines at the surface and secondary as well as tertiary amines in the interior. This causes a shift in pKa from 6.9 to 3.9. The strong protonation at a pH below 6 induces an osmotic gradient across the endosomal membrane, resulting in an influx of water, swelling, and, finally, disruption of the endosome with release of the PEI/DNA particles into the cytosol.

Though the literature reveals some discrepancies, there seems to exist an inverse relationship between the molecular weight of the PEI particles and their transfection efficiency. The interesting physicochemical characteristics of PEI-based gene transfer systems encouraged their further development, for example, to dendrimers (see below). In direct comparison, linear PEI complexes (e.g. PEI 22) seem to possess better transfection characteristics than branched ones (e.g. PEI 25). One explanation may be a premature dissociation and subsequent degradation of the DNA molecule.

Clinical trials with PEI complexes as gene transfer systems could so far not be undertaken because of their frequently intolerable general toxicity. Depending on the chemical structure, the lethal dose for mice ranges from 40 to 100 mg kg^{-1} body weight. The main problem lies in the strong interaction between PEI complexes and erythrocytes, leading to their aggregation and the danger of emboli. Pegylation of the PEI complexes may only partially help solve the problem, as a high degree of pegylation generally reduces particle uptake and thus transfection efficacy [77].

3.2.5 Dendrimers

The name ''dendrimer'' refers to the star- or tree-shaped, branched structures of this relatively new class of cationic gene transfer systems. They are frequently synthesized from polyamidoamines with special chemical or physical features. Probably best known are the ''starburst'' – dendrimers with particle sizes ranging from 5 to 100 nm. These particles reveal a highly regular branches ''dendritic'' symmetry. Starburst dendrimers are three-dimensional oligomeric or polymeric compounds, which, initiated from small molecules as nuclei, are built layer by layer (''generations'') by repeated chemical reaction cycles. This allows an exquisite steering of the final size, three-dimensional form, and surface chemistry of a starburst polymer by the individual selection of

components and binding procedures for each generation.

The physical and chemical characteristics of dendrimers are mainly the result of number and type or amine functions on the particle surface, but the secondary and tertiary amines in the inside also affect their biological features. Despite their high molecular weights, dendrimers are soluble in water. They complex DNA with great efficiency, thus giving excellent vehicles for gene transfer. Their high transfer efficiency, however, is probably less due to high DNA adsorption rates and more to protonation of the amine functions after endosomal uptake. As described above for the PEI complexes, this induces an osmotic gradient, leading to osmotic lysis of the organelle and enhanced release of the complex into the cytosol. Dendrimer/DNA complexes have proven their gene transfer efficacy in *in vivo* studies. However, as already exhibited by the PEI complexes, they show strong, undesired interaction with erythrocytes, causing hemolysis. Again, the free primary amine functions on the particle surface are held responsible. Depending on the type of dendrimer and the target cell, cationic dendrimers also reveal general cytotoxicity at concentrations ranging from 50 to 300 $\mu g\,mL^{-1}$. On the other hand, no dendrimer has to date been reported to induce tumors or to substantially affect the immune system.

3.2.6 Chitosan

Chitosan is a fiber produced by hydrolyzing chitin, mostly from crustaceans. Owing to its free amine functions, chitosan may also be protonated (pKa = 5.6). In *in vitro* studies with Hela cells, chitosan/DNA complexes showed gene-transfection potency similar to that reported for PEI/DNA complexes. Plain chitosan, however, is almost insoluble in water at neutral pH (but soluble at acidic pH). For this reason, tri-methylated, quaternary chitosan derivatives have been produced that are sufficiently soluble under physiological conditions and easily complex DNA molecules. In *in vitro* experiments with COS-1 and CaCo-2 cells, these innovative chitosan derivatives proved superior to nontreated chitosan polymer, particularly as they showed no unspecific cytotoxicity.

3.2.7 Poly(2-Dimethylamino) Ethylmethacrylate

Methacrylate polymers are used in pharmaceutical technology for microencapsulation. They are synthesized by polymerization of monomeric dimethylaminoacrylic acid to poly(2-dimethylamino)ethylmethacrylate (pDMAEMA), which is both simple and cheap. Their low general toxicity makes these polymers interesting also as gene transfer vehicles. In *in vitro* experiments with OVCAR-3 and COS-7 cells, some pDMAEMA/DNA particles showed high transfection rates. This proved to be highly dependent on their size and charge. In HEPES-buffer (pH 7.4), pDMAEMA particles exhibit a positive zeta potential of around 25 mV and an average size of 100 to 200 nm. Following endosomal uptake, again the outer primary amine functions are protonated, leading to osmotic lysis of the endosome and release of the pDMAEMA/DNA particles into the cytosol.

Studies on DNA absorption onto pDMAEMA particles show that linear DNA (e.g. antisense oligonucleotides) is adsorbed more strongly than circular plasmid DNA. However, this stronger adsorption has a negative influence on the gene transfer efficiency, as the DNA molecule is less likely to dissociate from

the pDMAEMA particles in the cytosol. For this reason, circular DNA is preferred. As expected, DNA that is adsorbed to pDMAEMA is protected from degradation by DNAse I.

4 Perspectives

The nonviral gene-transfection systems introduced in this review bear significant advantages over the viral systems, but have serious drawbacks as well. One fact in favor is that many such systems are already well established in classical areas of pharmaceutical technology. Their production methods have already been optimized and safety aspect investigated in detail. Simple transfer of knowledge may substantially reduce developing costs. Nonviral systems are noninfectious. They allow significantly higher DNA-loading rates than viral systems, which reach their limits around 30 kb (Herpes virus). Nonviral systems are only weakly immunogenic and therefore allow – in stark contrast to viral systems – multiple application.

The main drawback of nonviral systems is that they normally only lead to transient expression of the therapeutic gene as it is not permanently integrated into the host genome. In consequence, the therapeutic gene transfer must be regularly repeated, possibly over a long period of time. Further disadvantages are insufficient cell or tissue specificity and low DNA transfer rates from the cytosol to the nucleus. Taken together, the gene-transfection performances of nonviral systems are even weaker than those of viral systems.

To date, it is still not possible to make a clear decision between viral and nonviral gene transfer systems. Mixed systems, hybrid vectors, which can be envisaged as "de-nucleated" viruses, are in the pipeline. A combination of viral surface proteins and liposomes or the integration of therapeutic DNA into artificial cells or viruses are further innovative ideas for improving somatic gene therapy. Most important is rapid progress on three fields: In cell biology, unspecific and specific intracellular trafficking of macromolecules still raises questions. In biochemistry, further DNA carriers must be brought forward for testing, and pharmaceutical technology must supply improved and cell-/tissue-specific drug delivery systems. Brought together in a rational form, such progress should make somatic gene therapy possible for selected disease forms already in the near future.

Somatic gene therapy might develop into one of the most important therapeutic strategies of the near future. Innate or acquired genetic defects are held responsible for a number of diseases such as hemophilia, cystic fibrosis (mucoviscidosis), adenosine-deaminase deficit and AIDS. Substituting or supplementing malfunctioning or missing genetic information by transiently or permanently inserting the appropriate gene appears to be a plausible therapeutic strategy especially from the patients' point of view. Attempts in gene therapy began in the early 1990s with great expectations that have only partially been met. No disease with a defined genetic background has so far been causally cured by gene therapy. Viral gene transfer systems have caused severe problems that could not be brought under control to date. The death of the 18-year-old Jesse Gelsinger is a tragic evidence for the basic deficits of viral transfection systems. In consequence, attention is now focusing on chemical and physical gene transfer systems.

Keywords

Receptor
Proteins with a recognition function for a vitamin or its derivative, that is, proteins that bind to the vitamin ligand.

Response Element
The characteristic DNA-binding sites for hormones, vitamins, or their active forms.

Transcription
Synthesis of mRNA or mRNA precursor.

Transcription Factor
Direct-acting factors that control transcription by interacting with DNA sites near the target gene.

Vitamer
Derivatives of a vitamin that function as a vitamin.

Vitamins
Accessory factors of diverse chemical structure required for the maintenance and growth of protozoans and metazoans.

Interlocking ligand–receptor systems constitute an intra- and intercellular communication system in which exogenous or endogenous molecules such as vitamins, hormones, cytokines, and foreign macromolecules convey signals through association with membrane structures (i.e. receptors). Sequential interactions between ligands and receptors on membranes of cells or organelles coordinate metabolism within the same and between different cells and organs. Cell communication is regulated by activation events and by processes that limit such activation.

This article presents current information on the ligand (vitamin)-receptor (binding protein) interaction as it applies to vitamins, from the site of enteric absorption to the site of vitamin function. For the absorption and transport of most vitamins, specific proteins, which have a recognition factor incorporated into them, are involved. At the plasma membrane of the cell, a second recognition factor has to function before the vitamin is internalized. Intracellular vitamin-binding proteins and their interaction with cellular systems resulting in the biological action of the vitamins provide the last step in the successive stages of communication. Thus, we have the concept of a ligand (vitamin), an extraorganismic molecule, reacting with a specific protein entity, the receptor, facilitating absorption and transport of the ligand to its site of action with the resultant sequence of physiological events to which we refer as *vitamin function*. The term ''receptor,'' in the context of vitamins, refers to proteins with a recognition function, not to receptors in the traditional pharmacological sense. It includes proteins that bind to the vitamin ligand and function as extracellular or intracellular transporters as well as the smaller number of vitamin-binding nuclear proteins. In the latter case, vitamins might act as small molecular modulators of protein-DNA interaction, a situation analogous to that of some hormones. The designation ''receptors'' for these categories of vitamin-binding proteins appears to be appropriate inasmuch as it connotes a function more than ligand binding.

The transcriptional patterns of selected genes are often altered by external signals that the cell receives. Thus, changes in nutritional supplies can either induce or repress the transcription of specific genes or gene sets. In many cases, the regulation of transcription (up or down) is mediated by alterations in the availability of essential transcription factors or by change in the factors' ability to bind to specific regulatory sequence motifs.

1 Introduction

Vitamins are required by all protozoans and metazoans that have been studied. They do not conform to any single chemical classification. Some vitamins, such as retinol (vitamin A), cholecalciferol (vitamin D), α-tocopherol (vitamin E), and phylloquinone (vitamin K), are lipid soluble; others, such as thiamine (vitamin B_1), riboflavin (vitamin B_2), niacin, pyridoxine (vitamin B_6), panthothenic acid, lipoic acid, biotin, folic acid, cyanocobalamin (vitamin B_{12}), and ascorbic acid (vitamin C), are watersoluble.

While the unlimited availability of vitamins may have permitted the evolutionary loss of the ability of animals to synthesize vitamins, the ability to absorb vitamins from the environment or from digested food is essential. The modes of uptake and intra- and intercellular transport of these two broad categories of vitamins are different based on their solubility characteristics. Lipoprotein binders are implicated in the transport of the lipid-soluble vitamins. Investigators recognized early, among the water-soluble vitamins, the bindings of cyanocobalamin and folate, respectively, to specific proteins. lncreasing evidence has accumulated to indicate that the absorption of many water-soluble vitamins in the gastrointestinal tract is through saturable mechanisms. In addition, the concentrations of many water-soluble vitamins are much higher in the brain than in plasma. This is true of placental transport as well, implicating specific transporters for individual vitamins across the blood-brain and placental barriers, respectively.

Absorption of vitamins by most cells occurs through membrane-associated transport systems, which are present in low concentrations. These receptorlike proteins may consist of an extracellular vitamin-binding domain linked to a transmembrane anchor. The fertilized egg and embryo obtain vitamins from the external environment using cell surface vitamin receptor/transporter proteins. The vitamins are used directly without storage. In contrast, the eggs of birds and reptiles contain both the vitamins and their respective vitamin-binding proteins deposited in the yolk for transport to the oocyte.

The physiological effects of vitamins follow their entry into the cell, and subsequent metabolic transformation and association with specific apoenzymes, resulting in an accentuation of a metabolic pathway. In this respect, vitamins are metabolic initiators. Where the vitamin function is other than as a coenzyme or prosthetic group of an enzyme, its effect is through regulation of cellular protein synthesis. The mechanisms of action of lipid-soluble vitamins are similar to those of the steroid hormones. Water-soluble vitamins such as biotin, ascorbic acid, and vitamin B_6 also seem to have a modulatory influence on cellular protein synthesis acting through similar mechanisms.

2
Vitamin A

2.1
Absorption and Transport

Vitamin A, an essential nutrient in the diet, plays a significant role in diverse physiological processes such as development, differentiation, and vision. Its role in embryogenesis is evident from certain known effects of a deficiency or excess of vitamin A, namely, malformation or teratogenicity. Vitamin A deficiency has profound effects on the immune system, and retinoids seem to affect differentiation, the stimulation of phagocytosis, and the modulation of cytokines and eicosanoids. Several clinical studies have demonstrated beneficial effects of retinoids on skin diseases such as acne, psoriasis, keratodermas, and skin cancers. Retinoids play a role in the development of the central body axis and limbs of vertebrates. High levels of endogenous retinoids are found in proximity to the developing axis in a variety of species. They exert their wide spectrum of biological functions through their ability to regulate gene expression at specific targets. The

term retinoid includes the natural forms of vitamin A as well as synthetic analogues, which may or may not have the biological activity of vitamin A. The natural forms of vitamin A include retinol, retinal, and retinoic acid (RA).

Ingested retinyl esters are hydrolyzed to retinol by the lipases in the intestinal lumen. Retinoid production from carotenoids occurs by oxidative or eccentric cleavage of the central double bond of carotenoids. The transport of retinol across the brush border of enterocyte is the first step in the absorption of vitamin A into the organism. A carrier-mediated mechanism specific for *all-trans*- and 3-dehydroretinol with passive diffusion of the 13-*cis* compound and retinal has been suggested.

In the intestinal mucosal cell, free retinol is esterified and incorporated into chylomicrons for transport. Chylomicron remnants are primarily cleared by liver, although extrahepatic uptake occurs in other tissues such as bone marrow and spleen. In the liver, retinyl esters from chylomicron remnants are taken up by the parenchymal cells, hydrolyzed to retinol, and bound to retinol-binding protein (RBP). This series of events is followed by paracrine transfer of retinol from hepatocytes to the perisinusoidal stellate cells for storage. Retinol is mobilized from the stellate cells bound to RBP and released into circulation. Retinol-RBP complex binds to transthyretin in the plasma compartment and thus, thyroid hormone and RBP-retinol complex are transported together. Retinol reaches target cells bound to the RBP transport protein. Transport of retinol across cell membrane follows receptor-mediated endocytosis, internalization, degradation of RBP, and liberation of retinol within the cells.

2.2 Retinoid Receptors: Cellular Binding Proteins

Retinol is oxidized to RA and other compounds such as 9-*cis* RA. Within the cell, retinol and RA, respectively, bind to ligand-specific cellular binding proteins: cellular retinol-binding protein (CRBP) and cellular retinoic acid–binding protein (CRABP). These proteins belong to the superfamily of fatty acid–binding proteins. CRABP-I, CRABP-II, and CRBP have been cloned from human and rat sources. CRABP-I and CRABP-II differ in their tissue distribution and affinity for RA. CRABP-II, the major form expressed in human epidermis, is upregulated by RA during differentiation. The promoter of the CRABP-II gene has been shown to have an RA-response element. Retinoid translocation into target cells is regulated by binding to specific high-affinity cellular receptors.

2.3 Nuclear Retinoic Acid Receptors

Almost all the biological activity of vitamin A is due to the ability of its metabolite RA (all-*trans* RA, or atRA) to regulate gene expression, a receptor-mediated event. By analogy with lipid-soluble hormones, the RA receptor is a nuclear-acting transcription factor. These receptors belong to a highly conserved superfamily of proteins with similar structural and functional domains.

Following the isolation of the human RA receptor (hRAR$_\alpha$), it was shown that its DNA-binding and ligand-binding domain (LBD) was highly conserved with other members of the nuclear receptor family. There are three subtypes of RAR (RAR$_\alpha$, RAP$_\beta$, RAR$_\gamma$) in various species, and their LBDs are highly conserved. A second

class of retinoid-responsive transcription factor – the human retinoid X receptor ($hRXR_\alpha$), isolated later – had a sequence dissimilar to that of RAR, although both had the ability to respond to RA. RAR and RXR significantly differ in terms of their binding to tritiated all-*trans* RA, leading to the suggestion that a metabolite of RA might be the ligand for RXR. An isomer of RA, 9-*cis*-retinoic acid (9cRA) was identified as this RA metabolite, which was 40 times more potent than RA in transacting RXR. It is also active with RAR. RXRs bind and respond to 9cRA, and they are able to activate target organs in the absence of RAR gene products.

The superfamily of RARs and RXRs share a common structure consisting of functionally distinct domains. The N-terminal A/B domain, which is the least homogenous between the receptors, participates in ligand-independent transactivation function (AF-1). AF-1 synergizes with the AF-2 function of the E domain. Domain C is very highly conserved and is involved in DNA binding. This domain also contains a pair of zinc-binding motifs (zinc fingers) that make contact with the major groove of the DNA. Domain D is the hinge region and is involved in determining the receptor's response as well as binding with corepressors. Domain E, which is also highly conserved, is the LBD and also has the dimerization motifs and ligand-dependent transactivation activity. Domain F is the C-terminal end of RARs and is absent in RXRs.

The presence of two receptor systems suggests that target genes – responsive to each receptor system – are distinct. RA seems to modulate positively the expressions of CRBP and CRABP. CRBP binds retinol with high affinity and is involved in its esterification to retinyl esters. Similarly, CRABP binds to RA and seems to be involved in the oxidative inactivation of RA. An additional regulatory step is the isomerization of RA to 9cRA.

Gene expression is modulated by members of the nuclear receptor superfamily by binding as homo- or heterodimers to specific DNA sequences, the hormone response elements (HREs). Sequence analysis of the response elements activated by RARs and RXRs indicates that similar to the HREs for other nonsteroid members of the nuclear receptor family, the retinoid response elements consist of a minimal half-site consensus sequence (AGGT-CA) configured into a variety of structured motifs, including direct repeats and palindromes. Unlike the heterogeneity of RAREs, RXREs are exclusively of the DR-1 type (a direct repeat separated by one nucleotide). Most of the RXREs discovered seem to occur in promoters of genes involved in vitamin A and lipid metabolism, suggesting a role for RXRs in several distinct but coregulated metabolic pathways. RXR has a role both as a ligand-dependent transcription factor (as homodimer) and as a partner (as heterodimer) to several nuclear receptors. It is interesting that 9cRA, which promotes RXR homodimer formation, is derived from RA, which activates only the RAR heterodimer. RAR-RXR heterodimer can repress RXR homodimer function. Thus, under limiting concentration of RXR, the target genes for RAR will be preferentially activated. When the concentration of 9cRA is high, the RXR homodimer is stabilized. Also, the RAR-RXR heterodimer has a higher affinity for DNA than the RXR homodimer, and might compete more favorably for binding to RXREs. A combinatorial regulation of receptor expression and ligand availability seems to increase the diversity of the signaling pathways. Experiments using knockout mice and cultured cells indicate

that each subtype of RAR and RXR has a distinct effect on target gene expression. For example, RXR_α seems to be involved in determining the life span of hepatocytes. In skin, RXR_α plays an important role in postnatal skin maturation and in hair follicle growth. It is also important in adipogenesis. The cellular retinoid-binding proteins also play a significant role in the retinoid-signaling pathway by regulating the intracellular transport and metabolism of retinoids.

3 Vitamin D

3.1 General

Vitamin D is grouped along with vitamins A, E, and K as one of the fat-soluble vitamins; it is formed in the skin of mammals by ultraviolet irradiation, upon conversion of the precursor 7-dehydrocholesterol to cholecalciferol (vitamin D_3). Its physiological function is related to whole-body calcium homeostasis, inasmuch as a deficiency of this vitamin leads to rickets in children and osteomalacia in adults. Ultraviolet irradiation prevents or heals bone disorders induced by a deficiency.

In the vitamin-deficient state, the absorptive capacity of small intestine for calcium is decreased. One of the physiological functions of vitamin D is the maintenance of a constant extracellular concentration of calcium acting in concert with parathyroid hormone and possibly, calcitonin, thus preventing hypo- or hypercalcemia. Cholecalciferol is converted to 1,25-dihydroxycholecalciferol, the biologically active form of the vitamin. This is a two-step process. The product of the initial hydroxylation, which takes place in the liver, is 25-hydroxycholecalciferol ($25[OH]D_3$). This is secreted into blood, where it circulates bound to a specific vitamin D–binding globulin. The final step takes place in the kidney through a 1-hydroxylation reaction, and the product 1,25-dihydroxycholecalciferol ($1,25[OH]_2D_3$) is the active form of vitamin D. In addition to the role in calcium homeostasis, vitamin D is now recognized to be involved in regulating growth and differentiation of a variety of cell types.

3.2 Vitamin D Receptors

Most of the biological actions of vitamin D occur through a $1,25(OH)_2D_3$-mediated regulation of the transcription of specific genes in target tissues. This active form of vitamin D binds to a specific nuclear receptor (VDR), which belongs to the superfamily of steroid, thyroid hormone (TR), and vitamin A (RAR) receptors. Ligand binding is necessary for the high-affinity binding of VDR to specific vitamin D DNA response elements (VDREs) located in the promoter region of the target genes. This is similar to the binding of TR and RAR to their cognate receptors, since TR, RAR, and VDR belong to the same subfamily of receptors. Interaction between the ligand-receptor complex with VDREs modulates the transcription of genes specific for the biological action of vitamin D.

Osteoporosis is an age-related loss of bone mineral. Bone mineral mass is affected by both genetic and nongenetic factors. A correlation between alleles of VDR and bone density has been identified. In bone, $1,25(OH)_2D_3$ recruits bone-resorbing osteoclasts from hematopoietic precursor cells. It also modulates, through VDR, the bone-forming osteoblasts. Restriction fragment length polymorphism

analysis indicates the presence of two alleles of VDR. In a study of 250 Caucasian twins and a second study of 311 unrelated healthy women, it was shown that common allelic variants of the VDR gene can be used to predict differences in bone mineral density, hence susceptibility to osteoporosis. The magnitude of the VDR allele difference between the two genotypes could mean a 10-year difference for postmenopausal women in the onset of vertebrate fractures.

3.3 Vitamin D Responsive Genes

Vitamin D acting through $1,25(OH)_2D_3$ enhances intestinal calcium absorption by stimulating transcellular calcium transport. The stimulation is achieved by both nongenomic and genomic actions of vitamin D. One such genomic action is the induction of the calcium-binding protein calbindin-D, which could facilitate the diffusion of calcium from the brush border to the basolateral membrane of the enterocyte. Other vitamin D–responsive calcium-binding proteins such as Ca^{2+}-ATPase and the integral membrane calcium-binding protein have been characterized. A list of 51 gene products that are reported to be $1,2(OH)D_3$ sensitive in terms of altered mRNA levels has been assembled. This list includes genes associated in the mineral homeostasis, vitamin D metabolism, cell differentiation and proliferation, bone matrix protein, extracellular matrix proteins, oncogenes, chromosomal proteins, growth factors, signal transduction proteins, peptide hormones, and energy metabolism. In clonal rat pituitary tumor (GH) cells in culture, $1,25(OH)_2D_3$ selectively increased prolactin production, prolactin mRNA, and agonist-induced prolactin release. In primary cultures of rat anterior pituitary cells, $1,25(OH)_2D_3$ selectively enhanced TRH-induced thyrotropin (TSH) release. In studies using primary dispersed and clonal pituitary cells, $1,25(OH)_2D_3$ has been shown to stimulate pituitary hormone production and agonist-induced hormone release. There was an upregulation of thyrotropin-releasing hormone (TRH)-binding sites as shown by an increase in TRH receptor–specific mRNA. Incubation of pituitary GH4C1 cells with vitamin D markedly reduces the response of rat growth hormone (GH) mRNA to thyroid hormone (T3) and RA. Rat GH gene expression is stimulated by T3. The 5′-flanking region of rat GE gene contains a TRE that mediates T3 stimulation. RA also increases the transcription of the GH gene. The RA response was mapped to the same sequence that mediated regulation by T3, indicating that TRE also functioned as RARE. Vitamin D inhibited the T3 and RA transactivation of the rat GH gene by interference with the common response element present in the 5′-flanking region of the gene. Vitamin D also inhibited the activation of other T3- and RA-responsive promoters. The formation of TR-VDR and RAR-VDR heterodimers, which have low affinities for these response elements, can inhibit binding of more active heterodimers with RXR. These results highlight the repressive role of VDR and indicate that the biological response to T3 and RA could be selectively inhibited in cells that contain receptors for vitamin D.

3.4 Vitamin D Target Cells

It has been established that many tissues other than the kidney convert $25(OH)D_3$, to $1,25(OH)_2D_3$ although it is not released into the blood stream. They seem to act in

an autocrine or paracrine fashion by binding locally to VDR and affecting cell proliferation, differentiation or apoptosis locally. Such target tissues include the central nervous system, skin and hair follicles, and immune and endocrine systems. Vitamin D modulates this growth regulatory pathways of many normal and transformed cells. Treatment of cells with $1,25(OH)_2D_3$ induces antiproliferative and/or proapoptotic effects or differentiation.

In many transformed cells including breast, prostrate, and leukemic cells, $1,25(OH)_2D_3$ induces cell cycle arrest in Go/Gi. This arrest is associated with the inhibition of cyclin-dependent kinases. In colon cancer cells, the VDR ligand complex interacts with protein phosphatases, which inactivate p70S6 kinase that is essential for Gi/S phase transition.

$1,25(OH)_2D_3$ induces apoptosis in cell lines derived from breast cancer, prostrate cancer, myeloma, retinoblastoma, neuroblastoma, and glioma. Its actions are also synergistic with other triggers of apoptosis. The sensitivity to $1,25(OH)_2D_3$-mediated apoptosis is related to the expression as well as the subcellular localization of the BCl-2 family of pro- and antiapoptotic proteins.

Vitamin D is a regulator of proliferation, differentiation, and apoptosis of cells of different lineage, and growth inhibition of tumors in response to vitamin D or its analogs has much therapeutic potential.

4
Vitamin E

4.1
General

"Vitamin E" is the generic term for two groups of naturally occurring fat-soluble compounds, tocopherols and tocotrienols. The members of each group are designated α, β, γ, or δ, depending on the numbers and position of the methyl groups attached to the chroman nucleus. The most biologically active of these compounds is α-tocopherol, which functions as an antioxidant in membranes to prevent lipid peroxidation. The intake of γ-tocopherol is two to four times that of α-tocopherol because of its prevalence in many diets. Both α- and γ-tocopherol are absorbed equally by the intestine and transferred to the bloodstream by chylomicrons, which are taken up by the liver. However, α-tocopherol is present in human plasma at a concentration many times higher than that of γ-tocopherol, suggesting a mechanism of discrimination in the liver. This accounts for the generally recognized lower biopotency of γ-tocopherol.

It has been suggested that specific membrane tocopherol-binding proteins are involved in peripheral cellular uptake of tocopherol. A 46-KDa tocopherol associated protein (TAP) with substantial sequence homology to α-TPP is expressed in most tissues with high levels in liver, brain, and prostate.

α-TTP has been purified and characterized and shown to consist of two closely similar isoforms of molecular mass 30.5 KDa with high specificity for binding to the α isomer of tocopherol. This protein is present in rat liver and absent in other rat tissues such as heart, spleen, testes, and lung. The α-TTP gene was sequenced and shown to have homology with bovine and human 11-*cis*-retinaldehyde-binding protein of the retina. It has been suggested that the liver α-TTP, in view of its specificity for the α isomer, discriminates against the γ-tocopherol, which is excreted into the bile. The α-tocopherol is transferred to

very low density lipoprotein (VLDL). A familial vitamin E deficiency, which results in spinocerebellar lesions with progressive development of ataxia and areflexia, has been described. Vitamin E is almost absent in the plasma of these patients, although lipid absorption, pancreatic, and intestinal functions, as well as lipoprotein transport, were normal. The only abnormality was in the transfer of α-tocopherol into VLDL, with the suggestion of an abnormality in the α-TTP of these patients.

4.2 Transport of *d*-Tocopherol

There does not seem to be a special carrier for Vitamin E in circulation. It is incorporated into lipoprotein particles in a nonspecific manner. In liver cells, tocopherol is transferred from chylomicron remnants to cytosolic α-tocopherol transfer protein (α-TTP), which mediates its transfer to rough endoplasmic reticulum and the golgi, the site of VLDL synthesis. α-TTP is stereo specific so that only α-tocopherol is incorporated into the nascent VLDL particles.

4.3 Binding of α-Tocopherol to Erythrocyte Membranes

α-Tocopherol has been shown to decrease the hemolytic damage to erythrocytes by oxidative stress. Since the disruption of erythrocyte membrane is the likely locus of oxidative stress, and since α-tocopherol has been proposed to have a role in membrane structure and function, it is possible that α-tocopherol-binding proteins or receptors are present on these membranes. Red blood cell membranes have specific binding sites for α-tocopherol. These binding sites have the properties expected of membrane receptors (i.e. specificity, saturability, moderate affinity, time-, protein-, and temperature-dependence, reversibility). The binding of α-tocopherol to the membrane is highly specific, inasmuch as only γ-tocopherol competes with α-tocopherol for binding to the membrane.

4.4 α-Tocopherol and Cell Signaling

In terms of function, the antioxidant properties of α-tocopherol have received most attention. The nonantioxidant cell-signaling roles for α-tocopherol have now been recognized. Smooth muscle cell proliferation and protein kinase C (PKC) activity are inhibited by the α isoform, whereas other isomers and related chemicals with similar antioxidant properties are inactive. The inhibition of PKC by α-tocopherol is seen in other cell types as well. The inhibition of PKC by α-tocopherol is related to its activation of a protein phosphatase 2A. This phosphatase dephosphorylates PKC-α and inhibits its activity.

4.5 α-Tocopherol and Atherogenesis

Atherosclerosis, a major cause of cardiovascular disease, is an inflammatory process. Proinflammatory mediators such as prostaglandin E (PGE_2) and thromboxane A_2 (TXA_2) are important in the development of atherosclerosis. The age-associated increase in PGE_2 is the result of increased cyclooxygenase activity (COX), which converts arachidonic acid into PGE_2, the precursor of thromboxane and eicosanoids. The activity of the COX-2 isoform is regulated by growth factors, tumor promoters, cytokines, glucocorticoids, and lipopolysaccharides. Increased arachidonic acid metabolism by COX stimulates

cell proliferation through activation of PKC. α-tocopherol has been shown to decrease PGE_2 production through a decrease in COX activity, a posttranslational effect of vitamin E. Other homologs of vitamin E are also effective to different extents in inhibiting COX activity, although this difference is not correlated to their antioxidant potency. A direct inhibition of COX-2 by the tocopherols is indicated.

The expression of a spectrum of genes involved in the inflammatory and proliferative response of cells is controlled by the nuclear factor kappa B (NF-kB). This is present as a dimer in an inactive form while attached to an inhibitory protein. Activation by inflammatory or proliferative cytokines, reactive oxygen species, or bacterial wall components is followed by phosphorylation and proteolytic removal of the inhibitory component. The active NF-kB transfers to the nucleus where it interacts with the regulatory kappa B elements in the promoter and enhancer regions, thus regulating transcription of inducible genes. Incubation of human Jurkat T-cells with α-tocopheryl acetate or succinate resulted in a dose-dependent inhibition of NF-kB activation. Macrophage cell line THP-1 pretreated with α-tocopherol and then activated with lipopolysaccharide also showed a similar inhibition of NF-kB activation, thus indicating that α-tocopherol by itself inhibits NF-kB activation and/or translocation to the nucleus. Activated NF-kB has been identified in atherosclerotic plaques. It has been shown to regulate genes involved in development of atherosclerosis. NF-kB is also regulated by cellular redox status. Vitamin E, primarily the α-tocopherol isoform, thus regulates NF-kB activity either directly by modulating the key steps in the pathway of activation of NF-kB or indirectly by altering the intracellular redox status.

α-tocopherol has been shown to be involved in the expression of α-tropomyosin, cell adhesion proteins, and scavenger receptors. Soon after balloon injury, smooth muscle cells that migrate to the intima have decreased amounts of tropomyosin, which returns to normal levels later. α-tocopherol, but not the β-isomer, has been shown to induce tropomyosin in rat smooth muscle cells and thus, decrease the contractility of smooth muscle cells. Activation of endothelial cells results in the release of vascular cytokines, which induce the expression of cell surface adhesion molecules such as VCAM-1 and ICAM-1, which are necessary for the recruitment of neutrophils. The expression of the adhesion molecules is dependent on the activation of NF-kB. Treatment of endothelial cells with oxidized LDL transcriptionally increases the levels of VCAM1. Pretreatment of endothelial cells with α-tocopherol inhibited, dose-dependently, the oxidized LDL-induced expression of adhesion molecules, indicating that the antiatherogenic action of vitamin E might be related to its downregulation of cell adhesion molecules. CD36 is a scavenger receptor that transports oxidized LDL into the cytosol. α-tocopherol has been shown to downregulate the expression of CD36 and thus to inhibit the transport of oxidized LDL with resultant reduction in the formation of foam cells.

5 Ascorbic Acid

5.1 General

The antioxidant activity of ascorbic acid in all living organisms is the best-recognized function of this vitamin. Vitamin C and

vitamin E eliminate cytotoxic free radicals by redox cycling. Ascorbate and vitamin E function at physiological pH as donors of single hydrogen atoms, enabling these vitamins to react efficiently with free radicals and not with molecular oxygen. Ascorbic acid is a cofactor in the synthesis of collagen and proteoglycans, the two major constituents of the extracellular matrix. The synthesis of collagen by fibroblasts involves enzymes that hydroxylate lysine and proline in the procollagen molecule. Ascorbate has also been shown to be a cofactor of the enzyme peptidylglycine α–aminating monooxygenase, which amidates neuroendocrine peptides. The concentration of ascorbate in brain and endocrine glands is high. In addition, the presence of a complex system to regulate its intracellular and intravesicular availability indicates a critical role for ascorbate in these structures. Ascorbate is released from brain and endocrine tissues and can affect cellular functions by acting on plasma membrane receptors.

5.2 Ascorbic Acid Transport and Transporters

Most animals, exception primates and guinea pig, synthesize ascorbate from glucose in the liver. Hence, intestinal transport of ascorbate has special significance in primates and the guinea pig as the source of ascorbic acid. Vitamin C (L-dihydroascorbic acid) is a stereospecific compound. The L stereoisomer is the biologically active compound: the D form has only one-twentieth its biological activity. Once inside the cell, the D epimer (D-isoascorbic acid) is as efficient as the L form, at least in one aspect of its biological action, that of collagen synthesis. Thus, the cell membrane is the primary site of stereoselectivity. The carrier proteins in the cell membrane are stereospecific in terms of binding and transporting the vitamin across the cell membrane to its intracellular site of action.

Dietary vitamin C is a mixture of ascorbate and dehydroascorbic acid. Both compounds are antiscorbutic. Dehydroascorbic acid, the oxidized form, is not an acid, does not ionize, and is more hydrophobic than ascorbic acid. A net transepithelial absorption and transport of this form was shown in everted and noneverted loops of guinea pig intestine. The vitamer reaching the serosal side is in the reduced state. Such simultaneous absorption and reduction is characteristic of species that do not synthesize ascorbic acid. On the contrary, there is no net absorption of dehydroascorbic acid in the intestine of the rat, a species capable of synthesizing ascorbic acid in the liver.

In contrast to the intestinal transport of ascorbate by various mammalian species, renal handling of this substance seems to be very similar. Ascorbate is filtered in the glomerulus and is reabsorbed in the proximal convoluted tubule. The uptake was saturable, inhibited by D-iso-ascorbate and dehydroascorbic acid, temperature dependent, and susceptible to metabolic inhibitors. Ascorbate is reabsorbed by the kidney in a sodium-dependent active process not shared by other acid anions.

When incubated in a medium containing physiological amounts of ascorbic acid, human neutrophils accumulate millimolar amounts using two transporters. The high-affinity transporter with an apparent Michaelis constant K_m of 2 to 5 μM is saturated at normal extracellular ascorbic acid concentrations. The low-affinity transporter has an apparent K_m of 6 to 7 mM, and is in the linear phase of uptake at normal extracellular concentrations of ascorbic acid. The intracellular concentration of ascorbic acid in neutrophils, which

is dependent on the extracellular concentration, functions to preserve neutrophil integrity. It also protects host tissue by inactivating free radicals and oxidants produced by the phagolysosomes.

Ascorbic acid is essential for the formation of bone by osteoblasts. *In vivo* studies indicate that administered ^{14}C-labeled ascorbic acid accumulates preferentially at sites of active osteogenesis. *In vitro* studies have shown that ascorbic acid is essential for the formation of mineralized extracellular matrix by rabbit long bone cells and rat calvaria cells. Two cell systems, a clonal osteoblastlike cell line ROS 17/2.8 and a primary culture of rat calvaria cells, have been used as *in vitro* osteoblast models. Both cell cultures accumulate ascorbate. Consistent with a carrier-mediated mechanism, transport was saturable, temperature dependent, stereo selective, and dependent on external Na^+ concentration. Ascorbate taken up is rapidly compartmentalized in the lumen of the rough endoplasmic reticulum and is bound or metabolized to a nonpermeant species, in keeping with its putative role as a cofactor in the posttranslational modification of procollagen. Using the clonal osteosarcoma cell line UMR-106, it was shown that transforming growth factor β (TGFB), an important modulator of cell proliferation and differentiation, stimulates carrier-mediated ascorbate transport. Stimulation of ascorbate uptake was seen at TGFB concentrations similar to that required for stimulating the production of collagenous extracellular matrix. The enhancement by TGFB of ascorbate uptake was associated with an increase in the apparent V_{max} of the rate of transport without any change in the affinity of the transporter for ascorbic acid, indicating that either the number of functional transporters or the rate at which individual transporters translocate ascorbate is increased.

The effect of TGFB is completely blocked by cycloheximide. This would suggest that TGFB increases the rate of synthesis of the Na^+ ascorbate cotransporter or a regulatory protein that interacts with the existing transporters to increase their turnover number.

Ascorbic acid is transported into 3T6 fibroblasts, which synthesize collagen, by a carrier-mediated saturable active Na^+ cotransporter (SVCT) process that appears to be the mechanism of transport in most cell types. Ascorbic acid, the antiscorbutic form, stimulates chondrocyte expression of SVCT, which transports the L form more efficiently than the D-isoform. It was observed that serum from various animals contained a heat-labile factor that interacted with bacterial endotoxin and inhibited ascorbate transport. The inhibitor may have been generated during endotoxin-induced activation of complement in unheated serum. The inhibitor has been purified from insulin-activated human serum. This heat-stable serum protein factor, which is produced when serum complement is activated, has a molecular mass of 9000 Da. The reactivity of the purified inhibitor with antiserum to C3a suggests that the inhibitor is C3a or a very similar molecule. The inhibitor of ascorbate transport increases the apparent K_m for ascorbate without affecting the V_{max}. In view of the similarity of ascorbate transport in many cell types, it is possible that this protein can inhibit ascorbate transport in other cell types as well, resulting in depletion of tissue ascorbate during infection or autoimmune process when serum complement is activated.

Following intracardiac injection of [^{14}C]ascorbic acid into guinea pigs, the neurohypophysis takes up the label to

a high concentration (exceeded only by the adrenals). The uptake of [^{14}C]ascorbic acid by isolated nerve endings from ox neurohypophysis was demonstrated to be a saturable process, suggesting the presence of both glucose-dependent and sodium-dependent uptakes. Cortisol and triiodothyronine inhibited the uptake. Posttranslational processing of vasopressin and oxytocin precursors involves a trypsinlike enzyme, a carboxypeptidase, and an amidating enzyme (peptidylglycyl-α-amino monooxygenase (PAM)). PAM, which requires copper, molecular oxygen, and ascorbic acid, may be limiting in the processing of amidated peptides. In a study of pancreatic islet cells, in which several peptides (e.g. pancreastatin, TRH, pancreatic polypeptide, amylin) are C-terminally amidated, the presence of PAM activity has been reported. Research has demonstrated the presence of PAM, a high content of ascorbic acid, as well as a carrier-mediated process for its uptake in the islet cells. As in neurohypophyseal nerve terminals, ascorbate uptake was inhibited by triiodothyronine and glucocorticoids.

5.3 Ascorbic Acid and Extracellular Matrix Production

Collagen is a structural protein found in tissues such as bone, cartilage, tendon, and skin. The collagens are characterized by a triple-helical structure. For the three peptides to form a stable helix, a significant number of proline residues in the peptide chain have to be hydroxylated by the enzyme prolyl hydroxylase, which requires ascorbic acid. Elastin, another ECM (extracellular matrix) protein, is found in elastic tissues and also contains hydroxylated proline residues. In addition to its role in the hydroxylation reaction, vitamin C stimulates the synthesis of collagen in a number of cell types. Elastin synthesis is also affected by Vitamin C.

Vitamin C increases the amount of procollagen mRNA by stimulating the transcription of the procollagen gene and by stabilizing the mRNA. Ascorbic acid treatment of human skin fibroblasts increased procollagen mRNA twofold. In primary avian tendon (PAT) cells, there was a similar sixfold increase of procollagen mRNA. In PAT cells treated with α,α-dipyridyl, an inhibitor of hydroxylase, there was a significant decrease in the rate of procollagen synthesis without any inhibitory effect on procollagen mRNA. These results suggest that ascorbic acid might directly increase the transcription of the procollagen gene through interaction with an ascorbic acid–specific cis-regulatory element on the procollagen genes.

Cartilage is replaced by bone-forming cells during endochondral longitudinal bone growth at the epiphysis, and fracture healing. During the developmental process, cartilage tissue undergoes orderly morphological changes involving proliferation, cellular hypertrophy, production of ECM, and mineralization. Immature cells produce type I and type II collagen, and fibronectin. Proliferating chondrocytes synthesize and secrete large amounts of type II and type IX collagen, as well as cartilage-specific proteoglycans. Hypertrophic, nondividing cells produce type X collagen. Mineralizing tissue expresses alkaline phosphatase and type X collagen. Those changes in collagen types are accompanied by changes in their mRNA level. Proliferation of prehypertorphic cells requires vitamin C. The increase in alkaline phosphatase activity followed the expression of collagen type X. Mineralization in chondrocytes was also ascorbate dependent. Although vitamin C is not necessary

for general cell growth, it is essential for the production of ECM.

5.4 Ascorbic Acid and Noncollagen Gene Expression

Related to the role of ascorbic acid in normal ECM production is the report of the action of ascorbic acid on type IV collagenase (matrix metalloproteinase-2, MMP-2). A low intake of vitamin C during pregnancy is associated with a high risk of premature rupture of the membrane (PROM). A new effect of ascorbic acid as a modulator of MMP-2 gene expression at the level of transcription has been reported, and it suggests that collagen degradation might be a significant factor in PROM.

Skin fibroblasts from patients with Ehlers–Danlos syndrome type VI (EDS VI), an inherited connective tissue disorder, have decreased activity of lysyl hydroxylase (LH). LH hydroxylates lysine residues in peptide linkage, a key step in posttranslational modification of collagen. EDS patients with LH deficiency have extreme joint hypermobility, skin hyperextensibility, bruisability, and delayed wound healing. Treatment of skin fibroblasts from EDS patients with ascorbic acid increased LH levels, which paralleled LH mRNA levels. Ascorbate increased total collagen production twofold.

Ascorbic acid deficiency was studied in ODS rats (genotype od/od) with an inherited defect in ascorbic acid synthesis. Ascorbic acid deficiency decreased the serum apolipoprotein A-1 concentration, mediated by a decrease in its mRNA levels. Ascorbic acid deficiency also decreased the renal level of fatty acid–binding protein and the serum level of α_{2M}-globulin. The hepatic level of α_{2M}-globulin mRNA of the ascorbic acid–deficient rat was significantly reduced. The kidney fatty acid–binding protein is a proteolytic fragment of α_{2M}-globulin, which is synthesized in the liver. In further work, the effects of ascorbic acid deficiency in the ODS rats on the hepatic gene expression of the positive acute phase proteins, haptoglobin and α_1-acid glycoprotein, as well as negative acute phase proteins, apolipoprotein A-1 and albumin, were studied. Ascorbic acid deficiency significantly elevated the serum concentration of haptoglobin and lowered the concentrations of apolipoprotein A-1 and albumin. The increases in haptoglobin and α_1-acid glycoprotein corresponded to increases in their mRNA levels. Correspondingly, the decreases in apolipoprotein A-1 and albumin matched decreases in hepatic mRNA levels of these proteins in ascorbic acid–deficient ODS rats.

Ascorbic acid has a significant role in catecholamine synthesis in the sympathetic nervous system as a cofactor of dopamine-β-hydroxylase. Incubation of neuroblastoma cell line SK-N-SH with ascorbic acid for 2 h results in enhanced synthesis of 3,4-dihydroxyphenylalanine (DOPA) and dopamine. After five days of incubation of the cells with high levels of ascorbic acid, there was a threefold increase of tyrosine hydroxylase gene expression, whereas dopamine β-hydroxylase gene expression was not altered. The results suggest that ascorbic acid might be a useful adjunct in the treatment of early Parkinson's disease.

Ascorbic acid deficiency in guinea pigs caused decreases in the amount of various forms of cytochrome P450 in liver microsomes. Ascorbic acid deficiency decreases the expression of cytochrome P450 mRNA, specifically for the 1A1 and 1A2 subtypes, indicating that transcription of P450 is regulated by ascorbic acid in guinea pigs.

Vitamin C inhibits NF-κB activation by tumour necrosis factor (TNF) through activation of p38 mitogen-activated protein kinase (MAPK). NF-κB is a eukaryotic transcription factor, which regulates the expression of a number of genes involved in immune and inflammatory responses. It is activated by pathogenic signals including the proinflammatory cytokines interleukin-1 (IL-1) and TNF. In the cell cytosol, NF-κB exists in a latent form consisting of a transcriptionally active dimer (p50-p65) bound to an inhibitor protein IκB. Upon stimulation by cytokine inducers, IκB is phosphorylated by IκB kinase (IKK) and is then ubiquitinated and degraded by 26S proteosomes. The released NF-κB dimer then translocates to the nucleus, binds to κB elements in the promoters, and activates target gene expression. Vitamin C inhibits cytokine stimulation of NF-κB. This is not due to an antioxidant effect of vitamin C as other antioxidants do not mimic or augment the action of vitamin C. The effect of vitamin C is mediated through activation of stress-activated protein kinase p38 MAPK. It is not known yet how vitamin C activates p38 MAPK. Activated p38 MAPK inhibits TNF activation of NF-κB as well as the phosphorylation of IκB and activation of IKK. These actions of vitamin C correspond closely to those of vitamin E on NF-κB activation.

A role for vitamin C in augmenting the chemotherapeutic response of cervical carcinoma HeLa cells has been proposed. Human papilloma virus (HPV) is involved in the pathogenesis of cervical cancer. The oncopotential of high-risk GPV types is due to E6 and E7 oncoproteins, which transform the infected cell. The E6 oncoprotein targets p38 protein, which is ubiquitinated and degraded. Cell cycle regulation is affected. These oncoproteins also activate telomerase, contributing to the immortalization of transformed cells. HPV-positive HeLa cells were incubated with millimolar concentrations of vitamin C to study its effect on the transcriptional regulation of HPV E6/7 oncogene expression. Vitmain C treatment resulted in a downregulation of the viral oncoprotein E6, which paralleled a decrease of activator protein (AP-1) members c-jun and c-fos in a time- and dose-dependent manner. The downregulation of E6 was associated with an upregulation of the proapoptotic p53 and Bax protein, and a downregulation of apoptosis inhibitor Bcl-2.

Vitamin C mediates cellular responses to counter ultraviolet (UV) radiation-mediated cell damage and cell death. Ascorbic acid rescues keratinocytes from UV-mediated cytotoxicity directly by scavenging free radical species. In addition, ascorbic acid induces transcriptional downregulation of IL-1α mRNA. Oxidative stress due to UV radiation activates redox-sensitive transcription factors including NF-κB and members of the AP-1 complex such as c-jun and c-fos. Ascorbate inhibits the AP-1-dependent transactivation of specific promoters. Ascorbic acid is a negative regulator of AP-1 and AP-1-dependent transcription.

5.5
Ascorbic Acid and Differentiation

Embryonic stem cells can differentiate into specialized cells including cardiac myocytes. In a study of the effect of inducers of cardiac differentiation, additional treatment of these cells with ascorbic acid markedly enhanced differentiation with the induced cells displaying spontaneous and rhythmic contractile activity and also staining positively for sarcomeric myosin and α-actin. Ascorbic acid also induced the

expression of cardiac genes in a developmentally controlled manner. This effect of L-ascorbic acid was not mimicked by other antioxidants including vitamin E.

Ascorbic acid has been shown to enhance the expression of several genes in human keratinocytes. The upregulation of mut L homologue-1 (MLH1) and its downstream target p73, were seen as early as 2 h after treatment with ascorbic acid. Modulation of MLH1 and p73 gene expression improves cellular susceptibility to apoptosis triggered by DNA-damaging agents, and offers a potential mechanism of the anticarcinogenic action of vitamin C. Combinations of vitamin C and vitamin E modulate cellular antioxidant network and block survivin gene expression in androgen-responsive as well as in nonresponsive human prostate cancer cell lines through inducing apoptosis via suppression of survivin, an antiapoptotic factor.

6 Biotin

6.1 Noncovalent Biotin-binding Proteins

Biotin in most biological materials is covalently bound to a lysine residue of proteins (carboxylases). The noncovalent binding of biotin to various proteins seems to be crucial for the uptake, transport, and intracellular functions other than the prosthetic group functions of the vitamin.

A group of proteins bind to biotin noncovalently. Both avidin (the biotin-binding protein of egg white) and strepavidin (the extracellular biotin-binding protein of *Streptomyces avidinii*) have exceedingly high affinities for biotin, with a dissociation constant K_3 of 10^{-15} M. These are the strongest noncovalent bindings known between a protein and a small molecular weight ligand. Other biotin-binding proteins (e.g. the egg yolk biotin-binding proteins, biotinidase, biotin-holocarboxylase synthetase) have progressively lower affinities for biotin. Biotin-binding proteins vary considerably along the evolutionary scale. In *Escherichia coli*, the biotin-binding protein biotin-holocarboxylase synthetase has been shown to regulate the synthesis of the enzymes of biotin biosynthesis pathway.

In the laying hen, there are three biotin-binding proteins. In addition to avidin, which is present in albumen of egg, there are two biotin-binding proteins in egg yolk. The presence of distinct biotin-binding proteins in the yolk suggests a specialized role for biotin in the regulation of the development of the embryo. In mammals, only two proteins have so far been shown to bind noncovalently to biotin.

6.1.1 Avidins

Avidin has been isolated from hen egg white and the oviduct of the avian species. It is a basic glycoprotein with a molecular mass of 67 kDa and an isoelectric pH of 10.5. It is a tetramer of four identical subunits, each with 128 amino acid residues and one biotin-binding site. The composition and structural arrangement of the carbohydrate moiety of avidin has been shown to be heterogeneous. Strepavidin is a nonglycosylated neutral protein secreted by *Streptomyces avidinii*. Its binding to biotin is remarkably similar to that of avidin, with a dissociation constant of 4×10^{-14} M. Both avidin and strepavidin are tetrameric, with each subunit containing one biotin-binding site. However, they lack immunological cross-reactivity and evolutionary relatedness. Avidin is a secretory protein produced by the oviduct and concentrated in the egg white. It is

induced by progesterone. In addition to being an oviductal secretory protein, avidin is synthesized in areas of tissue damage and inflammation caused by diverse agents such as toxic doses of actinomycin D, septic infection, or thermal injury in chicken. This progesterone-independent synthesis of avidin is inhibited by antiinflammatory steroids.

The avidin-biotin system has been used in a wide range of biological studies including isolation, localization, cytochemistry, immunochemistry, and diagnostics, as well as for probing genes. Since there is some nonspecific adsorption of avidin, strepavidin is generally used instead. However, strepavidin has been shown to bind with high affinity to cell surfaces. Strepavidin itself can displace fibronectin from cell surfaces. The RYD (Arg-Tyr-Asp) sequence of strepavidin mimics the RGD (Arg-Gly-Asp) sequences, which is a universal recognition domain for adhesion receptors, as well as for the receptors for fibronectin, fibrinogen, and other adhesive proteins.

6.1.2 Nonavidin Biotin-binding Proteins

In addition to avidin and strepavidin, the two examples of proteins with exceptionally strong affinity for biotin, other biotin-binding proteins have lower affinities for biotin. These include the egg yolk biotin-binding proteins: Biotin-holocarboxylase synthetase and biotinidase.

Biotin-Holocarboxylase Synthetase. Biotin carboxylases are synthesized in the form of the apoproteins that undergo posttranslational covalent modification by the addition of biotin, the prosthetic group, to the ε-amino group of lysine of the apoprotein. This covalent attachment of biotin to a specific lysine in the apoenzyme is catalyzed by biotin-holocarboxylase synthetase in a two-step reaction. The synthetase catalyzes the biotination of apocarboxylase from heterologous sources.

The biotin locus in *E. coli* was shown to be located in the same region as *gal* and *att*, and the order was determined to be *gal, att, bio*. The biotin locus is composed of five consecutive genes in the order *A B F C D* (representing the genes coding for various enzymes of biotin biosynthesis) and three unlinked genes *bioH, bioR* (a regulatory gene coding for the biotin repressor protein), and *bioP* (a permeability gene). Transcription of this cluster of genes is from two "face-to-face" partially overlapping promoters. One transcript includes the *Bio F C D* genes, whereas the second transcript includes *bioA* gene and an open reading frame of unknown function. Transcription from both promoters was blocked *in vivo* upon addition of high levels of biotin to the medium of *E. coli* cultures. Starvation of *E. coli* biotin auxotrophs resulted in increased transcription. In the biotin operon, the repressor is the biotin-protein ligase and the corepressor is biotinyl AMP. Maximal rates of biotin operon transcription are associated with conditions of biotin limitation.

Biotinidase. Acid hydrolysis of biotin proteins releases free biotin, whereas proteolytic hydrolysis yields biotin peptides. The smallest among these is biocytin, ε-*N*-biotinyl-L-lysine. The name biotinidase (biotin-amide amidohydrolase, EC 3.5.1.12) was proposed for this enzyme, which also hydrolyzes biocytin. The rat liver enzyme is associated with membranes, although not an integral part of the membrane structure. The enzymes extracted from diverse sources such as rat liver and human serum are similar in many of their properties (e.g. optimal pH

and K_m for substrate, acidic nature, inhibition by chaotropic agents and sulfhydryl agents). The major difference between these two proteins is in the heat stability of the rat liver enzyme. It appears that the liver is the site of synthesis of the serum enzyme. Human serum biotinidase has been purified to homogeneity. The enzyme is a glycoprotein monomer with a molecular mass of 68 kDa. It contains sialic acid residues. However, these are not required for enzyme activity. Although the predicted amino acid sequence from the isolated biotinidase clone did not share extensive homology with avidin and streptavidin, there is a conservation of sequence around tryptophan residues that has been shown to be critical for biotin binding. It is possible that the hydrophobic binding of biotin to biotinidase and egg yolk biotin-binding proteins require tryptophan residues in the active center.

Egg Yolk Biotin-binding Proteins. The proteins of egg yolk differ from those of egg white in regard to time and place of synthesis. The entire egg white is secreted by the magnum of the oviduct within 4 to 6 h of ovulation. The yolk proteins, in contrast, are serum proteins synthesized by the liver, and contain high-affinity binding proteins for riboflavin, thiamine, cholecalciferol, retinol, vitamin B_{12}, and iron. Vitamins and minerals are transported protein-bound to the oocyte. The transport proteins such as the riboflavin and thiamine-binding proteins and transferrin present in both egg yolk and egg white are products of the respective single genes.

The exception seems to be the biotin-binding proteins. A biotin-binding protein (BBP-I) isolated from hen egg yolk was shown to be distinct from avidin. Avidin binds to biotin very tightly and does not exchange, whereas the yolk biotin-binding protein exchanges biotin at the body temperature of the bird. Thus, biotin could be made available to the developing embryo from its reserve in the yolk. Only about 15% of the biotin of the whole egg is associated with avidin, under normal conditions of biotin nutrition of the bird. The rest is associated with the yolk BBP. The plasma of laying hens and egg yolk contain another biotin-binding protein (BBP-II), which is stable up to 45 °C, whereas BBP-I was stable up to 65 °C. Both are tetrameric isoproteins, normally saturated with biotin, and together they account for most of the biotin of hen plasma and yolk. Yolk BBPs have a nutritional role, that of transporting biotin to the developing embryo. BBP-II is preferentially deposited in the yolk and is specifically involved in the transport of biotin to the oocyte. Both BBP-I and BBP-II cross-react with anti-BBP-II serum. The maximal production of BBP-I is attained at a lower level of dietary biotin ($\approx$50 μg kg^{-1}) than for BBP-II ($\approx$250 μg kg^{-1}). At this higher level of dietary biotin, the production of BBP-II is severalfold higher than that of BBP-I. The observation that the amount of these proteins is limited by dietary biotin within the normal dietary range would suggest that biotin is required for their synthesis, stability, or secretion. The synthesis of both BBP-I and BBP-II is stimulated during egg laying, indicating that the gene(s) for these two proteins are induced by estrogen. The difference in their response to dietary biotin content as well as in their distribution between hen and chick plasma would suggest that they are either products of different genes or differentially modified products of the same gene. Both estrogen and the specific ligand for BBP-I and BBP-II are involved in

the regulation of their synthesis, although the mechanism of action of biotin in this sequence is not known yet.

A biotin-binding protein analogous to BBP-II has been characterized in the serum of the pregnant or estrogenized female rat. This protein is not present in the sera of normal male rats. The molecular mass of this protein is 66 kDa and the isoelectric pH is 4.1. It exhibits immunological cross-reactivity with the purified egg yolk biotin-binding protein, BBP-II. The biological role of this protein is not known. The physiological relevance of the biotin-binding protein during rodent embryonic development was demonstrated by selective immunoneutralization of the maternal vitamin carrier, an intervention that led to a drastic decrease in the transport of biotin to the embryo, which in turn resulted in early embryonic mortality – without affecting maternal biotin nutrition.

6.2 Role of Biotinidase as a Biotin-carrier Protein

On the basis of investigations with HeLa cells and human fibroblasts, we suggested that biotin transport in mammalian cells might involve pinocytosis through the functioning of specific circulating proteins. Both biotinidase and biotin-binding activities coincided during serum fractionation, suggesting that biotinidase is the only protein that binds biotin in human serum and might be the biotin-carrier protein in human serum. We determined the binding of biotin to pure human serum biotinidase. The Scatchard plot as well as displacement curve analysis showed two linear parts, indicating that two classes of sites with high and low affinities for biotin (0.5 and 50 nM, respectively), were present. The high-capacity, low-affinity binding corresponds to that of other vitamin-binding proteins.

The decreased level of plasma biotin in biotinidase-deficient patients was tentatively attributed to decreased levels of biotinidase or a specific biotin-binding protein in plasma. Other indirect evidence for the existence of a biotin-binding protein comes from the study of epileptic patients on long-term therapy with anticonvulsants. Significantly low levels of serum biotin were observed in these patients, suggesting that these anticonvulsants probably compete with biotin for binding to a circulatory protein. These anticonvulsants share with biotin the common structural feature of a cyclic carbamide group. Protein binding involved this group of biotin and the anticonvulsants. We have shown that all these anticonvulsants compete with biotin for the binding to biotinidase, indicating that biotin in human serum is essentially noncovalently bound to protein(s) and that biotinidase is the only protein that exchanges with [^{3}H]*d*-biotin.

The uptake of biotin by various human cell lines was reported by us to be saturable. On the basis of the binding of avidin and avidin-biotin complex to rat liver plasma membrane, we suggested that avidin in these systems was mimicking a natural biotin-binding carrier involved in biotin transport. At concentrations of biotin less than 5 μM, absorption of biotin by rat jejunal segments proceeded largely by a saturable process. The biphasic transport of biotin and biocytin in the rat small intestine suggests that at biotin concentrations in the gut below 50 nM, the saturable uptake mechanism would operate. Such a system would have a tremendous advantage in the context of fluctuating amounts of biotin ingested in the diet. This is born out by the rarity

of primary biotin deficiency in humans. The late onset type of multiple carboxylase deficiency (MCD) was shown to be due to the deficiency of biotinidase, the patients lacking the system for absorbing biotin in the nanomolar range. Biotinidase is the only protein in brush border membrane of rat intestine that binds to biotin, indicating that biotinidase *in vivo* may have a role in the transport of biotin.

6.3 Nuclear Biotin-binding Protein

Intracellular fractionation of biotin in various tissues of the rat and the chicken indicated that a significant amount of biotin was associated with the nuclear fraction. The biotin content of biotin-deficient rat liver is about one-tenth that of normal rat liver, and a significant 20% of this is present in the nuclear fraction. Biotin is present in cell nuclei prepared from various tissues of cultured cells even though such nuclei do not possess any carbon dioxide–fixing capability, indicating that biotin in nuclei does not function as the prosthetic group of carboxylases. During biotin deficiency, biotin in the nuclear fraction seems to be conserved, whereas it is lost preferentially from other cellular organelles. Biotin in nuclei has been shown to be bound noncovalently to a protein. This protein binds reversibly to biotin *in vitro*, with a maximal binding of 3.54 pmol μg of protein and with a dissociation constant for biotin of 2.2×10^{-7} M. Polyacrylamide gel electrophoresis in the presence of sodium dodecyl sulphate indicates an apparent subunit molecular mass of 69 kDa for this protein.

There have been other reports of the presence of high concentrations of biotin in optically clear nuclei (OCN). Solid cell nests resembling mulberries (morules) have been reported in colorectal adenomas and carcinomas, endometrial tissue and in pulmonary endodermal tumors resembling fetal lung. The nuclei in morules in several organs are referred to as OCN, and have been found to contain significant amounts of biotin. OCN with significant accumulations of biotin unrelated to the development of a morule appear in endometrium during pregnancy and in ovarian endometroid carcinoma.

6.4 Requirement of Biotin by Cells in Culture

A requirement for biotin by cells in culture would be expected in view of the obligatory involvement of biotin in the metabolism of carbohydrates, lipids, and deaminated residues of certain amino acids. However, various earlier studies indicated that cells in culture do not require biotin. Using biotin-depleted fetal bovine serum (FBS) and Eagle's minimum essential medium, we demonstrated a requirement for biotin by HeLa cells, human fibroblasts and rous sarcoma virus-transformed (RST) baby hamster kidney (BHK) cells. This was based on the viability, biotin content, and activities of biotin-dependent and -independent enzymes. We also demonstrated that there was a significant decrease in the incorporation of leucine into protein of the homogenate or cytosol of biotin-deficient HeLa cells compared to cells grown in a biotin-supplemented medium. When biotin was added to the biotin-deficient medium, there was a twofold increase in the incorporation of leucine into proteins. Experiments using puromycin and cordycepin indicated that the appearance of new RNAs in the cytoplasm occurs when biotin-deficient cells are supplemented with biotin. Mammalian cultured cells, when they

do not receive specific signals, which include specific growth factors, come to a halt in a quiescent, nongrowing variant of the G_1 state, referred to as G_0. The synthesis of components of the cell cycle control system is switched off.

Normal cells in G_1 arrest due to serine starvation start incorporating [^{3}H] thymidine into DNA as soon as serine is restored to the medium. Biotin-deficient HeLa cells under similar conditions do not incorporate [^{3}H] thymidine into DNA even when serine is restored to the medium. However, within 4 h of supplementation of biotin to the biotin-deficient medium, the incorporation of [^{3}H] thymidine into DNA reaches a maximum. By this time, there is stimulation of protein synthesis. The two phenomena are related, and the growth-promoting effect of biotin might be achieved through the synthesis of certain proteins.

A requirement for high-density lipoprotein (HDL) has been shown for the growth of Madin–Darby canine kidney cells grown in Dulbecco's modified Eagle's medium (DMEM) supplemented with transferrin when the cells were exposed to a mixture (1 : 1) of DMEM and F-12 medium. The components of the F-12 medium responsible for support of growth in the absence of HDL include biotin, which is absent from DMEM, and choline, which is present in insufficient concentrations in DMEM. It is significant that the HDL fraction of plasma has a considerable amount of biotin associated with it. This biotin is nondialysable and is noncovalently attached to protein.

Various transformed cell lines produce transforming growth factors that enable them to grow in a serum-free medium supplemented with transferrin and insulin. The L1subline derived from the 3T3 mouse fibroblast cell line has the capacity to differentiate in the resting state into a cell type having the characteristics of adipocytes. When they reach confluence and start to differentiate, they greatly increase their rate of triglyceride synthesis. The increase in lipogenic rate parallels a coordinated increase in the activities of key enzymes of the fatty acid biosynthetic pathway. This increase correlates with a marked rise in nuclear run-off transcription rates for these mRNAs during differentiation. The process of differentiation can be accelerated in a number of ways, such as by increasing the amount of serum in the culture medium or by adding insulin or biotin. When serum in the cultures was dialyzed extensively, the morphological and enzyme changes characteristic of adipocyte differentiation were induced without fat deposition. It was presumed that dialysis removed biotin from serum, and the role of biotin was linked to the increase in acetyl-CoA carboxylase. However, it took 24 to 48 h after the addition of biotin to the medium before deposition of triglyceride. The delay suggests that some factor required for the induction of the whole set of lipogenic enzymes (which, with the exception of acetyl-CoA carboxylase, are not biotin enzymes) might be formed under the influence of biotin.

6.5 Biotin and Embryological Development

Congenital malformations have been reported in embryos of domestic fowl maintained on a biotin-deficient diet. Maternal biotin deficiency was strongly teratogenic in mice even when dams did not exhibit any typical signs of biotin deficiency. At mid-gestation, biotin-deficient embryos weighed less than normal embryos and had external malformations such as micognathia and micromelia.

There was a marked reduction in the size of the palatal process on day 15.5 of gestation, which may be due to altered proliferation of mesenchyme. The same may be said for the proliferation of mesenchyme in the limb bud.

We investigated the development of the palatal process in culture. After 72 h of organ culture, >90% of the explants from normal mouse embryos (biotin replete) were at stage 6 development. The corresponding figure for explants from biotin-deficient embryos cultured in a biotin-deficient medium was 6.5%. If the deficient explants were cultured in a medium containing biotin (10^{-8} M), the percentage at stage 6 of development rose to >30. Administration of biotin (20 mg) to biotin-deficient dams 24 h prior to removal of the embryos resulted in 33% of the explants at stage 6 development when cultured in a biotin-deficient medium, and >50% at stage 6 if cultured in a medium containing biotin (10^{-7} M).

In view of the role of biotin carboxylases in the major metabolic pathways, it was possible that the teratogenicity of biotin deficiency might be due to the accumulation of intermediary or secondary metabolites. However, there was no detrimental effect of any of the organic acid intermediates or secondary metabolites on palatal closure of the explants when these compounds were added to the organ culture medium at a concentration of 10^{-4} M. These results highlight the continuous requirement for biotin during the proliferation of the mesenchyme, perhaps for the synthesis of growth factors during organogenesis.

6.6 Biotin Requirement for Specific Functions

Evidence of delayed spermatogenesis and decreased numbers of spermatozoa due to biotin deficiency in the rat has been reported in early literature. In mammals, spermatogenesis is dependent primarily upon testosterone, which is produced by Leydig cells and acts on the Sertoli and peritubular cells of the seminiferous tubules to drive spermatogenesis. We have shown that testicular and serum levels of testosterone are decreased in the biotin-deficient rat. Biotin deficiency was accompanied by a significant degree of sloughing of the seminiferous tubule epithelium in these rats. Treatment of biotin-deficient rats with gonadotrophins or biotin increases serum levels of testosterone. However, even when testosterone levels are maintained at high levels in biotin-deficient rats by testosterone implants, the increase in serum testosterone does not result in normal spermatogenesis. The administration of biotin alone or biotin in addition to testosterone, to biotin-deficient rats, leads to normal spermatogenesis, thus suggesting that biotin might be involved in the formation of local testicular factor(s), which are required in addition to testosterone and follicle-stimulating hormone for the normal interaction between Leydig, Sertoli, and peritubular cells. The identity of these factors is not known, although we have shown that biotin is required for the synthesis of testicular proteins.

Brain-derived neurotrophic factor (BDNF) is a member of a family of cell-signaling molecules (neurotrophins), which have an important role in neuronal development and plasticity. BDNF has been implicated in developmental and adult plasticity within telencephalic brain regions that control learned vocal behavior in songbirds. BDNF expression seems to correlate with specific stages of songbird vocal learning. High levels of biotin have been reported in specific telencephalic nuclei (RA and HVC) among

juvenile males. It is possible that there may be a specific upregulation of biotinylated proteins within the HVA and RA nuclei in juvenile males. The developmental expression of this is correlated with vocal learning. High levels of biotin in the hippocampus, a brain region important for learning and memory, has also been reported, emphasizing the important role that biotin-regulated mechanisms might play in neuronal plasticity.

6.7 Effect of Biotin on the Regulation and Synthesis of Specific Proteins

Holocarboxylase synthetase (HCS) catalyzes the covalent attachment of biotin to the biotin-dependent carboxylases. MCD in humans is an inborn error of metabolism characterized by lack of carboxylase activities due to a lack of HCS activity. The obligatory participation of HCS in the biotin-dependent stimulation of the levels of HCS mRNA and those of acetyl-CoA carboxylase and the α subunit of propionyl CoA carboxylase in human fibroblasts has been reported. A regulatory role for biotin in the control of HCS and carboxylase mRNA levels via signaling cascade involving HCS, guanylate cyclase, and cGMP-dependent protein kinase has been proposed.

The asialoglycoprotein receptor is characteristic of fully differentiated hepatocytes. The human hepatoblastoma line HepG2 expresses maximum receptor activity only in confluent cultures. HepG2 cells grown to confluency in minimal essential medium made 10% with respect to FBS demonstrate an asialoglycoprotein receptor with ligand-binding characteristics and molecular mass comparable to those of the receptors purified from human liver. However, dialysis or ultrafiltration, with removal of the low molecular weight fraction of FBS, dramatically reduced expression of asialoglycoprotein receptor. The addition of biotin or biocytin to medium supplemented with dialyzed FBS during logarithmic growth supported normal expression of asialoglycoprotein receptor by confluent HepG2 cells. Biotin was most effective at a concentration of 10^{-8} M. Isolation of mRNA from HepG2 revealed no difference in asialoglycoprotein receptor transcripts when cells were grown in a dialyzed or undialyzed medium. Thus, a biotin-dependent posttranscriptional event seems to permit the ultimate expression of asialoglycoprotein receptor by HepG2 cells.

Glucokinase is specifically induced by biotin. Biotin is not a part of this protein. Earlier work from our laboratory demonstrated that liver glucokinase activity was altered in response to the biotin status of rats. Biotin also plays a role in the precocious development of glucokinase in young rats. In all these experiments, increase in enzyme activity was associated with protein synthesis. The synthesis of glucokinase is under developmental, nutritional, and hormonal control. The *in vivo* regulation of glucokinase mRNA of biotin-injected starved rats had increased 3.9-fold in comparison to normal-fed rats. Following this increase, there was a rapid decay of glucokinase mRNA, which was hardly detectable 4 h after biotin administration. The induction of glucokinase mRNA at 1 h following biotin administration to starved rats was 19-fold in comparison to starved rats not receiving the biotin injection. The induction of glucokinase mRNA by biotin is quite marked, relatively rapid, and correlated with the increase in glucokinase activity. In ''run-on'' transcription experiments with isolated liver nuclei,

biotin administration increased glucokinase gene transcription by about 6.7-fold. The increased transcription of glucokinase gene was not simply due to an increase in overall transcriptional efficiency, inasmuch as the transcription of the β-actin gene was unaffected by biotin. The difference between induction of mRNA and rate of transcription could also be due to the stabilization of glucokinase mRNA by biotin.

In both fasted and diabetic rats, hepatic phophoenol pyruvate carboxykinase (PEPCK) activities are markedly increased. Refeeding a high carbohydrate diet to fasted rats decreased PEPCK mRNA, which, in turn, is due to the repression of transcription of PEPCK gene by insulin. Since we had shown that the administration of biotin causes a rapid and marked induction of glucokinase mRNA in starved rats, we investigated the effect of biotin on the regulation of PEPCK in the liver and kidney of diabetic rats. After administration of biotin, hepatic PEPCK mRNA decreased to 15% of the non-biotin-injected control level at 3 h after injection. The level of hepatic mRNA had recovered significantly by 5 h after biotin injection. In parallel studies on insulin administration to diabetic rats, the inhibition was nearly fully reversed by 7 h after insulin injection. The relative rates of liver PEPCK gene transcription at various time intervals following biotin administration to diabetic rats was estimated in ''run-on'' transcription experiments. The transcription of the actin gene, included as internal control, was not influenced by biotin administration. Biotin suppressed the transcription rates of hepatic PEPCK gene by 55% at 30 min, and gradually, the rate of transcription increased back to the original level.

It is to be noted that the inhibition of transcription by biotin is dominant over other stimulatory effects. The elevated plasma glucagons characteristic of the fasting or diabetic condition induces PEPCK synthesis through enhanced transcription of the PEPCK gene. There are many similarities between biotin and insulin in their action on the enzymes of glucose metabolism. Both induce the mRNA that encodes glucokinase, a key glycolytic enzyme, and repress the mRNA that encodes PEPCK, a key gluconeogenic enzyme. This was the first demonstration that a water-soluble vitamin, biotin, exerted both positive and negative transcriptional control over key enzymes of glucose metabolism.

6.8 Biotinylation of Histones

Preteolytic hydrolysis of biotin proteins yields biotin peptides, the smallest of them being biocytin, ε-*N*-biotinyl-L-lysine. Biocytin and synthetic biotin peptides are hydrolyzed by biotinidase. Our studies indicated that this might not be its major function because the optimum pH for biotinidase hydrolysis of biocytin is 4.5 to 5, whereas the pH of serum is 7.4. The concentration of biocytin in serum is in the nanomolar range, whereas the affinity constant of biotinidase for biocytin is in the micromolar range. We proposed that biotinidase functions as a biotin-carrier protein. Later work indicated that biotinidase itself is biotinylated by biocytin. It was further shown that histone is a specific acceptor of biotin transferred from biotinylated biotinidase. This raised the possibility of histones being an endogeneous substrate of biotinyl transfer. Biotinylation of histones occurs *in vivo* in human cells, and there is increased biotinylation in response to cell proliferation. Histones *in vivo* are modified by

acytylation, methylation, phosphorylation, ubiquitination, and poly (ADP-ribsylation). Biotinylation of histones, by analogy with other modifications of histones, could lead to increased transcription of DNA.

7
Vitamin B_6

7.1
General

The term "vitamin B_6" refers to a group of naturally occurring pyridine derivatives that include pyridoxine, pyridoxal, pyridoxamine, and their phosphorylated derivates. Vitamin B_6 is essential for normal growth, development, and biological function. Pyridoxal phosphate, generally, is the active form of this vitamin and is a cofactor for many enzymes involved with the metabolism of amino acids and lipids. In addition to a role in general metabolism, its functions in the nervous and immune systems are well documented.

7.2
Pyridoxal Phosphate–binding Proteins

Pyridoxal phosphate in plasma is bound to albumin with high affinity and exists as a Schiff base. Virtually none of the pyridoxal phosphate in plasma is dialyzable. This binding protects against the renal glomerular filtration of pyridoxal phosphate. Pyridoxal is less tightly bound to albumin than pyridoxal phosphate, hence is susceptible to glomerular filtration. However, pyridoxal appearing in the glomerular filtrate is reabsorbed. The binding of pyridoxal phosphate to albumin also protects it against hydrolysis by alkaline phosphatase. Liver is the primary source of pyridoxal phosphate in plasma, and possesses a unique transport mechanism that possibly releases pyridoxal phosphate as an albumin complex. The complex contains pyridoxal phosphate and albumin in a molar ratio of 2 : 1. The binding of pyridoxal to hemoglobin results in the accumulation of the vitamer in the erythrocyte. This makes it possible for pyridoxal as well to be a transport form of vitamin B_6. The role of protein binding in the regulation of the liver cellular pyridoxal phosphate has also been indicated. When hepatic cytosol is dialyzed exhaustively, about 50% of the pyridoxal phosphate is still bound to proteins. This binding protects pyridoxal phosphate from hydrolysis by the liver plasma membrane–associated phosphatase activity. Thus, protein binding within cells as well as in plasma is a significant modifier of the hydrolysis of pyridoxal phosphate by phosphatase. It has been proposed that the distribution of pyridoxal phosphate between protein-bound and free forms within the cell, together with the enzymatic hydrolysis of pyridoxal phosphate, maintains the concentration of this vitamer form. In liver cytosol, pyridoxal phosphate is found as five major protein-bound forms.

Skeletal muscle is the major repository of vitamin B_6 in the body. About 60 to 90% of the total vitamin B_6 present in muscle is associated with glycogen phosphorylase, an enzyme that comprises about 5% of the total soluble protein of muscle. Pyridoxal phosphate is bound principally to glycogen phosphorylase. Phosphorylase requires pyridoxal phosphate for catalytic activity. Pyridoxal phosphate binds to Lys-679 in rabbit muscle glycogen phosphorylase with the 5′ phosphate adjacent to the substrate-binding site. The function of muscle phosphorylase as a storage depot for pyridoxal phosphate has been demonstrated by the effect of

vitamin B_6 deficiency on muscle phosphorylase activity.

7.3 Nuclear Pyridoxal Phosphate Binding

In rats fed on a diet adequate in vitamin B_6, the fraction of total pyridoxal phosphate found in the nuclei of liver cells was 21%, and this increased to 39% in rats fed on a vitamin B_6-deficient diet, indicating a conservation of the vitamin in the nuclear compartment. This is analogous to the distribution of biotin in biotin-replete and biotin-deficient animals. Pyridoxal phosphate is the only significant form of vitamin B_6 found in the nucleus, and there is one particularly prominent pyridoxal phosphate–binding protein in the nucleoplasmic fraction of nuclear preparations obtained from HTC cells. Results of analysis by sodium dodecyl sulfatelpolyacrylamide gel electrophoresis (SDS-PAGE) indicate that this protein has an apparent molecular mass of 50 to 55 kDa. The presence of pyridoxal phosphate in the nucleus could be of physiological significance. It is not known how the nucleus acquires pyridoxal phosphate or whether the phosphorylation of pyridoxal takes place in the nucleus, given the general assumption that phosphorylated vitamin B_6 vitamers do not cross membranes of mammalian cells.

7.4 Function of Pyridoxal Phosphate in the Nucleus

The function of the protein-bound pyridoxal phosphate in cell nucleus is of much interest. Various reports indicate that pyridoxal phosphate affects steroid hormone activity by altering the interaction of steroid receptor complexes with DNA, chromatin, and nuclei. Rat hepatoma cells when grown in presence of 5-mM pyridoxine have a significantly reduced glucocorticoid-dependent induction of tyrosine aminotransferase, and the enzyme activity is increased when the cells are grown in a medium deficient in pyridoxine. The addition of pyridoxal phosphate to the medium containing mouse mammary gland explants, however, results in a significant decrease of both dexamethasone binding to nuclear steroid receptor and dexamethasone-stimulated casein mRNA synthesis. The possibility that pyridoxal phosphate might act as a modulator of protein-DNA interaction was suggested.

The possibility that vitamin B_6 might regulate transcriptional activation by glucocorticoid receptors as well as by other members of the steroid hormone receptor family has been investigated. Elevated vitamin B_6 concentrations suppressed transcription mediated through glucocorticoid receptor. Conversely, such transcription was enhanced in mild vitamin B_6 deficiency. Under these conditions, the levels of hormone-independent constitutive gene expression were not affected. It was also shown that transcriptional activities mediated by androgen, progesterone, and estrogen were reduced by elevated vitamin B_6 levels and enhanced under conditions of vitamin deficiency. The glucocorticoid-induced expressions of cytosolic aspartate aminotransferase and cystathionase genes are modulated by pyridoxal phosphate. Gene expression is inhibited by pyridoxal phosphate, whereas it is enhanced in livers from pyridoxine-deficient rats.

The level of steroid-induced gene expression from simple promoters containing only hormone response elements and a TATA sequence was not affected by changes in the vitamin B_6 status. However, the modulatory influence of vitamin B_6 status was restored when a binding site

for a transcription factor, nuclear factor (NFl), was included within the hormone responsive promoter. These results suggest that vitamin B_6 modulates steroid hormone–mediated gene expression through its influence on a functional interaction between the steroid hormone receptors and the transcription factor NFI. Thus, the vitamin B_6 status of the cells introduces an additional level of cell-specific control over the regulation of gene expression by steroid hormones.

Keywords

Apoenzyme
A protein moiety of an enzyme that requires a coenzyme.

Avitaminosis
A disease condition, described as a deficiency syndrome, resulting from the lack of a vitamin.

Coenzyme
An organic molecule, generally derived from a vitamin that functions catalytically in an enzyme system.

Cofactor
A natural reactant, usually either a metal ion or coenzyme, required in an enzyme-catalyzed reaction.

Holoenzyme
A catalytically active enzyme constituted by coenzyme bound to apoenzyme.

Hypervitaminosis
An unhealthy condition resulting from excess of a vitamin.

Hypovitaminosis
An unhealthy condition resulting from too little of a vitamin; interchangeable with avitaminosis.

A vitamin is an organic compound that occurs as a natural component of foods and must be supplied exogenously in small amounts to maintain growth, health, and reproduction of an organism. Hence, a vitamin is essential because it cannot be made in the organism that requires it; yet it functions, usually after metabolic alteration, in indispensable ways. Since only small quantities, usually microgram to milligram amounts per human adult per day, are required to avoid a deficiency disease, vitamins are classified as micronutrients along with the trace elements.

1 Classification

1.1 Discovery

Symptoms of diseases that were likely the result of insufficient dietary intake of one or more vitamins are described in early writings. For example, signs of beri-beri (lack of thiamine) are described in the ancient Chinese herbals (ca. 2600 B.C.), and the Eber papyrus (ca. 1150 B.C.) gives the signs of scurvy (lack of vitamin C). That diet could influence such diseases was also suspected in early writings from ancient Greek, Roman, and Arab physicians, who recognized that ingestion of liver would both prevent and cure night blindness, which we know today to be an early symptom of hypovitaminosis A. Such empirical relationships set the stage for the experimental phase of vitamin discovery that became scientifically based around the beginning of this century.

1.2 Nomenclature

The historical manner in which vitamins have been named was first based on capital Arabic letters (A, B, C, etc.). When it was realized that some vitamins (e.g. B) were mixtures more complex than initially perceived, subscript numbers were added to the individually isolated compounds (e.g. vitamins B_1, B_2). In some instances, subscripts were used as it became evident that members of a group are functionally similar but differ in one or more particulars of structure [e.g. vitamin A, which is required for vision, exists as A_1 (retinol) and A_2 (3-dehydroretinol)]. Common chemical names, which are receiving greater usage, give a better indication of the types of compound involved. In some cases, these have replaced the earlier alphanumeric designations. Thus vitamin H is now called *biotin*, and vitamin B_3 is known as *niacin*. The common names often reflect the presence of a specific atom (e.g. *thia*mine denotes sulfur). Chemically functional groups are also indicated (e.g. pyridox*amine* with the amine function). Even larger portions of the molecular structure can be reflected (e.g. *ribo*flavin with a ribityl chain). Parts of some names reflect a biofunctional property as with chole*calciferol,* which is an alcohol that *carries* calcium, or reflect a source/location, as in *phyllo*quinone from plants.

2 Individual Vitamins

2.1 Fat-soluble Cases

The relative solubilities of vitamins continue to provide a generally useful division. Members of the *fat-soluble* group (i.e. A, D, E, K) are more soluble in organic solvents, which also relates generally to their fatlike absorption, transport, and storage. Hence, they are rather well retained in the body and in some cases become toxic at high dosage. Table 1 lists the fat-soluble vitamins required by humans and many animals. Aspects of chemistry, metabolism, and function of individual groups are considered in Sects. 2.1.1 through 2.1.4.

2.1.1 Vitamin A

The structure of retinol (A_1) as one form of vitamin A is shown in Fig. 1. 3-Dehydroretinol (A_2) has an additional double bond between carbons 3 and 4. These alcohol compounds are yellowish

Tab. 1 Fat-soluble vitamins.

Group/vitamers	*Adult RDA*[a]	*Dietary sources*	*Physiologic roles*	*Deficiency*	*Excess*
A Retinol Retinal	800–1000 μg as retinal equivalents	Provitamins are carotenoids with a β-ionone ring in green and yellow/orange vegetables; retinol in liver, whole milk products	Visual pigments, cellular differentiation and proliferation	Night blindness, xeroph-thalmia, keratomalacia	Headache, vomiting, diplopia, alopecia, desquamation, bone abnormalities
D Cholecalciferol Ergocalciferol	5–10 μg as cholecalciferol (= 400 IU of D)	Provitamins are 7-dehydrocholes-terol in skin and ergosterol from ergot; fortified milk and dairy products, eggs, margarine	Adsorption of calcium and mineralization of bones and teeth	Rickets (children) and osteomalacia (adults)	Nausea and vomiting, anorexia, diarrhea and loss of weight; calcification of soft tissue, especially kidney and heart
E Tocopherols Tocotrienols	8–10 mg as α-toco-pherol equivalents	Seeds/vegetable oils, margarine, and shortening; green leafy vegetables	Antioxidant for cell membrane unsaturated lipids and low-density lipoprotein	Anemia (premature infants), nerve and muscle degeneration	Relatively nontoxic, but may antagonize vitamin K in those on anticoagulant therapy
K Phylloquinones Menaquinones	55–80 μg	Green leafy vegetables; lesser amounts in milk and dairy products, meat, eggs, cereals, fruits	Formation of blood clotting proteins that bind calcium ions	Hemorrhagic disease	Relatively nontoxic, but synthetic menadione can lead to jaundice

[a]The lower range is for women, but needs are modestly higher in pregnancy or lactation.

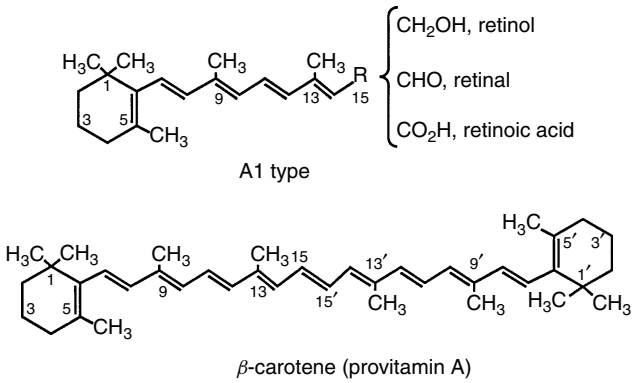

Fig. 1 Vitaminic forms of A_1, A_2, and carotene.

oils or low-melting solids that are practically insoluble in water but soluble in organic solvents and mineral oil. Vitamin A is sensitive to oxygen and ultraviolet light. Vitamin A_1 predominates, especially as long-chain fatty acid esters, in the liver of mammals and saltwater fish (e.g. cod), whereas the biologically less active vitamin A_2 is found in freshwater fish oils. Higher animals are unable to synthesize the β-ionone-type ring structure, but can derive the aldehyde retinal from provitamin carotenes and cryptoxanthin of plants. Retinal is then reversibly reduced to retinol. Retinoic acid is the irreversible oxidation product from retinal.

The structure for the most common and effective provitamin A, β-carotene, is also given in Fig. 1. The other carotenes yield less vitamin A_1 activity. Such carotenoid compounds, which constitute the yellow-to-orange pigments of most vegetables and fruits, vary considerably in their availability to the human; they often constitute the main dietary source of what ultimately becomes vitamin A.

The emulsification to micelles of forms of vitamin A and provitamin A by bile salts enhances their uptake by mucosal cells of the small intestine. Absorbed free retinol is reesterified with long-chain fatty acids within the cell. Retinyl esters in association with chylomicrons then pass via the lymphatic system to the liver and are stored in a lipoglycoprotein complex. Retinol associated with plasma retinol–building protein is released from hepatocytes to form, with circulating prealbumin, a molecular aggregate of sufficient size to avoid loss through glomerular filtration.

The best-understood physiological function of vitamin A is its participation as retinal in vision. Retinol and retinal are involved in a reversible cycle with opsin and rhodopsin, resulting in optic nerve transmission. Other broader functions of vitamin A occur in reproduction and growth. Systemic effects of an optimal level of vitamin A are the stabilization of cellular and intracellular membranes, maintenance of the integrity of epithelial tissue, and synthesis of glycoproteins. Retinoic acid also functions in the cell development and differentiation.

2.1.2 **Vitamin D**

The two forms of vitamin D, ergocalciferol (D_2) and cholecalciferol (D_3), are steroid-derived compounds. D_2 does not occur naturally but is produced by ultraviolet

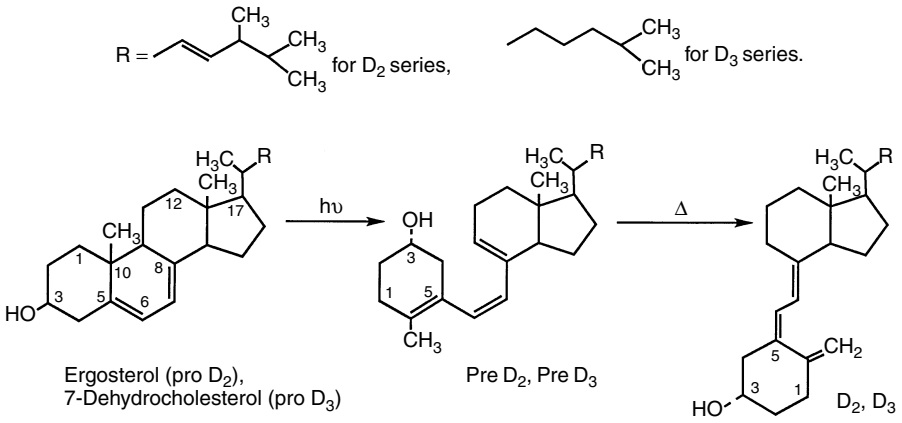

Fig. 2 Provitamins, previtamins, and vitamins D_2, and D_3.

irradiation of ergosterol, which occurs in molds, yeast, and higher plants. Vitamin D_3 in our bodies derives from irradiation of provitamin 7-dehydrocholesterol in skin. As shown by structures in Fig. 2, the only chemical difference between the two vitamin and provitamin forms is in the side chain. There are at least 10 compounds known to yield vitamin D–active compounds upon irradiation. Vitamin D forms white, odorless crystals that are soluble in fats and organic solvents. It is generally stable to heat, alkalies, acids, and oxidation.

The extent to which ultraviolet irradiation of 7-dehydrocholesterol in skin provides vitamin D_3 varies with seasonal changes in sunlight, amount of clothes worn, degree of skin pigmentation, and other factors. The availability and consumption of such vitamin D_3–containing foods as fatty fish, eggs, liver, and butter also varies. Hence, widespread fortification of food has been adopted to ensure an adequate supply. Because dairy foods in the United States supply about 75% of dietary calcium in a calcium/phosphorus ratio near-optimal for bone growth, milk, and infant formulas are desirable vehicles for vitamin D fortification. Though a poor source of vitamin D, milk that is now marketed contains 10 g (400 IU) of added vitamin D per quart.

Vitamin D is efficiently absorbed from the gastrointestinal tract unless there is fat malabsorption due to lack of bile salts, pancreatic insufficiency, or a defect of intestinal mucosal function. When absorbed, the vitamin is bound directly to chylomicrons. Much of the vitamin initially supplied to the liver is hydroxylated at the terminal side chain position to yield 25-hydroxy-D. This 25-hydroxycholecalciferol, which represents the major metabolite of D_3 in plasma, circulates by being bound to a vitamin D–binding α-globulin having a molecular weight (MW) of approximately 52 000. In kidneys, a second hydroxylation occurs at the 1α-position. This change is regulated by vitamin D status and by calcium/phosphate levels, which are controlled by parathormone (PTH) and calcitonin.

The 1α, 25-dihydroxycholecalciferol formed in the kidney complexes with the vitamin D–binding protein for transfer via blood to target tissues (e.g. small

intestine, bone). In the intestinal mucosal cell, the hormonally active dihydroxy-D mediates synthesis of a specific calcium-binding protein.

2.1.3 **Vitamin E**

The form of vitamin E that is biologically most active, and on which units are based, is D-α-tocopherol. There are eight related natural compounds in this vitaminic group, which is biosynthesized in plants and is especially abundant in vegetable oils. Structures are shown in Fig. 3. These compounds are soluble in fat solvents and insoluble in water, stable in acid and heat in the absence of oxygen, but labile to oxygen in alkaline solutions and to ultraviolet light.

Vitamin E is absorbed from the small intestine in the presence of bile. Most tocopherol enters the bloodstream via lymph, where the tocopherol is associated with chylomicrons and very low-density lipoproteins. The vitamin is stored in most tissues, with the largest amount stored in adipose tissue. Rapid exchange of tocopherol occurs between the erythrocyte membranes and plasma lipoproteins. When physiological amounts are administered, only a small fraction of the dose appears in urine.

The best-defined role of vitamin E is as an antioxidant for unsaturated fatty acyl moieties of lipids within membranes. Oxidative damage to polyunsaturated fatty acyl parts of phospholipids membrane can occur as a result of hydrogen peroxide production by flavoprotein oxidases. Concurrent free radical damage can ensue.

2.1.4 **Vitamin K**

Compounds in the vitamin K series, shown in Fig. 4, are the phylloquinones (K_1 type) synthesized in plants and the menaquinones (K_2 type) of bacterial origin. Several synthetic analogs and derivatives have been used; most relate to or derive from menadione (K_3), which lacks a side-chain substituent at position 3. The K vitamins are insoluble in water but dissolve in organic fat solvents. They are destroyed by alkaline solutions and reducing agents and are also sensitive to ultraviolet light.

The absorption of natural vitamin K from the small intestine is facilitated by bile. Vitamins K_1 and K_2 are bound to chylomicrons for transport from mucosal cells to the liver. Menadione (K_3) is more rapidly and completely absorbed. Vitamin K in the bloodstream is associated with circulating β-lipoproteins for transport. Whereas only traces of urinary metabolites of vitamins K_1 and K_2 appear in urine, a considerable

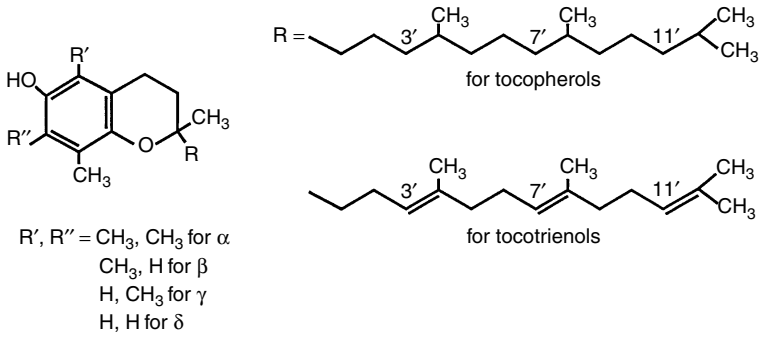

Fig. 3 Vitaminic forms of E.

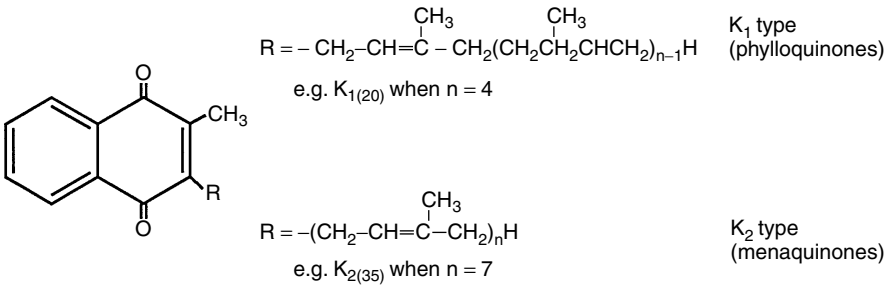

Fig. 4 Vitaminic forms of K.

portion of vitamin K_3 (menadione hydroquinone) is conjugated to β-glucuronide and sulfate esters, which are excreted.

Initially, vitamin K was recognized as a dietary antihemorrhagic factor. It has been found to be necessary for liver syntheses of plasma-clotting factors II (prothrombin), VII (proconvertin), IX (plasma thromboplastin component), and X (Stuart factor). It is now known that reduced K (hydroquinone) participates in the oxygen-dependent incorporation of CO_2 into the specific L-glutamyl residues of prothrombin and other plasma proteins. The formation of bone Gla protein (γ-carboxylglutamyl proteins) or osteocalcin, the possible regulators of mineralization, also depends on vitamin K.

Bis-4-hydroxycoumarin (dicumarol), the anticlotting compound from spoiled sweet clover, and synthetic 4-hydroxycoumarins such as warfarin, act as anticoagulants by interfering with the conversion of provitamin K to the functional hydroquinone. Hence, 4-hydroxy-coumarins are able to suppress the formation of prothrombin and other vitamin K–dependent Ca^2-binding proteins.

2.2 Water-soluble Cases

Vitamin C and the vitamins in the B-complex group are *water soluble* and as such share the fate of other solutes that are more compatible with an aqueous, physiological medium. Characteristics include a lesser tendency to be retained for long time in the body and a greater loss by way of urinary excretion. Table 2 lists the water-soluble vitamins required by the human and many plants and animals.

The eight vitamin groups that comprise the B-complex function after metabolic conversions to coenzymes, which are involved in holoenzymic systems, are also responsible for catalyzing numerous reactions. In the case of vitamin C, a cosubstrate-like function is seen with its oxidation coupled to certain hydroxylations. Aspects of chemistry, metabolism, and function of individual groups are considered in Sects. 2.2.1 through 2.2.9.

2.2.1 Thiamine

Thiamine (vitamin B_1) is a pyrimidyl-substituted thiazole (Fig. 5). The principal, if not the sole, coenzyme form is the pyrophosphate ester (TPP). Monophosphate and triphosphate esters occur naturally. Small amounts of thiamine and its phosphates are present in most plant and animal tissues, but more abundant sources are unrefined cereal grains, liver, heart, kidney, and lean cuts of pork. Thiamine is somewhat heat labile, particularly in alkaline solutions.

Tab. 2 Water-soluble vitamins.

Group/Vitamers	*Adult RDA*[a]	*Dietary sources*	*Physiologic roles*	*Deficiency*
B_1: Thiamine	1.1–1.2 mg	Pork, organ meat, whole grains, legumes	Coenzyme functions in metabolism of carbohydrates and branched-chain amino acids	Beri-beri, polyneuritis, Wernicke–Korsakoff syndrome
B_2: Riboflavin	1.1–1.3 mg	Milk and dairy products, meat, green vegetables	Coenzyme functions in numerous redox reactions	Cheilosis, angular stomatitis, dermatitis
Niacin Nicotinic acid Nicotinamide	14–16 mg as niacin equivalents	Liver, lean meat, grains, legumes; can be formed from tryptophan	Cosubstrates/coenzymes for H-transfer with numerous dehydrogenases	Pellagra with diarrhea, dermatitis, and dementia
B_6 Pyridoxine Pyridoxamine Pyridoxal	1.3 mg	Meat, vegetables, whole-grain cereals	Coenzyme functions in metabolism of amino acids, glycogen, and sphingoid bases	Nasolateral seborrhea, glossitis, peripheral neuropathy (epileptiform convulsions in infants)
Folacin Folic acid Folyl polyglutamates	400 µg	Liver, yeast, leafy vegetables, legumes, whole-wheat products	Coenzyme functions in single- carbon transfers in metabolism of nucleic and amino acids	Megaloblastic anemia, mental disorder, gastrointestinal disturbances, glossitis, pallor
B_{12}: Cyanocobalamin	2.4 µg	Meat, eggs, dairy products (not in plant foods)	Coenzyme functions in metabolism of odd-number fatty acids and methyl transfers	Pernicious anemia, neurological disorders, pallor
Biotin	60–100 µg (ranges recommended)	Liver, yeast, egg, yolk, soy flour, cereals	Coenzyme functions in bicarbonate-dependent carboxylations	Fatigue, depression, nausea, dermatitis, muscular pains

(*continued overleaf*)

Tab. 2 (*Continued*)

Group/vitamers	*Adult RDA*[a]	*Dietary sources*	*Physiologic roles*	*Deficiency*
Pantothenic acid	30 mg (adequate intake)	Animal tissues, whole-grain cereals, legumes; widely distributed	Constituent of CoA and phosphopantetheine involved in fatty acid metabolism	Fatigue, sleep disturbances, impaired coordination, nausea
C L-ascorbic acid Dehydroascorbic acid	5 mg (adequate intake)	Vegetables and fruits, especially broccoli and citrus	Formation of collagen and carnitine; important as antioxidant	Scurvy with petechiae, ecchy moses, peri-follicular hemorrhage, spongy and bleeding gums

[a]The lower range is for women, but needs are modestly higher in pregnancy or lactation.

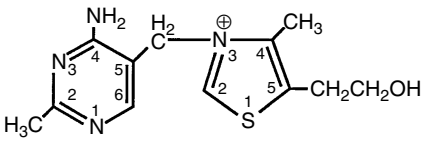

Fig. 5 Structure and ring numbering for thiamine.

Thiamine is readily absorbed in the small intestine by an active transport process when intake is less than 5 mg/day; at higher levels of intake, passive diffusion increasingly contributes to absorption. Phosphorylation takes place in the jejunal mucosa to yield thiamine pyrophosphate. Thiamine is carried by the portal blood to the liver. The free vitamin occurs in the plasma, but the coenzyme, TPP, predominates in the cellular components. About half the body stores are found in skeletal muscles, with much of the remainder in heart, liver, kidneys, and nervous tissue, including brain. Thiamine, as well as several of its catabolites, is excreted into the urine by the renal tubules.

As thiamine deficiency develops, there is a rather rapid loss of the vitamin from all tissues except the brain. The decrease of TPP in the erythrocytes roughly parallels the decrease of this coenzyme in other tissues. During this time, the thiamine in urine falls to near zero; the urinary metabolites remain high for some time before decreasing.

TPP functioning as the Mg(II)-coordinated coenzyme for the so-called active aldehyde transfers in the oxidative decarboxylation of α-keto acids, and the formation of α-ketols (ketoses) catalyzed by transketolase.

2.2.2 **Riboflavin**

Riboflavin (vitamin B_2) is a ribityl-substituted isoalloxazine (Fig. 6). This vitamin and its natural derivatives are yellow fluorescent compounds that are widely distributed throughout the plant and animal kingdoms. Principal among these flavins are the coenzymes, flavin mononucleotide (FMN) and flavin adenine dinucleotide (FAD). Such coenzyme forms are rich sources of the vitamin in liver, kidney, and heart. Many vegetables are also good sources, but cereals are rather low in flavin content. Raw milk is a good source of the vitamin, but considerable loss can occur from exposure to light during pasteurization and bottling, or as a result of irradiation to increase the vitamin D content. Flavins are stable to heat but are decomposed by light.

The process by which riboflavin and lesser amounts of natural derivatives are released by digestion of complexes with food proteins involves hydrolysis of coenzyme forms of the vitamin (mainly

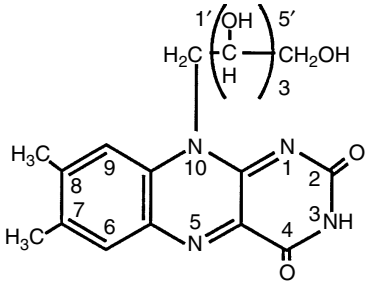

Fig. 6 Structure and numbering for riboflavin.

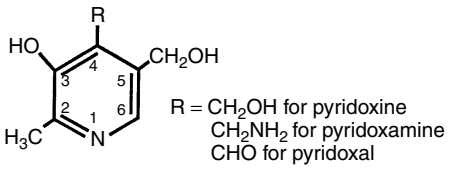

Fig. 7 Natural forms of vitamin B_6.

FAD; less FMN) as a consequence of gastric acidification. The vitamin is primarily absorbed in the proximal small intestine by a saturable transport system that is rapid and proportional to intake before leveling off at higher doses. Bile salts appear to facilitate the uptake. Much of the riboflavin circulating in blood plasma is loosely associated with albumin; lesser amounts complex with other proteins. One subfraction of immunoglobulin G (IgG) avidly binds a small portion of the total flavin in blood. Conversion of riboflavin to the coenzymes FMN and FAD occurs within the cell cytoplasm of most tissues, but particularly in the small intestine, liver, heart, and kidneys. Thyroxine and triiodothyronine stimulate FMN and FAD synthesis in mammalian systems. FAD is the predominant flavocoenzyme present in tissues, where it is mainly complexed with numerous flavoprotein dehydrogenases and oxidases. Since there is little storage of riboflavin as such, the urinary excretion reflects dietary intake.

In bound coenzymatic form, riboflavin participates in oxidation–reduction reactions in numerous metabolic pathways and in energy production via the respiratory chain. Flavins serve as redox carriers upon differential binding to proteins, participating, as well, in both one- and two-electron transfers. In reduced (1,5-dihydro) form, flavins react rapidly with oxygen.

2.2.3 **Vitamin B_6**

The three natural members of the vitamin B_6 group – pyridoxine (pyridoxol), pyridoxamine, and pyridoxal – are all 2-methyl-3-hydroxy-5-hydroxymethyl pyridines, as shown in Fig. 7. Both pyridoxamine-5′-phosphate and pyridoxal-5′-phosphate (PLP) interconvert as coenzyme forms during reactions catalyzed by aminotransferases (transaminases). Vitamin B_6 is widely distributed in animal and plant tissues, where the phosphorylated forms, and particularly PLP, predominate. Meats, poultry, and fish are good sources, as are yeast, certain seeds, and bran; somewhat more limited sources are milk, eggs, and green leafy vegetables. The common commercial form of the vitamin is pyridoxine hydrochloride, which is a water soluble, white, and crystalline solid. Solutions of the B_6 vitamins are decomposed by light, especially in the UV region, at neutral to alkaline pH. There is significant loss of PLP during the thermal processing of foods.

The three B_6 vitamers are readily absorbed by the mucosal cells. PLP binds for catalytic function with numerous specific apoenzymes throughout the cell. The erythrocytes, in addition, trap PLP as a conjugate Schiff base with hemoglobin. Glycogen phosphorylase contains most of the PLP in skeletal muscle.

Free vitamin is released when the phosphates are hydrolyzed by the nonspecific alkaline phosphatase located on the plasma membrane of cells or when pyridoxine-5′-β-D-Glucoside is hydrolyzed by the nonspecific glucosidase within the cells. The vitamin released from animal-derived foods is mainly pyridoxal; from plants, pyridoxine is preponderant. Some PLP is also released into the circulation by the

liver. Although PLP is the principal tissue form of vitamin B_6 and pyridoxal constitutes much of the circulating vitamin, the main catabolite excreted in urine is 4-pyridoxic acid.

As coenzyme PLP, vitamin B_6 functions in the metabolism of proteins, carbohydrates, lipids, and amino acids. PLP coenzyme-dependent reactions include formation of amines such as epinephrine and norepinephrine, formation of aminolevulinate in heme synthesis, and phosphorolysis of the α-1,4-linkages of glycogen.

2.2.4 Niacin and Niacinamide

Though the term *niacin* is chemically synonymous with the nicotinic (pyridine-3-carboxylic) acid, it is now used as the generic name for the specific compound as well as for the derivatives exhibiting qualitatively the biological activity of niacinamide (nicotinamide, nicotinic acid amide). Thus, *niacin activity* and *niacin deficiency* carry this broader meaning in nutritional literature. Figure 8 gives the structures of both vitamers.

The coenzymes nicotinamide adenine dinucleotide (NAD) (NAD; diphosphopyridine nucleotide (DPN)) and nicotinamide adenine dinucleotide phosphate (NADP) (NADP; triphosphopyridine nucleotide TPN) represent most of the niacin activity found in food sources that include yeast, lean meats, liver, and poultry. Milk, canned salmon, and several leafy green vegetables have lesser amounts. Protein provides a considerable portion of niacin equivalent because of the tryptophan content. As much as two-thirds of niacin required by adults can be derived from tryptophan metabolism via nicotinic acid ribonucleotide to NAD and NADP. Free forms of the vitamin are white, stable solids that are quite soluble in water. The oxidized coenzymes are labile to alkali, whereas the reduced (dihydro) coenzymes are labile to acid. Reduction of the oxidized coenzymes commonly occurs by the addition of a hydride ion to the para (4) position of the nicotinamide ring, with the simultaneous formation of a solvated proton. NADH and NADPH (but not NAD and NADP) absorb light in the near-ultraviolet region (339 nm).

The coenzymes are hydrolyzed in the intestinal tract, and both the acid and amide forms of the vitamin are readily absorbed. Nicotinic acid and nicotinamide are both present in the blood and move between blood and cerebrospinal fluid. Both compounds are converted to the coenzyme forms in blood cells, kidneys, brain, and liver. In the tissues, most of the vitamin is present as nicotinamide in NAD and NADP, although liver may contain a significant fraction of the free vitamin. There is little storage of niacin as such. Although nicotinamide can be converted to nicotinic acid by a rather widespread microsomal deamidase, there is no direct reamidation of nicotinic acid. Humans excrete 1-methylnicotinamide and 1-methyl-3-carboxamido-6-pyridone, which are primary urinary metabolites.

There are hundreds of enzymes that require the nicotinamide moiety within

Nicotinic acid (niacin) Nicotinamide (niacinamide)

Fig. 8 Structures for niacin and niacinamide.

either NAD or NADP. Most of these oxidoreductases function as dehydrogenases and catalyze such diverse reactions as the conversion of alcohols (often sugars and polyols) to aldehydes or ketones, hemiacetals to lactones, aldehydes to acids, and certain amino acids to keto acids. Generally, most NAD-dependent enzymes are involved in catabolic reactions, whereas NADP systems are more common to biosynthetic reactions.

2.2.5 **Folacin**

Folacin is the term covering both folic acid (pteroyl monoglutamate) and its natural polyglutamyl forms. The structure of the unconjugated acid, given in Fig. 9, comprises a pterin linked through a *p*-aminobenzoyl residue to the glutamate terminus. Reduction proceeds through the 7,8-dihydro to the 5,6,7,8-tetrahydro level before coenzymic activity is generated. Green leafy vegetables (e.g. spinach) are excellent sources of the vitamin.

Folacin is digested in the upper small intestine by cleavage of excess glutamyl residues by *conjugases*: Substances that hydrolyze the predominant coenzymic forms present in foods to liberate the free folate, which is then absorbed. Folate-binding proteins occur in plasma. In tissues, folate is reduced by the NADPH-dependent dihydrofolate reductase to tetrahydrofolate, which is then polyglutamylated by an ATP-dependent synthetase.

Coenzymic cycling is generally at the tetrahydro level for one-carbon-transfer reactions, though an oxidation–reduction shift from the tetrahydro to dihydro occurs with thymidylate synthetase. In this case, the transfer of a methylene function from 5,10-methylene tetrahydrofolyl coenzyme to deoxyuridylate involves its reduction to a methyl on the thymidylate product concomitant to oxidation of the pterin portion to generate the dihydrofolyl coenzyme that must be recycled. Other important roles of tetrahydrofolyl (THF) coenzymes relating to biosynthesis of nucleic acid precursors include the transformylase-catalyzed conversions of glycinamide ribonucleotide to the *N*-formyl compound with the participation of 5,10-methenyl-THF, and 5-aminoimidazole-4-carboxamide ribonucleotide to the 5-formamido compound with the participation of 10-formyl-THF.

With respect to amino acid metabolism, enzyme systems include the hydroxymethyltransferase-catalyzed conversion of serine with THF to glycine and

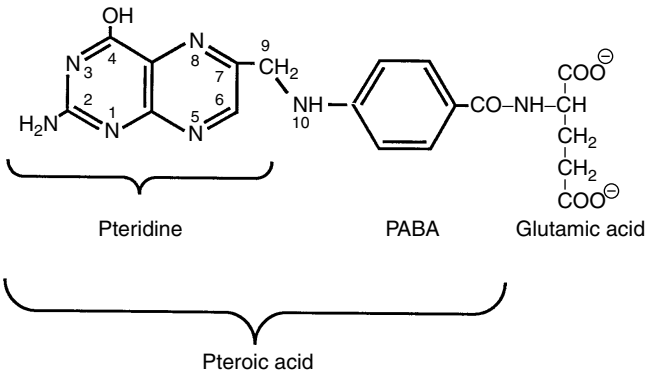

Fig. 9 Structure with numbering for folic acid.

5,10-methylene-THF, the formiminotransferase reaction with formiminoglutamate and THF to yield glutamate plus 5-formimino-THF, and the biosynthesis of methionine from homocysteine plus 5-methyl-THF to regenerate THF.

2.2.6 **Vitamin B_{12}**

The commercial form of vitamin B_{12} is cyanocobalamin, shown in Fig. 10, but the tissue-predominate B_{12} has water or the hydroxyl ion in place of the coordinate cyanide. Primary structural features include a central cobinamide with a corrin ring system and an affixed dimethylbenzimidazole nucleotide with coordination of this nitrogen base to the corrin cobalt. The cobalamins are photolabile and also unstable at extremes of pH. Cyanocobalamin exhibits a distinctive absorption spectrum with a long wavelength maximum at 550 nm for the reddish aqueous solutions. Best food sources are meats and dairy products; higher plants, which cannot synthesize this vitamin, provide little or none. Hence, true vegetarians are at risk for deficiency.

Upon ingestion, vitamin B_{12} (extrinsic factor) forms a complex with a glycoprotein called *intrinsic factor* that is absorbed in the distal ileum. Additional B_{12}-binding proteins (transcobalamins, R proteins) help vector the vitamin through plasma and into cells. For conversion to functional coenzymes, the aquocobalamin (B_{12a}) is reduced through the radical (B_{12r}) to the Co(I) reactive B_{12s} that can react with ATP to add the 5′-deoxyadenosyl moiety of coenzyme B_{12} in a transferase-catalyzed step or with methyl-THF to form

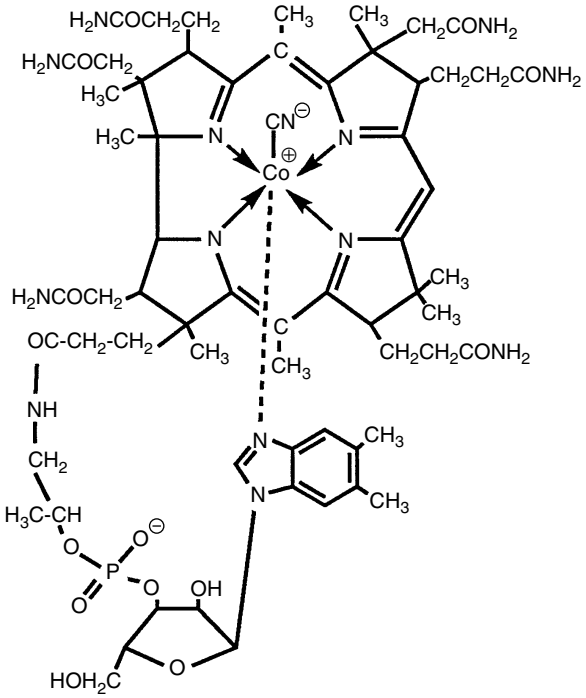

Fig. 10 Structure of cyanocobalamin (B_{12}).

methyl B_{12} that participates in methionine biosynthesis.

Besides the essential function of B_{12} in formation of methionine in mammals including the human, the coenzyme form is required for the methylmalonyl–coenzyme A mutase that routes L-methylmalonyl–CoA to succinyl–CoA and the Krebs cycle. More broadly in other organisms, B_{12} coenzymes function in ribonucleotide reductase, diol dehydratase, ethanolamine ammonia lyase, L-β-lysine mutase, glutamate mutase, and so on. In some cases (e.g. the adenylcobamide coenzyme used in a bacterial glutamate mutase), the N base that is a dimethyl-benzimidazole in the Co-B_{12} in our bodies is replaced by a different N base.

2.2.7 **Biotin**

Biotin (vitamin H) is a fused biocyclic system. In most organisms, this vitamin, shown in Fig. 11, occurs mainly bound to protein. Good sources of biotin include liver, kidney, pancreas, eggs, yeast, and milk.

Digestion of dietary proteins containing bound biotin yields considerable biocytin (ε-N-biotinyl lysine). Biocytin and biotin are readily absorbed. Biotinidase releases biotin from biocytin. Biotin is cleared from the circulating blood and is taken up by such tissues as liver, muscle, and kidney. Careful balance studies show that in humans, the urinary excretion of biotin often exceeds dietary intake and fecal excretion is always more than dietary intake because of microfloral biosynthesis. For the average adult, total body content of biotin is perhaps only 1 mg.

Four biotin-dependent enzymes have been found in human tissues. They are carboxylases for acetyl–CoA, propionyl–CoA, methylcrotonyl–CoA, and pyruvate.

2.2.8 **Pantothenic Acid**

Pantothenic acid is the amide formed from pantoic acid and alanine, as shown in Fig. 12. This vitamin is ubiquitous in nature and is synthesized by most microorganisms and plants. The vitamin is an integral part of a covalently attached prosthetic group of acyl carrier proteins and is within the structure of coenzyme A. The vitamin is widely distributed in foods and is particularly abundant in animal sources, legumes, and whole-grain cereals. Excellent food sources include egg yolk, kidney, liver, and yeast. Fair sources include broccoli, lean beef, skimmed milk, sweet potatoes, and molasses. More than half the pantothenate in wheat may be lost during the manufacture of flour, and up to a third is lost during the cooking of meat. The most common commercial synthetic form is the calcium salt.

Coenzyme A, the form in which much of the pantothenic acid is ingested, is hydrolyzed by intestinal pyrophosphatase

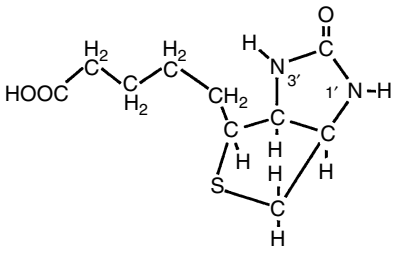

Fig. 11 Structure of biotin.

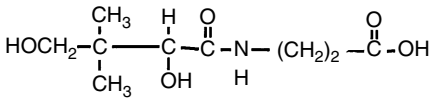

Fig. 12 Structure of pantothenic acid.

and phosphatase to pantetheine, which together with pantothenate is absorbed into the portal circulation. Within cells, resynthesis of coenzyme compounds occurs. About 80% of the vitamin in animal tissues is in CoA form. Cleavage enzymes operate during turnover and release of the vitamin that is excreted in the urine. Only a small fraction of pantothenate is secreted in milk, and even less into colostrum.

The myriad acyl thiol esters of CoA, of which pantothenic acid is a constituent, are central to the metabolism of numerous compounds (especially lipids) and the ultimate catabolic disposition of carbohydrates and ketogenic amino acids. For example, acetyl–CoA, which derives from the metabolism of carbohydrates, fats, and amino acids, can acetylate compounds such as choline and hexosamines to produce essential biochemicals; it can also condense with other metabolites such as oxaloacetate or with itself to supply citrate and cholesterol, respectively. Another essential role of pantothenic acid is its participation in the 4′-phosphopantetheine moiety of acyl carrier protein (ACP), where it facilitates chain elongation during fatty acid biosynthesis. Although the reactive thiol function of CoA and ACP is not an integral part of pantothenate, the steric and chemical properties conferred by the vitamin structure are important for enzymic recognition.

2.2.9 **Vitamin C**

Vitamin C (L-ascorbic acid) is a white, crystalline solid that is readily soluble in water. Ascorbic acid is a relatively strong reductant with an E_0 (pH 7) of 0.58 V. Ascorbic acid is reversibly oxidized to dehydroascorbic acid (ascorbone); both compounds are shown in Fig. 13. The dehydro form is more labile than the reduced form. Some mammals, including the human, lack the enzyme L-gulonolactonase that catalyzes the formation of 2-keto-L-gulonolactone, which spontaneously tautomerizes to L-ascorbic acid. The best sources of the vitamin are citrus fruits, berries, melons, tomatoes, green peppers, raw cabbage, and leafy green vegetables. Losses during processing, especially with heat and aerobic conditions, can be considerable.

Absorption of vitamin C occurs readily, mostly from the stomach, where some of the ascorbic acid is converted to the dehydro form. At physiological pH, the uncharged dehydroascorbic acid passes across cell membranes faster than the

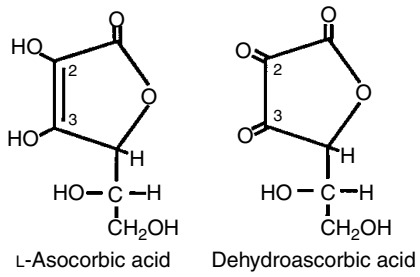

Fig. 13 Structure for L-ascorbic and dehydroascorbic acids.

anionic L-ascorbate. Passive diffusion of vitamin C accounts significantly for entry into some cells, such as leukocytes and erythrocytes, but an active transport mechanism also operates, especially for platelets, liver, adrenals, and retina. Vitamin C is found in most tissues, but glandular tissues such as the pituitary, adrenal cortex, corpus luteum, and thymus have the highest amounts, and the retina has 20 to 30 times the plasma concentration. The half-life for vitamin C in humans is only about 16 days. Ascorbate, dehydroascorbic acid, and lesser amounts of a number of catabolites are present in urine.

The most clearly established and critical functional role for ascorbic acid is a cofactor for protocollagen hydroxylase, the enzyme responsible for hydroxylation of prolyl and lysyl residues within nascent peptides in the connective tissue proteins. Among these are collagen and related proteins that comprise the intercellular material of cartilage, dentin, and bone. Vitamin C may also be involved in carnitine biosynthesis, tyrosine metabolism, microsomal drug metabolism, synthesis of epinephrine and antiinflammatory steroids by the adrenals, folic acid metabolism, and leukocyte functions. Absorption of Fe(II) is enhanced by simultaneous ingestion of the vitamin.

3 Perspectives

3.1 Quasi-vitamins

Some compounds not listed in Tables 1 and 2 are legitimate vitamins for certain species, though not the human. For example, lipoic and *P*-aminobenzoic acids for certain microorganisms or carnitine for the common mealworm represent essential organic micronutrients that cannot be synthesized adequately by the organisms that depend on dietary supply of these compounds. More than micro amounts of choline and myoinositol are required at early growth stages for rodents. There are, furthermore, several compounds that at one time or another have been falsely claimed to be vitamins with reputed benefit to humans. These include such ineffective factors as B_{15} or pangamic acid and B_{17} or laetrile. Only the 13 vitaminic groups listed in Tables 1 and 2 presently account for human needs.

3.2 Pharmacologic Uses

As mentioned in connection with the fat-soluble vitamins, particularly A and D, toxicity can result from the ingestion of too much, especially chronically. Excessive amounts of at least a couple of water-soluble vitamins can also pose a health hazard. Hepatoxicity can result from high amounts of nicotinic acid, and neurologic dysfunction has been associated with chronic excess of pyridoxine.

There is a growing certainty, however, that amounts of L-ascorbate (C) and α-tocopherol (E) that are modestly above the present recommended daily allowance (RDA) levels, have beneficial effects as natural antioxidants. The decrease in some specific cancers has been associated epidemiologically with higher intakes of foods rich in C, E, and carotenoids, including the provitamin A β-carotene. Extra folic acid also seems to protect the fetuses in a subset of women who have a history of neural tube defects in their newborns. More specific and direct experimentation will be needed to clarify such pharmacological roles of vitamins.

Keywords

***Alu* Repeat**
A 300-bp DNA interspersed repeat sequence that occurs about once every 5000 bp. The most common repeat element in the human genome, it is CG rich and appears to occur preferentially in light Giemsa bands on condensed chromosomes.

Encyclopedia of Molecular Cell Biology and Molecular Medicine, 2nd Edition. Volume 15

Bacterial Artificial Chromosome (BAC)
An artificial chromosome cloning system in *E. coli* based on elements of the native circular chromosome.

Cloneless Library
A library of genomic fragments consisting of gel slices of electrophoretically fractionated DNA.

Comparative Genomic Hybridization (CGH)
A molecular cytogenetic method capable of detecting and locating relative genomic sequence copy number differences between pairs of DNA samples. Equal concentrations of differentially labeled DNAs are hybridized simultaneously to metaphase chromosome spreads. Regions with deleted or amplified DNA sequences are seen as changes in the ratio of the intensities of these two labels along the target chromosome.

Expressed Sequence Tag (EST)
A segment of a sequence from cDNA clone that corresponds to an mRNA. Mapping ESTs helps make maps and points directly to expressed genes.

Fluorescence *In Situ* Hybridization (FISH)
Hybridization of nucleic acid probes to chromosomes immobilized on microscope slides or filters.

Inter-*Alu* PCR
A polymerase chain reaction method that uses primers contained in *Alu* repeat element to amplify single-copy sequences between adjacent *Alu* elements.

Jumping Libraries
A library of clones containing DNA sequences from the ends of the same restriction fragment.

***Kpn* Repeat**
The second most commonly occurring repeat sequence in the human genome, occurring on average once every 50 000 bp. It is a relatively AT-rich, LINE repeat and occurs preferentially in dark Giemsa bands on condensed chromosomes.

Linking Libraries
Libraries of clones containing DNA sequences that span a selected restriction enzyme recognition site.

Locus
A region on a chromosome linked to a functional unit such as a gene, telomere, centromere, and replication origin.

Long Interspersed Repeat Elements (LINEs)
Long interspersed repeating sequences that appear to be similar to retroposons.

Multiplex Analysis
An analytical approach to increase throughput by collecting multiple data simultaneously.

P1-derived Artificial Chromosomes (PAC)
An *E. coli* bacteriophage cloning system used for cloning of fragments up to 150 kb in size.

Polonies
Isolation of DNA sequences on beads rather than in clones.

Polymerase Chain Reaction (PCR)
A method for amplifying DNA by alternatively denaturing double-stranded DNA, annealing pairs of primers located near each other on complementary strands, and synthesizing the DNA between the primers using DNA polymerase.

Polymorphism Link-up
A mapping approach that establishes continuity between restriction fragments by taking advantage of the naturally occurring polymorphism in different DNAs. In some cell lines, hybridized probes appear to identify different fragments, whereas in others they appear to identify the same fragment. The pattern of occurrence of these fragments can be used to assess whether the probes identify the same or adjacent fragments.

Pulsed Field Gel (PFG) Electrophoresis
A method of electrophoresis that exposes nucleic acids to alternating electrical fields. Fractionation is based on the speed at which the molecules can change directions.

Radiation Hybrid Maps
Radiation hybrid maps are created by analyzing randomly broken DNA cloned into hybrid cell lines. The breakage is done using X rays and the centiRay distance is a function of how often two loci remain together in a library of radiation hybrid cell lines.

RARE (RecA-assisted Restriction Endonuclease) Cleavage
A site-specific DNA cleavage method based on the ability of RecA protein from *E. coli* to pair an oligonucleotide to its homologous sequence in duplex DNA. This three-stranded DNA complex is protected from methylase. After methylation and removal of RecA, restriction endonuclease cleavage is limited to the site previously protected from methylation. If pairs of oligonucleotides are used, a specific fragment can be cleaved out of genomes.

Retroposons
A group of DNA sequence elements that appear to transpose through an RNA intermediate. Retroposon elements do not code for reverse transcriptase, do not have terminally redundant sequences, and do have a 39-poly(A)$_n$ stretch. A variable-sized target duplication occurs at the site of integration.

Sequence-tagged Restriction Site (STAR)
A short DNA sequence used to identify the DNA surrounding a restriction nuclease cleavage site.

Sequence-tagged Site (STS)
A short DNA sequence used to identify a DNA segment.

Short Interspersed Repeat Elements (SINEs)
Repeated sequences less than 500-bp long and present in a high copy number (10^5 per human genome). The *Alu* repeat element consists of SINEs.

Yeast Artificial Chromosome (YAC)
An artificial yeast chromosome constructed by cloning genomic fragments into vectors that can replicate in yeast. YACs have the following characteristics: a yeast centromere, two telomeric sequences, and a selectable marker.

This entry reviews the types of physical map that can be constructed, the methods used to construct them and their most likely current use. In particular, the emphasis is on the construction of genomic restriction maps and ordering overlapping libraries using top-down mapping approaches to enable *de novo* genome sequencing and for gap filling in sequencing projects. Also explored is the use of these approaches in functional studies.

1 Introduction

In the past, most genome studies were limited to organisms having well-developed genetic systems. Thus, a few model systems were studied intensely (e.g. bacteriophage lambda, *Eschericia coli*, Drosophila, mice) in a large number of different ways. The accumulation of diverse knowledge on these model organisms further promoted research on these model systems. Now, a number of molecular approaches have been developed that allow the construction of physical maps for virtually any chromosome. This means that analysis of an uncharacterized organism can begin with physical dissection including sequencing. Knowledge gained from this initial foray provides the foundation for functional studies. Hence, a new synergism in biology is provided by bottom-up genome studies.

Bacterial genomes are small and range from ~1 to 15 Mb in size, reflecting in part, the relative ability of these organisms to be free living. The entire genomic sequence of an increasing number of bacterial genomes is becoming available. These genomes are small enough so that sequencing of random clones is used to obtain the entire genome sequence. Hence, physical genomic maps for these organisms are used to study global gene expression or other global genomic activities.

In the past, the study of some lower eukaryotic genomes such as protozoa was hampered by the lack of well-developed genetic systems. Also, these chromosomes did not condense during cell division and could not be visualized microscopically. The application of pulsed field gel electrophoresis (PFG) to examine the genetic make up of these organisms was quite useful. PFG separates DNA chromosomal DNAs or large fragments that range up to ~10 Mb in size. Protozoan genomes range in size from the length that overlaps large bacterial genomes, up to about 100 Mb. Surprisingly, one parasitic protozoan genome, the *Giardia lamblia* genome, was found to be only about 12 Mb in size (i.e. smaller than the *Saccharomyces* genome).

Until recently, large, complex genomes, like the human genome (~3000 Mb in size) have been particularly recalcitrant to molecular dissection. Human and other higher eukaryotic chromosomes are 50 to 300 Mb in size, condense and are visible microscopically. Differential staining of the condensed chromosomes allows a finer division into regions (''bands'') estimated to be 5 to 30 Mb in size that appear to reflect regional differences in GC content. The banding patterns serve as anchors to a large amount of genomic data. Also, the division of the genome into chromosomes and chromosomal bands provides convenient pieces for top-down mapping approaches.

In top-down mapping approaches, the genome is divided into units to facilitate study. For instance, chromosomes naturally divide the genome, and chromosome-banding patterns represent another division. Further division will depend on the method of analysis. Conventional recombinant DNA approaches to genome analysis allowed the characterization of molecules up to only about 0.05 Mb. The ''resolution gap,'' 0.05 to 10 Mb was exactly the size range that was most amenable to study by PFG techniques and the entire size range of DNA molecules could be analyzed. PFG also promoted the extension of recombinant DNA methods to large cloning system such as yeast artificial chromosomes (YACs), P1 artificial

chromosomes (PACs), and bacterial artificial chromosomes (BACs).

2 Genomic Mapping Terms and Concepts

Many molecular techniques with varying degrees of resolution can be used to characterize chromosomes. Hence, there is no unifying concept of what constitutes a chromosomal physical map. Further, there are ambiguities in the literature with respect to the distinction of physical versus genetic maps.

Any map will consist of markers or objects. The order, and perhaps the distance, between pairs of objects will be known (some might argue that a map must consist of both order and distance). Object ordering along a chromosome should be maintained irrespective of the method used to construct the map, whereas map distances are method dependent. For instance, the amount of recombination along a chromosome is not constant. Hence, it is not surprising that a comparison of the physical and genetic distances along the long arm of chromosome 21 revealed at least a sixfold variation in the distances. It is quite clear that the ultimate map is the entire sequence of a chromosomal DNA. All maps and objects will be anchored to the DNA sequence once it is available. Some imprecision will always exist because map objects may be imprecisely defined, or have imprecisely defined locations by their very nature.

Classically, a genetic map was composed of chromosomal loci and the amount of recombination between the loci was the genetic distance. For eukaryotic organisms, genetic distance, expressed in centimorgans (cM), is a measure of the coinheritance of genetic markers. This type of analysis requires the examination of two loci in multiple generations. In bacteria like *E. coli*, recombination is measured as the time of transfer and integration of DNA from one cell into the chromosome of another cell.

In some instances, the placement of genes on various physical maps has been referred to as a *genetic map* (i.e. ''a gene map''), although only physical distances and locations were known. Cytogenetic maps lead to further confusion in terminology. In these maps, the presence or absence of a gene or map object is correlated with an observable genomic location (i.e. a chromosome band).

Another concept whose use results in some confusion is ''locus.'' Classically, this term defined the location genes (i.e. ''genetic locus''). More generally, however, a chromosomal locus, representing a location on a chromosome, can consist of objects other than genes. Examples include DNA sequences, sequenced tagged sites (STS), expressed sequenced tags (ESTs), probe sites, restriction enzyme sites, clone sites, centromeres, telomeres, and chromosomal breakpoints (such as those that occur naturally or are induced by ultraviolet breakage). To add to the confusion, new genetic markers based on anonymous DNA sequences now define genetic loci because they are used in genetic mapping experiments. In this entry, a *chromosomal locus* is any chromosomal location that has been identified in a distinctive manner.

Here, a physical map is considered to be any map consisting of objects that have been located by physical rather than by genetic methods. Thus, a physical map can consist of objects located along the chromosome, such as a chromosomal band, a breakpoint, a genomic restriction fragment, and the location of a clone

on a chromosome. Here, the ordering of restriction fragments and clones will be used. These maps are constructed using molecular methods.

3 Evolving Approaches for Physical Mapping

The term ''physical maps'' has been used to describe both genomic restriction maps and genomic clone libraries. Low-resolution whole-genome restriction maps are created by ordering fragments that have been fractionated by size electrophoretically. These maps have been created by hybridization experiments using cloned sequences as probes or by PCR (polymerase chain reaction) testing for the presence of specific STSs/ESTs.

Another physical type of map is a radiation hybrid map. In this case, randomly fragmented DNA is cloned to create a hybrid cell line library. Different fragments are present in each hybrid cell line that is tested for the presence of a library of loci. The distance loci are reflected in the frequency of co-occurrence of two loci in the same cell line.

Also, genome restriction maps may be created by analysis of restriction sites contained on overlapping clones. The resolution of such restriction maps depends on the restriction enzyme used, and the frequency at which its recognition site occurs within the genomic DNA sample. Furthermore, an overlapping library may in itself represent a map consisting of ordered objects whose size can be approximated but not stated with certainty.

More efficient ''cloneless'' library approaches use PCR to analyze gel slices of lanes containing specific fragments. Here, the gel slices represent the cloneless library units that can be used in place of cloned DNA. In the future, cloneless approaches will likely replace time-consuming clone library construction and ordering.

4 Genomic Restriction Maps

The first step in creating a genomic restriction map is choosing the DNA source. For many organisms or chromosomes, this is obvious, since there is a well-characterized isolate or a cell line that may be useful. For most eukaryotic genomes, if available, some complications associated with the analysis of polymorphic diploid DNA can be avoided by using DNA from hybrid cell lines containing a single chromosome.

Usually, the genomic DNA is extracted and purified intact, in agarose to prevent shear damage. Small, 10-Mb chromosomal DNAs may be sized directly by PFG. Other chromosomal DNAs must be cleaved with a restriction enzyme before they are subjected to PFG analysis. The largest size standard for PFG electrophoresis is 6 Mb. Thus, analytical results use this limit, although enhanced versions of the technique allow the fractionation of molecules greater than 6 Mb.

Usually, maps are constructed using restriction enzymes that have large recognition sequences or a recognition site that occurs infrequently in the genome of interest. In some cases, it has been useful to test a battery of enzymes. The usefulness of a particular enzyme may be estimated roughly from the size of the site or the GC content of the test organism. Even so, these predictions are somewhat inaccurate because the genomic DNA sequences do not occur at random, whereas calculated occurrences assume randomness. Furthermore, the frequency of occurrence

in known sequences may not be representative of the entire genome because in the past many molecular studies have focused on gene sequencing.

Besides restriction enzymes, a number of other enzymes or methods have been adapted for cutting genomic DNA into specific, large pieces. These methods usually depend on the formation of an unusual structure (e.g. a triplex or D-loop structure) having an associated single-stranded region. D-loops are formed with the aid of RecA protein at targeted sites. In one strategy, termed the *Achilles' heel* strategy, or RARE (RecA-assisted restriction endonuclease) cleavage, genomic DNA containing a D-loop is treated with DNA methylase. The methylase recognizes and modifies specific sequence except when the sites occur within the D-loop. The methylase is removed, and the DNA is then subjected to digestion with the cognate restriction enzyme. Only the restriction enzyme recognition site in the previously formed D-loop is now susceptible to cleavage by the restriction enzyme.

This type of approach allows for site-directed cleavage of genomic DNA at specific locations and has been used to map the end of human chromosomes, as only one RARE cleavage is required. The combination of two RARE reactions from nearby sites would produce an interstitial fragment whose length would be equivalent to the distance between the two sites. Furthermore, fragments smaller than 10 Mb in size could be purified from the remaining genomic DNA using PFG electrophoresis.

Genomic map construction is similar to putting a puzzle together. It is much easier if all the pieces are identified in advance. For small genomes, this is accomplished with a restriction enzyme that produces reasonable number of fragments resolvable by PFG analysis. In these experiments, all genomic DNA is visualized by simple ethidium bromide staining.

A method was developed for visualizing all the megabase restriction fragments for individual chromosomes from large genomes. This approach analyzes PFG-fractionated restriction fragments from genomic DNA that is obtained from monosomic hybrid cell lines. Here, a species-specific interspersed repetitive hybridization probe is used to identify the megabase restriction fragments. For example, the megabase restriction fragments from chromosome 20 are visualized with a human-specific *Alu* probe in Fig. 1. This approach works as long as the restriction enzyme digestion goes to completion. Otherwise, partial digestion products can obscure the complete and especially larger digestion fragments. For the human genome, the restriction enzymes *Not* I, *Sgr*A I, *Fse* I, and *Asc* I have this desired characteristic and cut the genome into fragments that appear to average 1 Mb in size. In higher eukaryotic organisms, partial cleavage by a restriction enzyme is due to partial CpG methylation of their recognition sites inhibiting cleavage.

Most organisms will have several interspersed repeats that are of different lengths. The most commonly occurring interspersed repeat in the human genome is the *Alu* repeat. This repeat is a short interspersed repeating element (SINE) that is estimated to occur about every 5000 bp. The second most commonly occurring interspersed human repeat is the *Kpn* repeat. The *Kpn* element, a LINE (long interspersed) repeat, is estimated to occur at a frequency tenfold less than that of the *Alu* repeat. Theoretically, these two repeats used as hybridization probes to hybrid cell line DNA cleaved with the appropriate enzyme should reveal all the

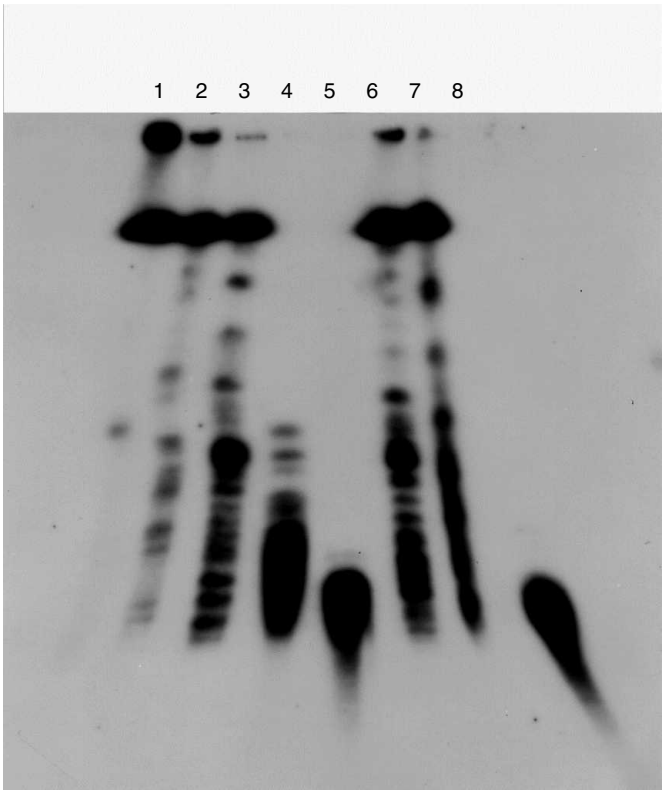

Fig. 1 Detection of PFG-fractionated restriction fragments of human chromosomes. DNA from a monosomic hybrid cell line containing chromosome 20 was digested to completion with different enzymes, PFG fractionated and hybridized to the human-specific *Alu* probe. The recognition sites for the enzymes used are: (1) *Sgf* I (GCGATCGC); (2) *Asc* I (GGCGCGCC); (3) *Fse* I (GGCCGG/CC); (4) *Pme* I (GTTTAAAC); (5) *Pac* I (TTAATTAA); (6) *Not* I (GCGGCCGC); (7) *Sgr*AI (CRCCGGYG); and (8) *Swa* I (ATTT/AAAT).

human megabase fragments. However, this approach may not distinguish two fragments of the same or very similar sizes even with high-resolution PFG fractionations.

The use of repeat sequences as hybridization probes can reveal information about the size and distribution of restriction fragments, but do not reveal order. Regional specific repetitive sequences, like those that occur at telomeric and centromeric regions may be used to identify the ends of physical map, as well as to provide an important anchor for regions of condensed chromosomes visualized microscopically. In human-hybrid cell lines, use of such sequences identifies ends of individual chromosomes.

In conventional mapping experiments, interstitial megabase fragments are linked to single-copy sequences by hybridization experiment or by the more efficient

PCR approach described in the following. Single-copy sequences, also called *STSs*, that have been located on genetic maps can be used for the regional assignment of restriction fragments and can serve as anchors between genetic and physical maps. The accuracy of fragment location will be a function of the resolution of the genetic map. When this approach is applied to a sample like that in Fig. 1, the cataloged megabase restriction fragments containing interspersed repeats are linked to specific single-copy sequences and, if known, genomic locations. ESTs are STS linked to mRNAs and their use would make a map of expressed genes. Note that any PCR primer pair can be used for mapping even if the genetic location of the specific sequence is unknown.

Complete genomic restriction maps do not identify neighboring fragments. At least one neighbor can be identified unambiguously using an STS to analyze partially digested DNA. The difficulty of interpreting the partial digestion data increases dramatically with the number of partial digestion products. For instance, it is important to consider that both the neighboring fragments may be of the same size, that is, the possibility that a single partial product band could represent two different products of the same size must always be borne in mind. This means that neighboring fragments must be confirmed in partial digestion experiments using STSs from the two complete digest fragments. Many times, the confusion associated with partial digest data can be sorted out by obtaining partial digest data on nearly adjacent fragments. In this approach, different sets of partial digest fragments are identified by sequences on different and complete digest fragments. The correct map interpretation is one that is consistent with all the data.

The analysis of partial products is simplified if the STS is from a telomere region or is situated on a small fragment located next to a very large fragment. In both cases, the partial digest information reflects the order of fragments in only one direction. Otherwise, the partial digest products results will represent bidirectional information. This approach also eliminates the problem of comigration of same-size products associated with bidirectional partial mapping data.

Megabase restriction fragments themselves may also be fingerprinted by cleavage with a second enzyme. The products are best analyzed using probes located at the end of the original megabase fragment. The partial digest product data will be different for the two probes located at different positions. The interpretation of the distribution of the cleavage sites of the second enzyme must be consistent with data obtained using the two interstitial (or terminal) probes. This approach is particularly useful for analyzing megabase fragments that are at the limit of the PFG technique, because the products of the second enzyme will be within the PFG limit.

There are several other approaches to proving that two restriction fragments are adjacent. By far the most powerful is the use of linking libraries – small-insert libraries that contain DNA segments from adjacent megabase restriction fragments. Hence, a *Not* I linking clone used as a hybridization probe to genomic DNA digested with *Not* I will identify adjacent *Not* I fragments. A complete linking library would suffice to construct, in the most efficient manner, a complete genomic restriction map. Without a complete linking library, partial digest strategies combined with polymorphism link-up and double restriction enzyme strategies can provide information on neighboring fragments. In

both approaches, parallel analysis of a region provides a regional signature.

The same polymorphism link-up refers to the results obtained when one probe is used to analyze restriction enzyme digested DNA from different cells. For instance, a restriction site may be missing in one cell line, either because there is a mutation at the restriction enzyme site or because methylation is interfering with restriction enzyme cleavage. When a number of DNA sources are examined, it is often possible to fingerprint the polymorphism of a restriction site (i.e. assuming that the site is polymorphic). The probes that are usually located on separate, but adjacent, fragments can, in some DNAs, be found on the same fragment. Many times this latter fragment will be equal to the total size of the two smaller fragments seen in other cell lines. In such a case, the pattern of occurrence of the two distinct smaller fragments, detected by the different probes, is self-consistent. This is very similar to the more familiar approach of fingerprinting a DNA using many different restriction enzymes.

5 Genomic Clone Libraries

The construction and ordering of an overlapping library begins with the selection of the genomic DNA sample as discussed earlier. The next decision entails choice of the type of vector that will be used. The most distinguishing feature of vector possibilities is the size of the DNA that can be cloned into them. It is helpful to begin whole-genome mapping projects using the largest DNA fragments possible, minimizing the number of clones to order. In the past, the largest cloning vectors were cosmids that contained 40-kb cloned sequences. Today, several systems are available for the cloning of larger segments. For instance, megabase fragments can be cloned into YACs (yeast artificial chromosomes) in yeast cells. These libraries have been replaced by the easier to use and more stable PAC (P1 artificial chromosomes) and BAC (bacterial artificial chromosomes) libraries that clone fragments of about 100 kb in size. Today, the construction and ordering of PAC/BAC libraries still remains a major effort.

Usually, today's top-down sequencing approaches begin by creating large clone BAC libraries. Then, random, small overlapping fragments of each BAC are subcloned into sequencing vectors. The large clone libraries are ordered using a variety of techniques (see the following), whereas sequencing is done on an unordered library. Ultimately, the small-insert library is ordered when overlaps are identified while the sequence is put together.

Clone Ordering. In the past, chromosome walking (or ''crawling'') experiments, involved hybridizing individual clones to an entire genomic library to detect overlapping clones. Although this approach is guaranteed to detect overlapping clones, it is slow and laborious.

Today, many efficient genomic approaches are used to order all the clones in a library. The genomic approaches analyze many samples at the same time in a ''multiplex'' approach and generally use methods that are easy to automate. For instance, clones are analyzed in pools to minimize the number of experiments that are needed to order the entire library. In some cases, a tiered pooling strategy is used, where the first testing is done on a small group of superpools, each composed of different pools. Only the pools that make

up a positive superpool needs to be further analyzed. Some designed pooling strategies have each clone present in multiple but distinct pools. The pattern of positive signals to such a set of pools will reveal the identity of the overlapping clones.

Most bottom-up, fingerprinting methods require that libraries be constructed using partial restriction enzyme digests to ensure that overlaps exist between different clones and that all or most of the genome is cloned. There are a number of ways to fingerprint clones to identify overlaps. Bottom-up strategies for library ordering usually involve testing individual clones to search for an overlapping restriction fragment or restriction site pattern. This type of fingerprinting is easy to automate. Clones may also be fingerprinted using interspersed repetitive sequences. Here, clones, or restriction fragments of the clones, are hybridized to a set of short oligonucleotides or longer interspersed repetitive sequences, and the patterns of hybridization are used to link clones.

A variation in this approach that has proven to be quite efficient is the use of genomic DNA restriction fragments as hybridization probes to order clone libraries. Megabase restriction fragment probes allow the assignment of clones to particular fragments. If the fragments are mapped, the clones can then be regionally assigned in the genome. Clones located in different regions are ordered simultaneously by further hybridization experiments using probes generated from a pool of restriction fragments. Here, the pools are created from gel slices containing small restriction fragments. Each pool consists of genomic restriction fragments of a particular size range from different regions of the genome. Overlapping clones will be located on the same megabase fragment and hybridize to the same pool of small fragments. This approach increases the efficiency of library ordering by eightfold.

Another ordering approach involves detecting overlaps by DNA sequencing. Here, the sequences may be chosen at random sites (e.g. STSs) or the sequences can be collected at specific locations originally called *sequence-tagged restriction sites* (STARs). The STAR approach may be used with both partial and complete digest libraries. DNA sequence information may be collected at specific restriction sites, including the ends of the cloned sequences. Clone linking is done using a linking clone library that spans the restriction enzyme site when the first library was created from completely digested DNA. Clones that generated from partial restriction enzyme digestions have ends that overlap. The later method eliminates the need for up-front clone ordering, but a highly representative library is required, and sequence read lengths must be long enough to span most small repeats.

6 Cloneless Genomic Libraries

Cloneless libraries have several advantages over clone libraries. These libraries can be made rapidly and inexpensively from any genomic source and all genomic DNA is present in the library. These libraries are made from agarose or acrylamide gels containing size fractionation DNA of low or high complexity. The gel slice containing the cloneless fraction is treated in the same manner as a cloned DNA sample.

In most of the discussion below, only complete digest cloneless libraries are discussed. However, partially digested or random broken DNAs could be used to

generate a cloneless library. In essence, the analysis and use of a cloneless library is very similar to that of a clone library.

The gel lane is carefully sliced into thin pieces using a clean coverslip for each cut to insure minimum cross-contamination. The DNA in each slice is used as a source for testing, for instance, with PCR. For small and medium size genome, the number of unique fragments within a slice will be small. For large genomes, there are many fragments in a single slice. In the case of samples from the gels, like those shown in Fig. 1, the only visible fragment is from the human DNA but other rodent fragments are present. The cloneless approach is a hybrid between genomic mapping and clone ordering.

One consideration with the cloneless approach is that DNA in agarose is believed to be difficult to manipulate enzymatically. However, others and we have developed robust and reliable simple methods for using DNA in agarose that avoids purification. Most methods were developed some time ago for PFG applications. Additional methods were developed more recently for PCR that involve the addition of preservatives to the stored fraction and the PCR.

Another potential problem with cloneless fractions is the low amount of DNA in each slice. There are a number of PCR methods that solve this problem by randomly amplifying the DNA in a fraction (or clone) to generate a large amount of additional material. Furthermore, these methods have been developed to minimize the introduction of mutations. Hence, the amplified DNA appears to be representative of the starting template.

Cloneless fractions can be used for a variety of experiments in addition to that of genomic sequencing. For instance, a recently developed method termed *comparative genome hybridization* (CGH) uses differentially labeled cDNA, or genomic DNA, from two samples. The labeled samples are mixed together in equal amounts and used as a hybridization probe. The target samples are metaphase chromosomes or clones. Quantitative analysis of the hybridization signal provides information on the relative amounts of DNA from different chromosomal regions. In summary, CGH experiments provide positional information of differences between samples.

An alternative to conventional CGH would utilize genome DNA arrays that have been generated from size-fractionated genomic restriction fragments. An array consisting of 2-mm slices from a 15-cm gel lane would have ~40-Mb resolution. Each fraction could be cleaved with a second enzyme and subjected to a second electrophoretic size fractionation. The ~1000 slices generated from the entire second fractionation would provide DNA at ~3-Mb resolution.

The cloneless, like a clone library approach does not provide positional genomic information directly. For instance, clones are linked to genomic position by FISH (fluorescence *in situ* hybridization) experiments to metaphase chromosomes. Similarly, the DNA in each slice can be used in a FISH experiment to metaphase chromosome and locate it to a specific genomic region. Genomic restriction maps, or ordered clone, or cloneless libraries can be used in place of metaphase chromosomes especially in those organisms, like protozoan, whose chromosomes do not condense during cell division.

The approaches used to order clone libraries may be applied to cloneless libraries. For instance, fraction can be linked to STSs/ESTs. Alternatively, hybridization experiments or other methods that were

described earlier can be used to detect overlaps with clone libraries or a second cloneless library generated with a second enzyme.

Cloneless libraries can be used in place of X-ray hybrid maps. X-ray hybrid maps are created by determining the frequency that two loci are separated by random breaks in DNA generated by X rays. In this approach, randomly broken DNA is cloned into a hybrid cell line and a library of different cell lines are created with different pieces of DNA. Then, each cell line is tested for the presence of a marker and a centiRay distance is calculated that reflects the frequency at which two loci occur in the same cell line. Like genetic mapping, the closer two loci are, the more likely they will be on the same randomly generate fragments. Here, instead of cell lines, randomly broken DNA fractionated by size could be used to create a cloneless library. Then each fraction could be tested for each loci and the distance between loci calculated as a function of the number of fractions that contain both loci.

7 Gap Closure

It is easy to start maps but difficult to finish them. Each gap in each map presents a unique problem. Gaps may be true gaps or pseudogaps. Pseudogaps contain repetitive sequences and require different strategies for closure than true gaps.

True gaps contain unique sequences and need to be treated individually. The best strategy will depend on the putative size of the gap, the amount of polymorphism in the region, the number of unassigned megabase fragments or clones. Gaps that arise from unclonable sequences may be filled using a cloneless library. For instance, STSs could be developed from cloneless fraction that overlap two regions as we have done for chromosome 21. For instance, single-copy human sequences located between *Alu* elements can be generated from inter-*Alu* PCR amplifications and used as probes to identify fragments in gap regions. Alternatively, the template contained within a fraction can be labeled and used as a hybridization probe to an array of samples at the borders of gaps. Ultimately, the DNA within a gap is identified in a cloneless library and directly sequenced using a direct genomic sequences approach.

8 Prospectus

What is the role of physical maps today and in the future? An increasing sequencing efficiency is coupled to a decreasing need to create and order expensive and time-consuming clone libraries. For small genomes, whole-genome sequencing projects use a bottom-up sequencing approach with unordered clone libraries. Soon a cloneless sequencing approach using ''polonies'' may replace the need for cloning of these small genomes. The polonies approach sequences pools of single DNA molecules that have been immobilized on beads. Sequencing is done on a library of immobilized DNAs simultaneously. Today, this method allows sequencing read of up to ~14 bases per fragment end, or ~28 bases per polony, and up to 1×10^9 beads/slide. Alternatively, imaging methods that directly view the sequence of individual DNA molecules may be used. Meanwhile, adaption of the cloneless approach for larger genome sequencing projects should considerably reduce *de novo* sequencing by eliminating

the need for creating clone libraries, as well as enable gap closure.

Keywords

Accommodation
Establishment of an organ transplant in a recipient from whom antidonor antibodies have been depleted. Rejection does not ensue when antidonor antibodies return to the circulation because of changes in the antibody, in the antigen, or in susceptibility of the organ to rejection.

Acute Vascular Rejection
A rejection that may begin within 24 hours of implantation of a vascular graft and leading to graft destruction over the ensuing days to weeks. Mediated by graft reactive antidonor antibodies, activation of the complement cascade, and possibly NK cells and macrophages.

Genetic Engineering
A general term that covers the use of various experimental techniques to produce molecules of DNA-containing new genes or novel combinations of genes, usually for insertion into a host cell for cloning.

Humoral Immunity
The component of the immune system involving B-lymphocytes, antibodies, and related cytokines. B-lymphocytes respond to the presence of antigen and differentiate to antibody-secreting plasma cells. The antibodies in turn neutralize antigen, activate phagocytic cells, recruit lytic enzymes and activate the complement cascade to destroy antigen-bearing cells.

Hyperacute Rejection
A rejection that usually develops in less than one hour from the implantation of a vascular graft, a form of antibody-mediated, usually irreversible, damage to a transplanted organ manifested predominantly by diffuse thrombotic lesions, usually confined to the organ itself and only rarely disseminated.

Xenotransplantation
The surgical removal of an organ or tissue from one species and transplanting it into a member of a different species, for example: the use of a baboon heart in a human being.

Zoonosis
The transmission of a disease from an animal or nonhuman species to humans. The natural reservoir is a nonhuman animal.

For nearly a century, xenotransplantation has been seen as a potential curative approach to replacing the function of diseased or damaged organs. Until recently, however, the application of xenotransplantation has seemed only a remote possibility. Genetic engineering of large animals has allowed the ability to add genes and remove genes from lines of animals, which could provide an enduring source of tissues and organs for clinical application. Genetic engineering could address the immunologic, physiologic, and infectious barriers to xenotransplantation, and could expand the utility of xenotransplantation to provide a source of cells with defined expression of exogenous genes for treatment of human disease.

1 Introduction

1.1 Alternative Sources of Transplantable Tissues

No area of medicine has generated more excitement or controversy than the field of transplantation. Organ allotransplantation allows ''curative'' treatments for failure of the heart, kidney, liver, and lungs by replacing these diseased organs with physiologically normal ones. Replacement of β cells via pancreatic islet or whole pancreas transplantation offers curative treatment to patients with diabetes. The main limitation to applying transplantation for the treatment of disease is a shortage of human donors. This shortage limits the clinical application of organ transplantation to approximately 5% of the number of transplants that would be performed where the supply of organs is unlimited. Possible solutions to this limitation have garnered considerable interest and include use of artificial organs, ''engineered tissues,'' stem cell transplants and xenotransplants. Although some newer technologies have excited interest, xenotransplants of the heart, lung, kidney, and pancreatic islets are known to function well enough to sustain life. Enthusiasm for xenotransplantation also stems from the possibility that animal tissues and organs might be less susceptible to disease recurrence compared to allotransplants. Advances in cellular and molecular biology and in genetics open possibilities for use of cells, tissues, and organs to address the complications of disease, not only by replacement of abnormal cells and tissues but also by the use of transplanted tissues to impart novel physiological functions. In this regard and for some purposes, xenografts may be an ideal vehicle for introducing a novel gene or biochemical process that could be of value to the transplant recipient.

If interest in xenotransplantation is substantial, the hurdles to its application are equally so. For the past three decades, the first and preeminent obstacle to transplanting organs and tissues between species has been the immune reaction of the host against the graft. A second, and still theoretical, hurdle is the possibility that beyond the immune barrier, there might be physiologic limitations to the survival or function of a xenograft and the possibility that a xenotransplant might engender medical complications for the xenogeneic host. A third hurdle is the possibility that a xenograft might transfer

infectious agents from the donor to the host and that from the host such agents might spread to other members of society. This communication will consider the current state of efforts to overcome the various hurdles to xenotransplantation and will evaluate how genetic engineering might be applied to this end.

1.2 The Pig as a Source of Tissues and Organs for Clinical Xenotransplantation

Although it might be intuitive that the best source of xenogeneic tissues for clinical transplantation is nonhuman primates, it is the pig that is the focus of most efforts in this field. The reasons for favoring the pig as a xenotransplant source include the availability of pigs in large numbers, the ease with which the pig can be bred, the limited risk of zoonotic disease engendered by the use of pigs, and the possibility of introducing new genes into the germline of the pig.

Genetic engineering of pigs using transgenic techniques and nuclear transfer has certain advantages over conventional gene therapy (Table 1). Introducing genetic material directly into the porcine germ cell obviates the need for a vehicle, which may vary in reliability of gene delivery and may introduce secondary unintended consequences due to the vector itself. Second, the genetic material introduced into the germline can be expressed constitutively in

Tab. 1 Genetic engineering in xenotransplantation: conventional gene therapy versus transgenic therapy versus cloning.

	Conventional gene therapy	***Conventional transgenic techniques***	***Cloning***
Delivery	Vector or vehicle required	Injection of genetic material directly into pro-nuclei of fertilized egg	Transfection of cultured somatic cells
Expression	Dependent on ability of each cell to take up genetic material	Genetic material introduced into the germline, leading to expression in a line of animals	Genetic material introduced into the germline, leading to expression in a line of animals
	Requires treatment for every transplant or recipient		
	May require repeated treatment	One manipulation	One manipulation
Immunogenicity	Delivery vehicle or transgene may be immunogenic	The transgene may elicit immune response	The transgene may elicit immune response
Target of genetic manipulation	The recipient and the graft may be transduced	Genetic manipulation of the donor only	Genetic manipulation of the donor only
Genetic manipulation	Gene addition Dominant negative	Gene addition Dominant negative	Gene addition Dominant negative Gene knock out

all cells, especially in stem cells, and passed on to subsequent generations. Third, with the use of transgenic techniques, only the donor is manipulated; in conventional gene therapy, both the donor and the recipient may be affected.

Recent advances in cloning pigs through nuclear transfer also allow "knocking out" genes. Besides the advantage of gene knockouts, nuclear transfer can be done with cultured somatic cells obviating the need for embryonic stem cells.

2 The Biologic and Immunologic Responses to Xenotransplantation

2.1 Graft Vascularization

All xenografts elicit an immune response, including antibodies, cell-mediated immunity, natural killer cells and inflammation. However, the fate of xenografts confronted with these responses is dictated in part by the way in which the graft receives its vascular supply (Fig. 1). Isolated cells, such as hepatocytes, and "free" tissues, such as pancreatic islets and skin, derive their vascular supply through the ingrowth of host blood vessels. The process of neovascularization, as such, might be impaired in a xenograft by incompatibility of donor growth factors with the host microvasculature. To the extent that neovascularization or graft function depends upon hormones and cytokines of host origin, the function of the xenograft might also be impaired. As the host microcirculation is established, however, a xenogeneic tissue may be relatively protected from attack by host immune elements. Whole-organ grafts provide their own microcirculation and growth factors, and, as a result, incompatibility between the donor and the recipient is less likely to have an impact on cellular function. On the other hand, because the circulation is of donor origin, the immune, inflammatory, and coagulation systems of the recipient can act directly on donor cells, sometimes with dramatic and devastating consequences.

2.2 Hyperacute Rejection

An organ transplanted from a pig into a primate such as a human is subject to hyperacute rejection. Hyperacute rejection begins immediately upon reperfusion of the graft and destroys the graft within minutes to a few hours. Hyperacute rejection is characterized histologically by interstitial hemorrhage and thrombosis, the thrombi consisting mainly of platelets.

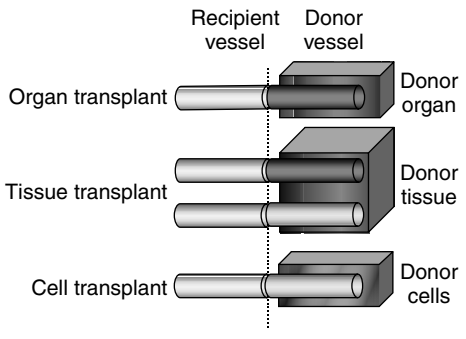

Fig. 1 Mechanisms of xenograft vascularization. Organ xenografts receive recipient blood exclusively through the donor blood vessels (top). Free tissue xenografts (e.g. Pancreatic islets and skin) are vascularized partly by the ingrowth of recipient blood vessels and partly by spontaneous anastomosis of donor and recipient capillaries (middle). Cellular xenografts (e.g. hepatocytes and bone-marrow cells) are vascularized by the ingrowth of recipient blood vessels (bottom).

Research over the past decade has clarified the molecular basis for the hyperacute rejection of pig organs by primates, and this knowledge has led to the development of new and incisive therapeutic approaches to averting this problem. Hyperacute rejection was once considered the most daunting hurdle to clinical application of xenotransplantation; however, hyperacute rejection can now be prevented in nearly every case.

Hyperacute rejection of porcine organ xenografts by primates is initiated by the binding of xenoreactive natural antibodies to the graft. Xenoreactive natural antibodies are present in the circulation without a known history of sensitization. Contrary to expectations, xenoreactive antibodies are predominantly directed against only one antigen, a saccharide consisting of terminal Galα1,3Gal. The importance of Galα1,3Gal as the primary antigenic barrier to xenotransplantation was demonstrated recently by experiments in which anti-Galα1,3Gal antibodies were specifically depleted from baboons using immunoaffinity columns before transplantation of pig organs. Antibody-binding to the newly transplanted organs was largely curtailed, and hyperacute rejection did not occur.

Although the identification of the relevant antigen for pig-to-primate xenotransplantation allows specific depletion of the offending antibodies, more enduring and less intrusive forms of therapy would be preferred. One approach to overcoming the antibody–antigen reaction is to develop lines of pigs with low levels of antigen expression. Various genetic approaches aimed at ''remodeling'' the antigenicity of donor tissues by reducing Galα1,3Gal expression are under investigation. These approaches can be separated into three categories: (1) interference with the function of α1,3-galactosyltransferase (α1,3GT), the enzyme that catalyzes the synthesis of the Galα1,3Gal moiety; (2) expression of α-galactosidase, which cleaves α-galactosyl residues; and (3) deletion of the gene encoding α1,3GT from the pig genome to prevent synthesis of the saccharide. The utility of genetic modification of pig tissues to reduce Galα1,3Gal expression has recently been demonstrated by Sharma and colleagues, who generated transgenic pigs expressing the H-transferase. Transgenic pigs expressing H-transferase express H antigen at the terminus of some sugar chains instead of Galα1,3Gal. Another genetic approach to modify expression of Galα1-3Gal was proposed by Osman et al. Expression of α-galactosidase, which cleaves α-galactosyl residues, in conjunction with other galactosyltransferases, significantly reduces expression of Galα1-3Gal. A third strategy to modify Galα1,3Gal was demonstrated by Miyagawa and coworkers who generated transgenic pigs expressing the human β-1,4 – *N*-acetylglucosaminyltransferase III gene (GnT-III). This enzyme catalyzes transfer of *N*-acetylglucosamine to maturing mannose-modified proteins as they pass through the Golgi apparatus and leads to diminished Galα1,3Gal expression both by competing with α1,3GT and by preventing subsequent modifications by α1,3GT by insertion of an *N*-acetylglucosamine onto the growing mannose chain. The net result was diminished natural antibody reactivity on transgenic pig tissue when transplanted into primates. Although these advances illustrate the utility of genetic modification of pig donor tissue, the main limitation of these genetic approaches is that residual Galα1,3Gal may be sufficient to allow rejection reactions to occur.

The most obvious approach to developing xenograft donors with diminished reactivity with host antibodies would be to genetically target or "knock out" the enzyme α1,3-galactosyltransferase. Embryonic stem cells were used to knock this gene out in mice, demonstrating that removal of this enzyme is not lethal. The intense interest in generating pigs that lack the α1,3GT gene has fueled a race to delete this gene from the pig genome, and recently several groups have succeeded in this endeavor. Prather and colleagues and Ayares and coworkers used similar strategies to disrupt one allele of the α1,3GT gene (GGTA1) in pigs by first targeting the gene for disruption in fetal porcine fibroblasts. Selected clones were used as nuclear donors for enucleated pig oocytes, the resulting embryos implanted into surrogate gilts. Both approaches yielded live, healthy piglet clones in which one copy of GGTA1 had been disrupted. These achievements demonstrated that nuclear transfer technology could be applied to pig embryos, which are notoriously fragile and difficult to manipulate. Recently, the generation of cloned pigs harboring a functional knockout of both alleles of α1,3GT was reported. This first success required some serendipity in that the α1,3GT-deficient pigs were found not to be homozygous knockouts, but rather a functional knockout arose from a process in which a knockout of one allele paired with a spontaneous single base change in the remaining GGTA1 gene resulted in an inactivating amino acid substitution in α1,3GT. Pigs with both alleles targeted were described by Dor and colleagues. These pigs were miniature swine with homozygous deletion of the α1,3GT gene (α1,3GT$^{-/-}$), do not express Galα1,3Gal epitopes on any tissue and, as might be expected, make anti-Galα1,3Gal reactive natural antibodies that are cytotoxic to cells from α1,3GT$^{+/+}$ pigs.

The availability of pigs with inactivation or deletion of α1,3GT should allow confirmation of the importance of Galα1,3Gal for hyperacute rejection, but may reveal other hurdles to xenotransplantation. For example, a cautionary note has recently come to light, indicating that pig cells that lack both copies of the GGTA1 gene may still synthesize the Galα1,3Gal antigen, albeit at very low levels. A further caution was suggested by Miyata et al., who found that murine lungs lacking Galα1,3Gal still bound natural antibodies and activate complement when perfused by human serum, and these events are associated with diminished lung perfusion. Thus, removal of Galα1,3Gal may not avert other potent xenogeneic immune responses, as will be discussed below.

2.3 Complement Activation

A second and essential step in the development of hyperacute rejection is activation of the complement system of the recipient on donor blood vessels. Complement activation is triggered by the binding of complement-fixing xenoreactive antibodies such as natural antibodies directed against Galα1,3Gal to graft endothelium and, to a smaller extent perhaps, by reperfusion injury. Regardless of the mechanism leading to complement activation, a xenograft is extraordinarily sensitive to complement-mediated injury because of multiple defects in the regulation of complement (Fig. 2). Under normal circumstances, the complement cascade is regulated or inhibited by various proteins in the plasma and on the surface of cells. These proteins protect normal

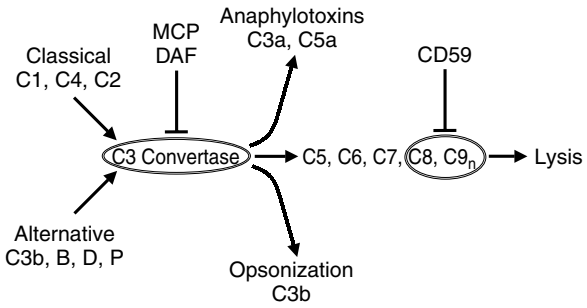

Fig. 2 Regulation of the complement system. The complement cascade, which can be activated via the classical or alternative pathway, is regulated under normal circumstances by various proteins in the plasma and on the cell surface. Three of the cell-surface complement regulatory proteins are shown here. Decay-accelerating factor (DAF) and membrane cofactor protein (MCP) regulates complement activation by dissociating or promoting the degradation of C3 convertase. CD59, also known as protectin, prevents the functions of terminal complement complexes by inhibiting C8 and C9. An organ graft transplanted into a xenogeneic recipient is especially sensitive to complement-mediated injury because decay-accelerating factor, membrane cofactor protein, and CD59 expressed on the xenograft endothelium cannot effectively regulate the complement system of the recipient.

cells from suffering inadvertent injury during the activation of complement. The proteins that regulate the complement cascade function in a species-restricted fashion; that is, complement regulatory proteins inhibit homologous complement far more effectively than heterologous complement. Accordingly, the complement regulatory proteins expressed in a xenograft are ineffective at controlling the complement cascade of the recipient, and the graft is subject to severe complement-mediated injury.

To address this problem, lines of animals have been developed that lack the Galα1,3Gal epitope recognized by natural antibodies (see Sect. 2.2) or that are transgenic for human complement regulatory proteins and that are able to control activation of complement in the xenograft (Fig. 2). Animals transgenic for human decay-accelerating factor (hDAF), which regulates complement at the level of C3 together with CD59, which regulates complement at the level of C8 and C9 or CD46, which controls complement activation at the level of C3 and C4, have demonstrated that the expression of even low levels of human decay-accelerating factor and CD59 or CD46 in porcine-to-primate xenografts is sufficient to allow a xenograft to avoid hyperacute rejection. These results, and the dramatic prolongation of xenograft survival achieved by expressing higher levels of human decay-accelerating factor in the pig, underscore the importance of complement regulation as a determinant of xenograft outcomes.

One of the major obstacles to testing the effects of transgenes in pig organs has

been the difficulty in generating transgenic pigs. Recent work by Lavitrano, et al. may accelerate the rate at which transgenic pigs may be generated and tested in transplant models. These investigators used sperm-mediated gene transfer to incorporate the human decay-accelerating factor gene into pigs and obtained a high efficiency of transgenesis (80% of pigs incorporated hDAF into the genome) and hDAF expression (43% of the transgenic pigs). The transgenic hDAF was functional *in vitro*, and transmitted to progeny as expected. This method in theory could be used to introduce multiple genes at once, or a tailor-made set of human genes that may be useful for transplant-mediated genetic therapies, as mentioned earlier.

2.4 Acute Vascular Rejection

If hyperacute rejection of a xenograft is averted, a xenograft is subject to the development of acute vascular rejection, so named because of its resemblance to acute vascular rejection of allografts. Acute vascular rejection (sometimes called *delayed xenograft rejection*) may begin within 24 hours of reperfusion and leads to graft destruction over the following days and weeks. Although the factors important in the pathogenesis of acute vascular rejection are incompletely understood, there is growing evidence that acute vascular rejection is triggered at least in part by the binding of xenoreactive antibodies to the graft. The importance of xenoreactive antibodies in triggering acute vascular rejection is suggested by three lines of evidence: (1) antidonor antibodies are present in the circulation of recipients whose grafts are subject to acute vascular rejection; (2) depletion of antidonor antibodies delays or prevents acute vascular rejection; and (3) administration of antidonor antibodies leads to the development of acute vascular rejection. Recent studies suggest that among the antibodies that provoke acute vascular rejection are those directed against Galα1-3Gal. This problem thus constitutes further impetus for the continued development of α1,3Gal-deficient pigs. Regardless of which elements of the immune system trigger acute vascular rejection, it is commonly thought that this type of rejection, and especially the intravascular coagulation characteristically associated with it, are caused by the activation of endothelial cells in the transplant. Activated endothelial cells express procoagulant molecules, such as tissue factor, and proinflammatory molecules, such as E-selectin and cytokines. The pathogenesis of acute vascular rejection is summarized in Fig. 3.

Although various therapeutic manipulations have proven successful in preventing hyperacute rejection, acute vascular rejection poses a more difficult problem, in part, because therapies are needed on an ongoing basis. For this reason, genetic modification of the donor may prove more important for dealing with acute vascular rejection than with hyperacute rejection. The various possible approaches for combating acute vascular rejection are listed in Table 2. Among these approaches, the reduction of Galα1,3Gal in xenotransplant donors may be an important part of the overall strategy, to the extent that Galα1,3Gal proves to be an important antigenic target in acute vascular xenograft rejection. Preliminary studies suggest that the level of antibody-binding needed to initiate acute vascular rejection is considerably lower than the level needed to initiate hyperacute rejection. Accordingly, the antigen expression

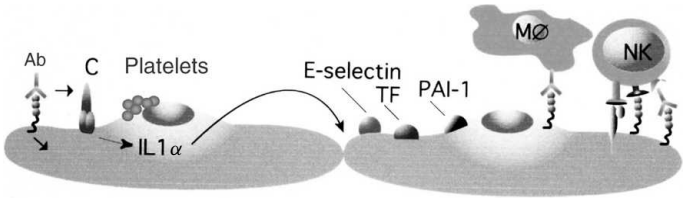

Fig. 3 Pathogenesis of acute vascular rejection. Activation of endothelium by xenoreactive antibodies (Ab), complement (C), platelets and perhaps by inflammatory cells (natural killer [NK] cells and macrophages [MØ]) leads to the expression of new pathophysiologic properties. These new properties, such as the synthesis of tissue factor (TF) and plasminogen activator inhibitor type 1 (PAI-1), promote coagulation; the synthesis of E-selectin and cytokines such as IL1α promote inflammation. These changes in turn cause thrombosis, ischemia, and endothelial injury, the hallmarks of acute vascular rejection. (Adapted from Platt, J. L. (1998) New directions for organ transplantation, *Nature* **392**(Suppl. 6679), 11–17, with permission).

Tab. 2 Therapeutic strategies for acute vascular xenograft rejection.

Possible mechanism targeted	***Manipulation of:***	
	Recipient	***Donor***
Antibody–antigen interaction	Specific depletion of xenoreactive antibodies Prevention of xenoreactive antibody synthesis (e.g. cyclophosphamide, leflunomide)	Generating transgenic pigs with low levels of antigen Generation of pig clones lacking antigen
Complement activation	Systemic anticomplement therapy (e.g. CVF, sCR1, gamma globulin)	Generation of donor pigs transgenic for human complement regulatory proteins
Endothelial-cell activation	Administration of anti-inflammatory agents	Inhibition of NFκB function Introduction of protective genes
Molecular incompatibilities	Administration of inhibitors (e.g. inhibitors of complement or coagulation)	Introduction of compatible molecules

would have to be reduced very significantly to achieve therapeutic benefit for acute vascular rejection. The availability of α1,3galactosyltransferase-deficient pigs should prove to be an ideal model to test this concept. In addition to lowering antigen expression, it is likely that expression of human complement regulatory proteins will be helpful in preventing acute vascular rejection. Preliminary studies suggest that interfering with the antigen–antibody reaction and controlling the complement cascade may be sufficient to prevent acute vascular rejection for at least

some period of time. These goals were accomplished by using animals transgenic for human decay-accelerating factor and CD59 as a source of organs and baboons depleted of immunoglobulin as recipients. Cozzi and associates achieved prolonged survival of xenografts, presumably preventing acute vascular rejection, by using transgenic pigs expressing high levels of decay-accelerating factor and cynomolgus monkeys treated with very high doses of cyclophosphamide. The immunosuppression perhaps prevented the synthesis of antidonor antibodies.

Work in rodents points to the potential involvement of natural killer (NK) cells and macrophages in mediating acute vascular rejection. However, the ability of immunoglobulin manipulation to prevent acute vascular rejection suggests that the involvement of NK cells and macrophages might be less important than *in vitro* studies and studies in rodents have suggested. On the other hand, NK cells might exacerbate the injury triggered by xenoreactive antibodies, as human NK cells have been shown to activate porcine endothelial cells *in vitro*.

2.5 Accommodation

Fortunately, the presence of antidonor antibodies in the circulation of a graft recipient does not inevitably trigger acute vascular rejection. If antidonor antibodies are temporarily depleted from a recipient, an organ transplant can be established so that rejection does not ensue when the antidonor antibodies are returned to the circulation. This phenomenon is referred to as *accommodation*. Accommodation may reflect a change in the antibodies, in the antigen, or in the susceptibility of the organ to rejection. If accommodation can be established, it may be especially important in xenotransplantation because it would obviate the need for ongoing interventions to inhibit antibody-binding to the graft. One potential approach to accommodation may be the use of genetic engineering to reduce the susceptibility of an organ transplant to acute vascular rejection and the endothelial-cell activation associated with it. Unfortunately, successful intervention at the level of such effector mechanisms has yet to be achieved. However, disruption of antibody–antigen interaction has brought about accommodation in human subjects.

2.6 Cellular Mediated Immune Responses

Organ transplants and cellular and free tissue transplants are subject to cellular rejection. In allotransplantation, cellular rejection is controlled by conventional immunosuppressive therapy, but there is concern that, for several reasons, cellular rejection may be especially severe in xenotransplants. First, the great variety of antigenic proteins in a xenograft may lead to recruitment of a diverse set of ''xenoreactive'' T cells. Second, the binding of xenoreactive antibodies and activation of the complement system may lead to amplification of elicited immune responses. For example, deposition of complement in a graft may cause activation of antigen-presenting cells, in turn stimulating T-cell responses. Still another factor that might amplify the elicited immune response to a xenotransplant involves ''immunoregulation,'' which ordinarily would circumscribe cellular immune responses, but may fail or be deficient across species. Such failure could reflect limitations in

the recognition of xenogeneic cells or incompatibility of relevant growth factors, as but two examples.

Induction of immunologic tolerance has been an erstwhile goal of transplant surgeons and physicians. Especially in the case of xenotransplantation, if the current immunosuppressive regimens are not sufficient, induction of immunologic tolerance may be required. At least three approaches are being pursued: (1) the generation of mixed hematopoietic chimerism, (2) the establishment of microchimerism by various means, and (3) thymic transplantation. The development of mixed hematopoietic chimerism through the introduction of donor bone marrow has worked very well across rodent species, although success may be limited by xenoreactive antibodies and the engraftment impaired by incompatibility of host growth factors or microenvironment. Fortunately, there is evidence that these problems can be overcome. Various approaches to peripheral tolerance, such as the blockade of costimulation by administration of a fusion protein consisting of a soluble form of the CTLA-4 molecule and immunoglobulin (CTLA-4-Ig), are being pursued.

Still another factor in the cellular response to a xenotransplant involves the action of NK cells. Natural killer cell functions can be amplified by cell-surface receptors that recognize Galα1-3Gal. Natural killer cell functions are downregulated by receptors that recognize homologous major histocompatibility complex (MHC) class I. Human NK cells may be especially active against xenogeneic cells because of stimulation on the one hand and failure of downregulation on the other. The possible involvement of NK cells in xenograft rejection might be addressed by generation of transgenic pigs expressing on the cell-surface MHC-like molecules that will more effectively recognize corresponding receptors on NK cells and that will downregulate the function of NK cells.

How a xenogeneic donor could be modified genetically to enhance the development of tolerance or to limit elicited immune responses is still uncertain. Clearly, efforts to control the natural immune barriers to xenotransplantation may contribute to limiting the elicited immune response. To the extent that recipient T cells recognize donor cells directly, that is, the T-cell receptors of the recipient recognizing native MHC antigens on donor cells, a xenogeneic donor might be engineered in such a way to reduce corecognition (through CD4 and CD8) or costimulation (through CD28 or other T-cell surface molecules) or to express inhibitory molecules such as CD59 or Fas ligand. These approaches and the expression of inhibitory molecules, which are being considered as approaches to gene therapy in allotransplantation, may well prove more effective in xenotransplantation because inhibitory genes can be introduced as transgenes and thereby expressed in all relevant cells in the graft. Another useful and perhaps necessary approach will involve genetic modifications to allow the survival and function of donor bone-marrow cells.

3 Physiologic and Infectious Hurdles to Xenotransplantation

3.1 Interspecies Challenges

Progress in addressing some of the immunological obstacles to xenotransplantation has brought into focus the question of

the extent to which a xenotransplant would function optimally in a foreign host. A recent demonstration that the porcine kidney and the porcine lung can replace the most important functions of the primate kidney and primate lung is encouraging. Subtle defects in physiology across species may nevertheless exist. Organs such as the liver, which secrete a variety of proteins and which depend on complex enzymatic cascades, may prove incompatible with a primate host. Accordingly, one important application of genetic engineering in xenotransplantation may be the amplification or modulation of xenograft function to allow for more complete establishment of physiologic function or to overcome critical defects; for example, recent studies by Akhter and associates and Kypson and coauthors aimed at improving the function of cardiac allografts by manipulation of β-adrenergic signaling, and this technique might be adapted to the xenotransplant to improve cardiac function. On the other hand, most cellular processes and biochemical cascades are intrinsically regulated to meet the overall physiologic needs of the whole individual. The key question, then, is which of the many potential defects actually need to be repaired.

Another potential hurdle to the clinical application of xenotransplantation is the possibility that the xenograft may disturb normal metabolic and physiologic functions in the recipient. For example, Lawson and coworkers have shown that porcine thrombomodulin fails to interact adequately with human thrombin and protein C to generate activated protein C. This defect could lead to a prothrombotic diathesis because of failure of generation of activated protein C. Of even greater concern is the possibility that the transplantation of an organ, such as the liver, could add prothrombotic or proinflammatory products into the blood of the recipient. Although perhaps a great many physiologic defects can be detected at the molecular level, the critical question will be which of these defects is important at the whole-organ level or with respect to the well-being of the recipient, and which must be repaired by pharmaceutical or genetic means.

3.2 Zoonosis

The increasing success of experimental xenotransplants and therapeutic trials bring to the fore the question of zoonosis, that is, infectious disease introduced from the graft into the recipient. The transfer of infectious agents from the graft to the recipient is a well-known complication of allotransplantation. To the extent that infection of the recipient in this way increases the risks of transplantation, that risk can generally be estimated and a decision made on the basis of the risk versus the potential benefits conferred by the transplant. The concern about zoonosis in xenotransplantation is not so much the risk to the recipient of the transplant, but the risk that an infectious agent will be transferred from the recipient to the population at large. Fortunately, all of the microbial agents known to infect the pig can be detected by screening and potentially eliminated from a population of xenotransplant donors. There is concern, however, that the pig may harbor endogenous retroviruses that are inherited with genomic DNA and that might become activated and transferred to the cells of the recipient.

The possibility that an endogenous retrovirus from swine might pose a hurdle to xenotransplantation was first raised by Patience et al. Reports from several laboratories have raised concern about transmission of porcine retroviruses. Patience and coauthors found that the porcine endogenous retrovirus (PERV) can be activated in pig cells, leading to the release of particles that can infect human cell lines. Whether this virus or other endogenous viruses can actually infect across species and whether such infection would lead to disease are unknown, but remain a subject of current epidemiologic investigation. Ogle and colleagues found that human hematopoietic stem cells introduced into swine acquire PERV by fusing with host cells to form human–swine hybrid synkaryons. The hybrid cells appear to have a survival advantage over unfused cells and transmit the virus to uninfected human cells. If cross-species infection does prove to be an important issue, genetic therapies might also be used to address this problem. The simplest genetic therapy would involve breeding out the organism, but this approach might fail if the organism were widespread or integrated at multiple loci. Some genetic therapies have been developed to potentially control human immunodeficiency viruses. Although these therapies have generally failed because it has been difficult or impossible to gain expression of the transferred genes in stem cells and at levels sufficient to deal with high viral loads, the application of such therapies might be much easier in xenotransplantation because the therapeutic genes could be delivered through the germline. Ultimately, if elimination of endogenous retroviruses were necessary, it could potentially be accomplished by gene targeting and cloning, as discussed above.

4 A Scenario for the Clinical Application of Xenotransplantation

Successful application of xenotransplantation in the clinical arena requires insights into not only immunology but also into physiology and infectious disease, all of which have been discussed briefly here in the context of genetic therapy. In recent years, important advances have been made in elucidating the immunologic hurdles of pig-to-primate transplantation. Although this scientific progress is important and exciting, xenotransplantation will likely enter the clinical arena through a step-by-step process. A first step, free tissue xenografting, is in limited clinical trials already and preliminary evidence is encouraging as porcine free tissue xenografts appear to endure in a human recipient. One immediate application of free tissue xenografting would be treatment of cirrhosis caused by hepatitis virus, using targeted infusion of porcine hepatocytes. The promise of this approach is enhanced because (1) pig hepatocytes are resistant to viral reinfection, (2) rat models of cirrhotic liver failure indicate that porcine hepatocyte xenotransplants may endure and function well, and (3) predicted demand for hepatic transplantation due to hepatitis C-induced cirrhotic liver disease is likely to worsen the already acute shortage of livers available for transplant. Another potential extension of free tissue xenografting is transplantation of xenogeneic islets of Langerhans for the treatment of type one diabetes. Xenogeneic islet transplants may prove to be less liable to destruction by the autoimmune processes that underlies this disease. Temporary or ''bridge'' organ transplantation will probably follow free tissue xenografting. Bridge transplants will not address the problem of the shortage of

human organs, but incisive analysis of the outcomes of these transplants will provide important information about the remaining immunologic hurdles and the potential physiologic and infectious considerations. With this information, further therapies including genetic engineering may allow the use of porcine organs as permanent replacements. Even then, one can envision ongoing efforts to apply genetic therapies that will optimize graft function and limit the complications of transplantation.

While it may be that the use of pigs as a source of organs and tissues for transplantation is not far off, exciting advances in tissue engineering, stem cell technology, and *in vitro* organogenesis may broaden the use of animals in human medicine. Adult and embryonic stem cell culture has given rise to organ-specific tissues with functional characteristics of the corresponding organs. Although these cultures are unlikely to yield fully developed functional organs for transplantation into humans, pigs or other animals could be used as recipients of these culture-initiated tissues and allow completion of development. These organs, grown and maintained in animals, may then be available for transplantation on an ''as needed'' basis. Pigs may thus serve as xenograft ''recipients'' prior to becoming organ ''donors.'' The recent success in cloning of animals, including pigs, raises the possibility of transferring nuclei from a human patient's cells into enucleated stem cells of an animal, and then growing the cells in animals to generate differentiated human tissue that is autologous with the patient. The lessons learned from genetic manipulation of animals in the quest to make animal organs suitable for transplantation into humans may find their best application in generating animals suitable for use as biological reactors to grow human organs suitable for transplantation into humans.

Keywords

Bacterial Artificial Chromosomes (BACs)
Genomic clones with 100 to 200 kb insert size used for physical mapping and genome sequencing.

Expressed Sequence Tags (ESTs)
Single-pass sequences of cDNA clones that provide rapid access to genes as well as information on expression and polymorphism.

Forward Genetics
Methods that identify an unknown gene by its mutant phenotype, usually by mutagenesis screening with a chemical mutagen or retrovirus, and cloning the affected locus.

Knockdown
Abolishment of activity of a known gene by injection of morpholino oligonucleotides complementary to its transcript into the fertilized egg, mainly feasible for genes required early in development.

Microsatellite Markers
Genetic markers consisting of a sequence of short repeats of variable length (in particular $(CA)_n$) flanked by a pair of primer sequences, useful for genetic mapping because they are widespread, codominant, and easily scored by PCR amplification and gel electrophoresis.

Positional Cloning
Molecular cloning of mutant loci for which no obvious candidate gene exists, by genetically mapping the mutation to a specific contig or genomic clone, and sequencing the transcripts of this critical region.

Radiation Hybrid Mapping
Mapping method for sequence-tagged site (STS) markers, based on fusion cell lines generated from irradiated cells of the species of interest and rodent cells. If two markers are found by PCR to be present or absent in the same radiation hybrid cell lines, they are likely to be close to each other.

Restriction Fingerprinting
Physical mapping method in which genomic clones are digested with a restriction enzyme, overlaps between the clones are identified by their similar restriction patterns, and contigs are constructed from the overlapping clones.

Reverse Genetics
Methods that identify the mutant genotype of a known gene for further investigation of its function, for example by knockdown or TILLING.

Single Nucleotide Polymorphisms (SNPs)
Changes of a single nucleotide between strains, useful for genetic mapping, for example by sequencing.

Targeting Induced Local Lesions In Genomes (TILLING)
Identification of mutations in a known gene by screening of a library of mutagenized animals, either by sequencing or with CEL-I heteronuclease; also referred to as targeted knockout.

Teleost Genome Duplication
Hypothesized genome duplication (tetraploidization) event in the evolution of ray-finned fish, followed by functional specialization or loss of duplicate genes; as a result, some mammalian genes have two zebrafish orthologs with distinct functions and expression domains.

Owing to its transparent, easily accessible embryos, simple breeding, and short generation time, the zebrafish has become one of the most important model organisms to study the genetic control of embryonic development. Zebrafish research initially focused on forward genetics (mutagenesis screening), but reverse genetic methods, transgenesis, and microarrays are now equally available to characterize known genes. The zebrafish genome consists of 25 chromosome pairs and has an estimated haploid size of 1.5 Gb. Several genome maps exist for the zebrafish. The meiotic MGH map is generally used for placement of mutant loci and, in combination with the T51 radiation hybrid map and BAC fingerprinting, forms the basis of genome sequencing. A genome sequence is being generated by a combination of whole-genome shotgun and BAC-based sequencing, and is expected to be finished in 2005.

1 The Zebrafish as a Model Organism for Developmental Biology

1.1 General Remarks

In recent years, the zebrafish has become a favorite model organism for biologists studying developmental as well as cell biological processes. It is uniquely suited to identifying novel regulatory genes in vertebrate development and elucidating their function in the developing animal. No other vertebrate model organism offers the same combination of transparent and easily accessible embryos, efficient mutagenesis screening that has led to several hundred characterized mutations, and more recently, a sequenced genome as well as microarray and knockout technologies.

In addition, the zebrafish is of interest to the pharmaceutical industry because the embryos can be used for screening small molecule libraries in high-throughput pipelines. This approach can be applied to toxicology and, with mutants that are models for human diseases, to drug discovery and development.

The potential of the zebrafish system has been only partially realized so far. A main reason is that prior to genome sequencing, cloning of zebrafish mutations relied mainly on candidate genes and was therefore biased to finding mutations in genes already known from other organisms. However, this is changing rapidly, and novel regulatory genes are increasingly being discovered and characterized in the zebrafish.

1.2 Advantages of the Zebrafish as a Model Organism

The zebrafish has many properties that make it ideally suited as a model organism for experimental biologists:

- Zebrafish are easy to maintain and breed, minimizing the cost and effort to keep large populations of animals.
- They develop externally (outside of the female), allowing easy access to the embryos at all stages of development.
- The embryos are sturdy and large enough for experimental manipulations, such as microinjections or transplantation of cells. However, the embryos are small enough to fit into standard 96-well plates, facilitating automated analyses.
- Sperm samples can easily be obtained (even from live fish), stored, and later used for *in vitro* fertilizations.
- Embryonic development of the zebrafish is synchronous, that is, at any given time, all the embryos in a clutch will be at the same developmental stage.
- Compared with other vertebrate models for development, such as the mouse or *Xenopus*, the organs in zebrafish larvae are composed of fewer cells, making them easier to study. However, the organs still function in much the same way as those in larger animals.
- Zebrafish have large numbers of offspring.

1.3 Zebrafish Development

In addition to these advantages, there are two main embryological advantages that set the zebrafish apart from other vertebrate model organisms: its very rapid early development and the fact that its development can easily be observed in great detail.

For a vertebrate, embryonic development in the zebrafish is extremely rapid (see Fig. 1). Embryogenesis takes approximately 2 days, the larvae hatch on the

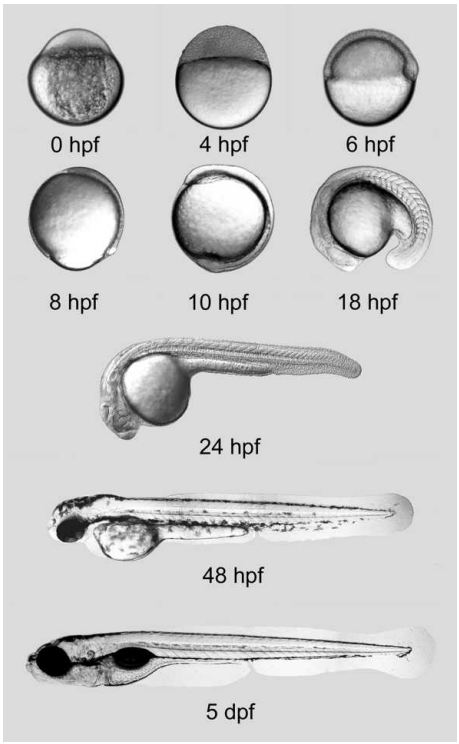

Fig. 1 A photographic overview of key aspects of early zebrafish development. hpf: hours postfertilization; dpf: days postfertilization. 0 hpf: At the one-cell stage immediately after fertilization, the zygote sits on top of a large ball of yolk. 4 hpf: Four hours following fertilization, the cells have undergone several rounds of cleavages to form a mass of cells located on top of the yolk. Please note that in contrast to species such as *Xenopus*, the yolk cell does not undergo cleavage divisions. 6 hpf: Gastrulation begins with epiboly of the cells. At this stage, the antero-posterior and dorso-ventral axes can be determined. 8 hpf: Onset of thickening in the region of the future head. 10 hpf: First somite forms (right) and the optic lobes evaginate from the diencephalon. 18 hpf: Body plan becomes recognizable, and the first voluntary muscle contractions are observable as movements of the tail. 24 hpf: Most vertebrate-specific body features and organs are already recognizable, including a compartmentalized brain, eyes, ears, and all internal organs. However, the majority of the organs are not yet functional. Notably though, the heart starts beating just before the end of the first day of development. Over the next 24 hpf, numerous cell types differentiate, and the organs gradually begin to function. 48 hpf: Zebrafish start to hatch and start swimming. 5 dpf: Larvae swim well and search for food independently. The speed of zebrafish development is temperature dependent. Zebrafish develop at temperatures ranging from approximately 18 to 32 °C. The higher the temperature, the faster the development. Normally, zebrafish are kept at temperatures ranging between 25 and 28.5 °C. In this text, all statements relating to the development of any given structure at any time point always refer to development having occurred at 28.5 °C. (Adapted from Haffter, P., Granato, M., Brand, M., Mullins, M.C., Hammerschmidt, M., Kane, D.A., Odenthal, J., van Eeden, F.J., Jiang, Y.J., Heisenberg, C.P., Kelsh, R.N., Furutani-Seiki, M., Vogelsang, E., Beuchle, D., Schach, U., Fabian, C., Nusslein-Volhard, C. (1996) The identification of genes with unique and essential functions in the development of the zebrafish, *Danio rerio, Development* **123**, 1–36.)

third day of development and as of day five, the vast majority of cell types have differentiated and the organs have taken up their function. This rapid development allows the observation of developmental processes and the completion of experiments generally within a few hours to days.

Despite the rapidity of embryonic and early larval development in zebrafish, the time needed to reach sexual maturity (generation time) is between two and four months (depending on the conditions under which they are raised; see Fig. 2).

The development of the zebrafish is similar to the embryogenesis in higher-ordered vertebrates, including humans and other mammals. But unlike in mammals, the embryonic development of zebrafish occurs outside the female. This allows easy access to the embryos without the need to sacrifice the female. Moreover, unlike in birds and reptiles, the shell of the zebrafish eggs (the chorion) is transparent, allowing the continuous observation of the developing embryo in its ''natural'' environment without the need to open the

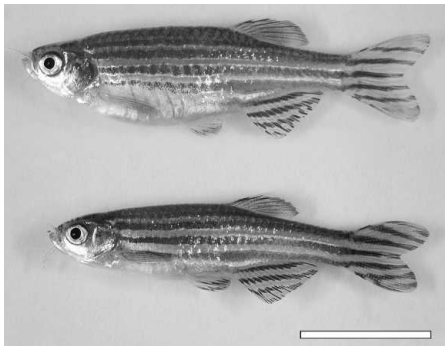

Fig. 2 Photographs of age-matched adult female (top) and male (bottom) zebrafish. The characteristic horizontal stripes running along the body and fins gave this species its name. Adult zebrafish measure about 3 to 5 cm in length. Females can be recognized by their larger belly accommodating the eggs. Males tend to be more reddish in color than female zebrafish. The scale bar is 1 cm. (See color plate p. xxix).

shell. This property is shared with, for example, the African claw-toed frog *Xenopus*, another model for early development.

The most important advantage of the zebrafish, however, is that the embryos themselves are completely transparent during early development. This is due both to their relatively small size and the absence of pigment throughout the first 36 h of development (the time when pigmentation in the melanocytes and the cells of the retinal pigment epithelium begins). Yet, even after the onset of pigmentation, most parts of the body can still be observed between the relatively few melanophores. Also, in contrast to *Xenopus*, in zebrafish, the yolk does not participate in the cleavage divisions of the early embryo but remains distinct from the embryo throughout development.

This transparency of the zebrafish embryos and larvae allows the visualization of many processes that occur deep inside the developing animal. These include, the development of internal organs, such as the brain, the cardiovascular system or the digestive tract, the migration of cells as well as the path finding of axons. In the zebrafish, these developmental processes can be visualized in real time without the need for invasive intervention (e.g. dissection or histological sectioning) or sophisticated imaging techniques (e.g. MRI).

The external development and the transparency of the zebrafish embryos facilitate numerous experimental approaches. These include, for example, laser manipulations, such as cell ablation or uncaging experiments as well as the generation of extensive fate maps. Moreover, in techniques, such as mRNA *in situ* hybridization and antibody staining to test for the expression patterns of genes and proteins, the translucency of the embryos in many cases obliterates the need for sectioning as the staining can be performed and imaged on whole embyros.

In contrast to mammals, zebrafish can generate large numbers of offspring. When kept under optimal conditions, a single female can lay up to 200 eggs per week. This greatly facilitates high-throughput approaches and statistical analyses, including the reliable identification of mutant phenotypes, for example in a genetic screen. This fact, together with the small size and easy maintenance of zebrafish embryos as well as their rapid embryonic development, allows for forward genetic approaches to be taken that are often too labor intensive and too costly to be carried out with other vertebrate models, such as the mouse. The zebrafish thus combines being a vertebrate with many of the advantages of invertebrate model organisms.

For a summary of key properties of commonly used animal model organisms, please refer to Table 1.

1.4 Phylogeny

The zebrafish (*Danio rerio*, formerly also known as *Brachydanio rerio*) is a small tropical freshwater fish. Its natural habitats are rivers of South Asia, mainly northern India as well as northern Pakistan, Nepal, and Bhutan. The zebrafish belongs to the family of the cyprinids (*Cyprinidae*) in the class of ray-finned fishes (*Actinopterygii*) and within this class to the bony fishes (teleosts or *Teleostei*) to which most extant ray-finned fishes belong (Fig. 3). The teleost fishes comprise other model organisms:

- Medaka (*Oryzias latipes*), a species, which is mainly used to study developmental biology.
- The three-spined stickleback (*Gasterosteus aculeatus*) and the guppy (*Poecilia reticulata*), the two species with a long tradition in behavioral studies and more recently, in population genetics also.
- The two pufferfish species *Takifugu rubripes* (also referred to as *Fugu rubripes*) and *Tetraodon nigroviridis* (recently also referred to as *Monotreta nigroviridis*), which with their relatively small and simple genomes are important organisms to understand genome architecture, organization, and function. *Takifugu rubripes* was the first fish and second vertebrate species whose genome was fully sequenced (in 2002). The genome of *T. nigroviridis* is currently also being sequenced.

These five species belong to the teleost crown group, a large radiation whose last common ancestor with the zebrafish lived about 100 million years ago (a similar evolutionary time span as that between humans and mice). The lineages leading to the cyprinids and mammals split about 400 to 450 million years ago.

It is assumed that during the evolution of the ray-finned fishes, there has been a genome duplication event, which lead to a tetraploidization of the genome. This duplication was followed by a functional specialization of some of the duplicated genes on the one hand and the loss of other genes on the other hand. As a result, an estimated 20% of mammalian genes have two zebrafish orthologs with distinct functions and expression domains. This subfunction partitioning can help to understand different aspects of the mammalian gene function as they can be studied in isolation.

1.5 Laboratory Strains

Several wild-type laboratory strains of the zebrafish have been established by the major research laboratories. While these strains are inbred to some extent, none of them is completely isogenic, and all of them have somewhat overlapping distributions of marker alleles. The choice of a mapping strain is thus often a matter of personal preference. Only the most common strains will be mentioned here.

The primary strains used for mutagenesis experiments are AB and Tübingen (Tü). The AB strain was generated by G. Streisinger in Eugene, Oregon, by crossing the strains obtained at a pet shop. It has been used for a major mutagenesis screen by the laboratory of W. Driever, and for several smaller

Tab. 1 Comparison of key properties of commonly used model organisms.

Organism	*Size egg (mm)*	*Length adult*	*Number of offspring*	*Duration of embryogenesis*	*Generation time*	*Genome size [bp]*	*Number of genes*
Caenorhabditis elegans	0.05	1 mm	300–350/life time	20 h	50 h	0.097×10^9	20 000
Drosophila melanogaster	0.5	3 mm	50/day	24 h	9 days	0.18×10^9	13 600
Zebrafish (*Danio rerio*)	0.7	5 cm	200/week	2 days	2–3 months	1.5×10^9	est. 30 000
Xenopus laevis	1–1.3	10–14 cm	300–1000/2–3 months	2–2.5 days	1–2 years	3.1×10^9	Unknown
Xenopus tropicalis	0.6–0.8	4–5 cm	1000–3000/2–3 months	2 days	3–4 months	1.7×10^9	Unknown
Chicken (*Gallus gallus*)	60–80	30 cm	1/1–2 days	6 days	9 months	1.1×10^9	Unknown
Mouse (*Mus musculus*)	0.1	6–10 cm	4–8/4–6 weeks	14 days	2 months	2.6×10^9	30 000

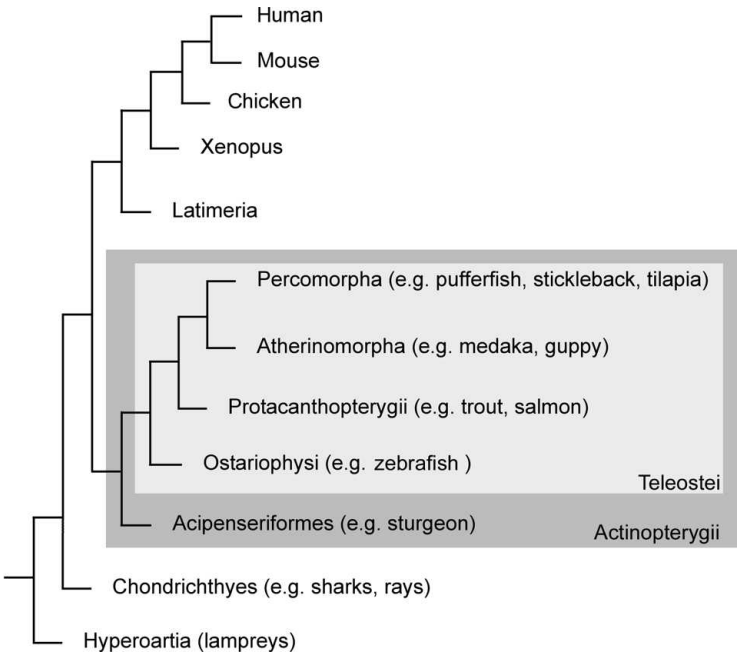

Fig. 3 Schematic representation of the major vertebrate lineages.

screens. The Tübingen strain, likewise originating from a pet shop, has been used as the genetic background of most mutagenesis screens including the two largest ones, performed in the laboratory of C. Nüsslein-Volhard. For this reason, it was also chosen as the strain to be sequenced in the zebrafish genome project.

Wild-type India Calcutta (WIK) was generated from a wild catch in India as a highly polymorphic reference strain for mapcrosses with mutations in the Tü background. In crosses of Tü x WIK, 68% of microsatellite markers give a scorable polymorphism. India (IN) was used for the MGH meiotic mapping panel in combination with AB; however, it is more difficult to breed than WIK and may contain mutations that affect viability. The strain SJD was isogenized over several generations by the laboratory of S. L. Johnson, and it is more polymorphic in crosses to Tü (75% scorable polymorphism). It would thus be better suited as a reference strain, but it is more difficult to breed because of a skewed sex ratio (a common problem with inbred zebrafish strains).

In the zebrafish, visible markers are not as useful for the maintenance of mutations as, for example, in *Drosophila* because it has 25 chromosomes and lacks balancer chromosomes (which would prevent recombination between the marker and the mutant locus). A common strain with visible markers is Tübingen long fin (TL, formerly named Tup long fin), which carries a recessive mutation (leo^{t1}) that causes spotting, and a dominant mutation (lof^{dt2}) causing long fins.

Wild-type strains can be obtained either from the Zebrafish International Resource Center (ZIRC) or from the laboratories in which they originated.

2
Genetic Tools and Methods Available to Study Development in the Zebrafish

2.1
General Remarks

When compared to other model organisms, such as the nematode *Caenorhabditis elegans*, the fruit fly *Drosophila melanogaster,* or the mouse *Mus musculus,* the number of tools and methods that are available when working with the zebrafish is still relatively limited. This is not surprising when considering that the zebrafish is a comparatively recent addition to the list of model organisms. It was established largely by George Streisinger in the late 1970s and early 1980s. Since then, the zebrafish community has grown steadily, the tools and methods available to zebrafish researchers have increased considerably over the past two decades, and there is now a substantial number of protocols, reagents, as well as transgenic and mutant zebrafish lines.

2.2
Genetic Screens (Forward Genetics)

To date, genetic screens are the most successful approach for identifying genes with an essential function in the development of an organism. Genetic screens rely on the random induction of mutations in the genome and the subsequent search for individuals with a mutant phenotype. They have the advantage that they are relatively unbiased with respect to prior knowledge, and thus also allow the identification of previously unknown genes. However, being able to identify mutants for a given process, morphological structure or behavior relies on the capability to develop an assay for the detection of the corresponding phenotypes. Furthermore, as genetic screening relies on the identification of a phenotype, it selects genes with unique or at least partially nonredundant functions. Genes with redundant functions, however, cannot be detected in genetic screens.

The possibility to perform large-scale genetic screens in the zebrafish is a powerful feature of this model organism. When compared to other vertebrate model organisms (mouse, chicken, frog), the generation time of the zebrafish is similar (2–4 months). But the large number of offspring greatly facilitates phenotypic and genetic analyses, such as the collecting of sufficient numbers of mutant individuals for different assays and phenotypic analyses as well as of recombinant individuals for the subsequent mapping of mutations (see below). Moreover, the moderate space required to breed large numbers of zebrafish significantly reduces the cost of such undertakings. Finally, the speed of zebrafish development and the ease with which it can be observed greatly facilitate the identification of mutant phenotypes for virtually any organ, tissue, or cell type.

Several mutagenesis protocols have been established for the zebrafish. The mutagens used include ENU, radiation (mainly γ-rays), as well as insertional mutagenesis with retroviruses or transposable elements.

2.2.1 Chemical Mutagenesis

The generation of mutants by chemical mutagenesis has been one of the most successful approaches in elucidating the function of genes and the genetic control of biological processes, particularly those of embryonic development. One of the most widely used substances to induce mutations is the chemical *N*-ethyl-*N*-nitrosourea (ENU). ENU is a potent mutagen, which has been used to induce mutations in various organisms. For

example, in the mouse, it has the highest mutation rate of all germ cell mutagens examined, and also for the zebrafish, ENU has been the mutagen of choice in the majority of genetic screens carried out to date.

ENU is a synthetic alkylating agent, which induces mutations by transferring its ethyl group to oxygen or nitrogen radicals in individual bases of DNA, including the N1, N3, and N7 groups of adenine, the O2 and N3 groups of cytosine, the O6, N3, and N7 groups of guanine, and the O2, O4, and N3 groups of thymine. Generally, ENU induces point mutations: The ethylation of a base can lead to the modified base being misread during DNA replication, resulting in the integration of a noncomplementary base in the second DNA strand (see Fig. 4). Following a second round of replication, one of the four double helices derived from the initially modified double helix carries a complete base-pair substitution. ENU-induced mutations chiefly involve the base thymidine (AT to TA transversions and AT to GC transitions as shown in Fig. 3 are the most common mutations induced by ENU). However, chromosomal rearrangements (translocations, inversions, deletions) have also been described for post-meiotically mutagenized male germ cells.

When animals are exposed to ENU (in the case of zebrafish by bathing them in a solution containing ENU), it induces mutations in all cells of the body, including in the precursors of the germ cells. It has been shown for mice that the rate of mutagenesis by ENU in testes is highest in spermatogonial stem cells

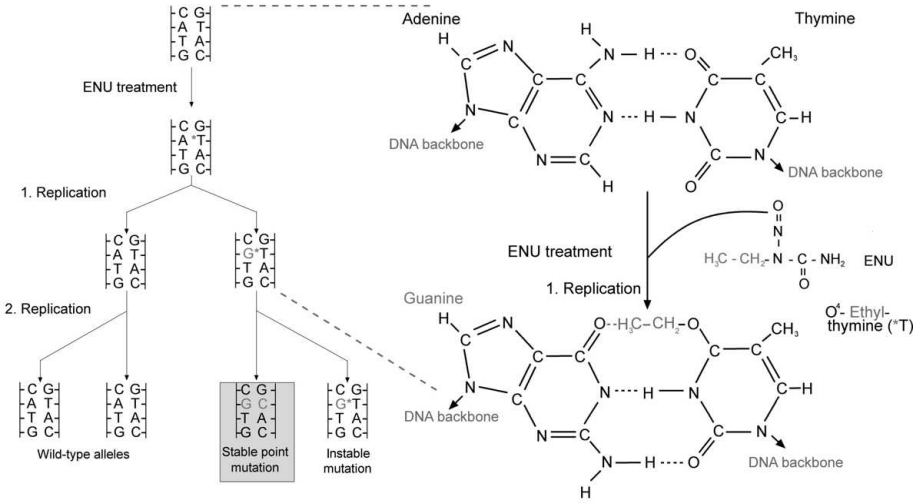

Fig. 4 Mechanism of mutagenesis by ENU leading to an AT → GC transition. The ethyl group in ENU (shown in red or indicated as a red asterisk) is transferred to the O^4-atom of thymine, resulting in an O^4-ethylthymine adduct. Failing an excision of the O^4-ethylthymine adduct by the DNA repair machinery, the O^4-ethylthymine mispairs with a guanine in a subsequent replication of the DNA. In this mispairing, the ENU-derived ethyl group forms a third hydrogen bond with the O^6 of the guanine base in the complementary DNA strand. A successive second replication leads to a complete AT → GC transition in one of the four double helices produced, thus fixing the mutation. Substitutions of bases are indicated in blue. Figure adapted after Noveroske, J.K., Weber, J.S., Justice, M.J. (2000) The mutagenic action of *N*-ethyl-*N*-nitrosourea in the mouse, *Mamm. Genome* **11**, 478–483. (See color plate p. xxx).

where optimal doses of ENU result in one mutation per gene in every 175 to 655 gametes (corresponding to a specific locus rate of $1.5–5.7 \times 10^{-3}$). In the zebrafish, the specific locus rate ranges from 0.6 to 4.8×10^{-3}, indicating that either the mutagenesis rates that can be achieved are slightly lower than those for the mouse or that the optimum conditions for mutagenesis in the zebrafish have not yet been found.

As the mutations induced by ENU primarily occur only in one of the DNA strands (see Fig. 3), there is a difference in the offspring resulting from mutagenized germ cells, depending on whether the exposure to ENU occurred before or after meiosis: mutations in premeiotic spermatogonia lead to sperm, which carry the mutation in both strands (due to DNA replication during meiosis), whereas mutations in postmeiotic germ cells result in sperm with only one of the DNA strands mutagenized. As a consequence, animals arising from spermatogonia carry the mutation in every cell. However, the progeny from germ cells that were mutagenized postmeiotically are mosaic with respect to the mutation.

Figure 5 depicts a typical breeding scheme for a two generation ENU mutagenesis screen in the zebrafish. Genetic screens using the zebrafish have resulted in the isolation of nearly 2000 mutant lines up until today. The vast majority of these mutations are recessive and affect embryonic or larval development (most are embryonic or larval lethal). However, a few dominant mutations as well as some mutations with adult phenotypes have been isolated. For a list of published mutants with brief phenotypic and – where available – molecular characterizations, refer to the searchable database at http://www.zfin.org.

2.2.2 Insertional Mutagenesis

The most significant disadvantage of working with mutants generated by chemical mutagenesis is the difficulty in identifying the mutation. The localization of chemically mutated genes in the genome requires a laborious genetic mapping of the mutated locus followed by positional cloning and/or a candidate gene approach (see below). This drawback can be circumvented if the mutagenesis is achieved by the insertion of a known sequence (e.g. a transposon or a retroviral vector), which can be used as a starting point for the sequencing of the regions flanking the insert. This strategy has been successfully applied in mutagenesis screens in other model organisms. Famously, the P-element transposon has been used to generate numerous mutants in *Drosophila*, and retroviral vectors were employed to mutate, for example, mice.

In the zebrafish, insertional mutants have been generated using one of three methods: injection of plasmid DNA, transposons, and pseudotyped retroviral vectors. However, the only efficient protocols for insertional mutagenesis in the zebrafish have been established using retroviruses.

Briefly, retroviral vectors are injected into zebrafish embryos at the blastula stage, resulting in mosaic founder fish carrying insertions also in the precursors of the germ cells (up to 25–30 insertions in the germ line per individual with a given insertion occurring in 3–20% of the gametes). Incrossing of these founders generates a nonmosaic F_1 generation. Typically, approximately 20% of these fish have 5 to 10 insertions per individual. The F_1 fish carrying multiple insertions are incrossed to raise F_2 families with at least 10 independently segregating inserts,

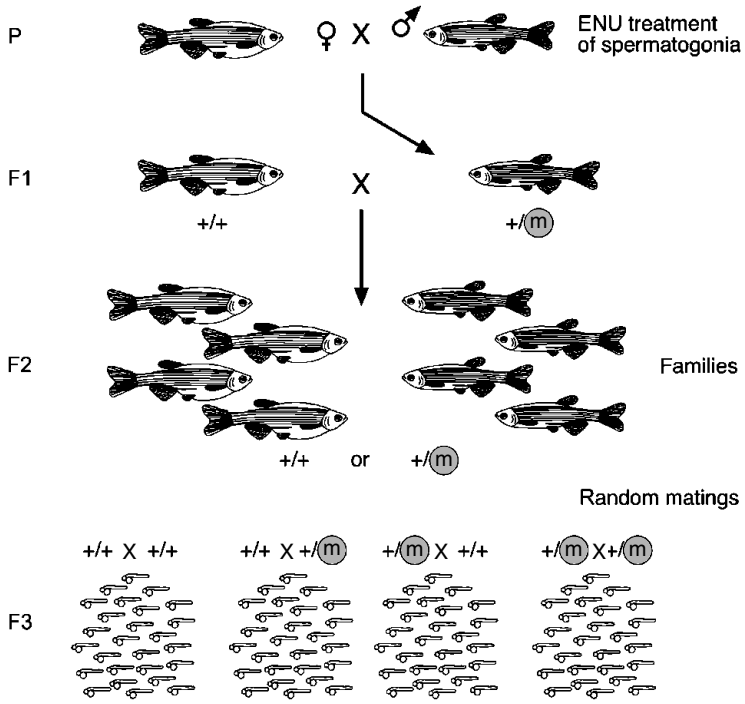

Fig. 5 Depiction of a mutagenesis and crossing scheme. Male fish are mutagenized with ENU and subsequently mated with wild-type female fish. The fish of the resulting F_1 generation are heterozygous for individual mutations (depicted as ''m'' in this example). These F_1 fish are again mated with wild-type fish in single-pair matings. The offspring from each of these matings are commonly referred to as ''F_2 families.'' In these F_2 families, approx. 50% of the individuals are heterozygous for a particular mutation (+/m); the other 50% carry two wild-type alleles of this locus (+/+). Random single-pair matings between the siblings of an F_2 family give rise to the F_3 generation. This is the first generation in which a particular mutation can occur in a homozygous state and which hence first show a mutant phenotype for recessive mutations (the vast majority of ENU-induced mutations are recessive; rarely dominant phenotypes can already be observed in the F_1 and F_2 generations). On the level of the mutated locus, four different cases can be distinguished: Two homozygous F_2 individuals are mated (+/+ X +/+), a genotypically wild-type F_2 female is mated with a heterozygous F_2 male (+/+ X +/m), a heterozygous F_2 female is mated with a genotypically wild-type F_2 male (+/m X +/+), and two heterozygous F_2 individuals are mated (+/m X +/m). In the case of a recessive mutation, the latter cross results in phenotypically mutant F_3 offspring (approximately 25% of the individuals). (Figure adapted from Haffter, P., Granato, M., Brand, M., Mullins, M.C., Hammerschmidt, M., Kane, D.A., Odenthal, J., van Eeden, F.J., Jiang, Y.J., Heisenberg, C.P., Kelsh, R.N., Furutani-Seiki, M., Vogelsang, E., Beuchle, D., Schach, U., Fabian, C., Nusslein-Volhard, C. (1996) The identification of genes with unique and essential functions in the development of the zebrafish, *Danio rerio, Development* **123**, 1–36.)

which in turn are incrossed and their offspring (F_3) screened for phenotypes.

In a zebrafish mutagenesis screen using a pseudotyped retroviral vector, approximately one in every 80 insertions results in an embryonic/early larval phenotype that can be identified on the basis of morphologically observable criteria. With an average number of 12 insertions that can be screened per F_2 family, the mutagenesis rate in zebrafish insertional mutagenesis screens using retroviruses is an estimated seven- to tenfold lower than in equivalent genetic screens using ENU. This means that significantly larger numbers of insertion lines have to be screened in order to obtain the same number of mutant phenotypes as when using an ENU protocol. However, once an interesting phenotype resulting from an insertion has been identified, the affected gene can be cloned much faster than is normally the case for ENU-induced mutations (approximately 2 weeks for insertions compared to several months or more for ENU mutations).

To date, over 500 zebrafish mutants with retroviral insertions have been identified. The range of phenotypes, which can be obtained with either chemical or insertional mutagenesis, is comparable. As observed in genetic screens based on chemical mutagenesis, roughly one-third of these mutants show defects in the development of one or very few parts of the body, organs, or cell types, while two-thirds display general or pleiotropic phenotypes, such as necrosis, heart edema, or small heads and eyes.

A major advantage of mutagenesis approaches relying on the insertion of retroviral or transposon sequences is that they allow a very easy cloning of the disrupted genes via the inserted sequences. The experience with cloning the mutated genes in the zebrafish insertional mutants has shown that in 80% of the cases, it was sufficient to sequence up to a few kilobases of the genomic DNA flanking the inserted sequence to identify the gene. This has led to the cloning of over 280 disrupted genes in the zebrafish to date – including some whose function *in vivo* had not previously been described. In comparison, approximately 100 chemically mutated zebrafish genes were cloned to date.

The differences in the efficiencies of mutagenesis and identification of the mutated genes lead to a difference in the kinds of genes, which tend to be identified using the two methods. Owing to the very large numbers of mutants generated in chemical mutagenesis screens, generally only those displaying specific developmental phenotypes are kept. The comparatively lower numbers generated in insertional mutagenesis screens leave more capacity to also keep mutant lines with less specific phenotypes. The need to focus on specific phenotypes in chemical mutagenesis screens is increased by the fact that the effort required to clone a chemically mutated gene is considerably bigger when compared to the identification of a gene disrupted by an insertion. This results in mutations in genes with more pleiotropic effects during development being underrepresented in collections of mutants resulting from chemical mutagenesis screens. Additionally, the cloning of the majority of ENU-mutated zebrafish genes at least partially relied on a candidate gene approach (favoring the identification of known genes), while the cloning of insertion mutations is less biased. As a consequence, the majority of ENU mutations identified to date are in transcription factors as well as signaling molecules and their receptors. The insertion mutants, on the other hand, also identified a number of genes involved in more general

cellular processes, such as the control of the cell cycle, vesicle trafficking, protein sorting between organelles or protein glycosylation.

2.2.3 Radiation Mutagenesis

In the past, ionising radiation has been a commonly used means for inducing mutations in a wide range of organisms. Ionising radiation carries enough energy to cause double-strand breaks in DNA helices and thus leads to chromosomal rearrangements, such as deletions, inversions, and translocations. As the majority of mutations induced by ionising radiation tend to be large chromosomal deficiencies generally comprising more than one gene, the usefulness of such mutants in the study of gene function is limited. Moreover, many radiation-induced mutations tend to be dominant lethal, and therefore mutants carrying such mutations cannot be maintained. For these reasons, ionising radiation has only been used infrequently and on a comparatively small scale to generate zebrafish mutants, and, compared to chemical and insertional mutagenesis, radiation plays a marginal role in the zebrafish as a means to generate mutants.

There are however studies in which γ-radiation has been used to induce mutations in the zebrafish, and several mutants with developmental defects have been isolated. γ-rays were shown to efficiently induce mutations, for example, in mature sperm cells, fertilized eggs, and blastula embryos of the zebrafish with specific locus mutation rates of up to 10^{-2}. With the current protocols, the survival rate to adulthood is approximately 25% for zebrafish raised using irradiated sperm in *in vitro* fertilizations and between 25 and 50% for irradiated zygotes (http://zfin.org/zf_info/zfbook/chapt7/7.9.html).

2.3 Reverse Genetics

In recent years, genome sequencing projects have yielded an enormous wealth of information, including numerous predicted genes with, as of yet, unidentified functions. The elucidation of the functions of these genes is one of the major challenges in the years to come. Reverse genetics approaches offer efficient ways to address this challenge. They allow to specifically knock out or knock down genes of interest either by generating mutants in these genes or by preventing the translation of the corresponding mRNA(s) into proteins respectively. The function of the targeted genes is subsequently elucidated via analyses of the resulting phenotypes.

For two decades, the mouse was the only vertebrate model organism for which reverse genetics methods could be established. These methods are based on homologous recombination in embryonic stem (ES) cells: an endogenous locus is replaced by a homologous extra-genomic construct engineered to carry a desired mutation. Following a selection step, ES cells carrying the mutation are introduced into mouse blastocysts where they participate in the normal development and contribute progeny to all organs including the germ line. These chimeric mice (always males) are mated with wild-type females to generate heterozygous offspring, which is generally outcrossed to generate a larger number of heterozygous F_2 individuals. The F_2 is then incrossed to produce the first homozygous embryos.

Despite efforts to establish zebrafish ES cell lines, there is currently no protocol for ES cell–based knockout or targeted gene expression by homologous recombination in the zebrafish. However, the advent of reverse genetics technology in the form

of morpholino knockdown and, more recently, the TILLING (Targeting Induced Local Lesions In Genomes) approach had a significant impact on zebrafish research. Particularly, in combination with the zebrafish genome-sequencing project, which is nearing its completion, these two techniques will increasingly contribute to elucidate the function of novel genes. Taken together, the morpholino and TILLING techniques will allow reverse genetics approaches to be performed routinely and on a large scale in the zebrafish.

2.3.1 Morpholino Knockdown

Morpholinos provide a very rapid means to obtain a phenotype, and thus assay the *in vivo* function of a specific gene. The technique is based on injecting modified oligonucleotides that prevent the expression of the targeted gene by blocking the translation of the corresponding mRNA(s). As zebrafish produce large numbers of offspring, which develop externally, they are ideally suited to large-scale knockdown approaches. Importantly, their eggs are large enough for sufficient quantities of morpholinos to be injected to block the expression of target genes over the full duration of embryonic development. Since the establishment of protocols for morpholino knockdown in the zebrafish, the technique has rapidly spread through the zebrafish community and is now widely used to rapidly confirm or exclude candidate genes for mutants obtained in mutagenesis screens as well as to obtain phenotypes for novel genes. Particularly for the latter, the zebrafish will play an increasingly important role in the future.

When performing a targeted mutagenesis of a locus by homologous recombination in mice, it typically takes one year to obtain the first homozygous offspring and another six months to generate the first 100 homozygous embryos to work with. Importantly, one heterozygous female has to be sacrificed each time to obtain (on an average) two homozygous embryos. This makes targeted mutagenesis in the mouse a time-consuming, laborious, and costly process. In comparison, the knockdown of genes by morpholino injection in zebrafish is faster, as there is no need for time-consuming manipulations of ES cells or for the breeding and crossing of several generations of animals to obtain homozygous individuals. Instead, the desired phenotype can be observed in the ''first'' generation from within a few hours to days. Also, in a single experiment, hundreds of embryos can be injected in a couple of hours.

Morpholinos cannot be used in mice, mainly because the morpholinos are rapidly diluted during mouse development, and their effect is thus lost before a number of interesting processes occur. This is due to two features characteristic for mammalian development: Firstly, the eggs are small such that only relatively small quantities of morpholino can be injected. Secondly, the embryos rapidly grow following implantation into the uterus.

Morpholinos are short oligonucleotides (18- to 25-bases long). In contrast to naturally occurring nucleic acids, the backbone of morpholinos is chemically modified: Each of the four bases A, C, G, and T is linked to a six-membered morpholine ring (hence the name) instead of the sugar moieties normally occurring in nucleic acids. These rings are connected with each other via nonionic phosphorodiamidate units (see Fig. 6). This chemical modification renders morpholinos resistant to degradation by nucleases. Morpholinos are generally designed to be complementary (antisense) to the region including the START

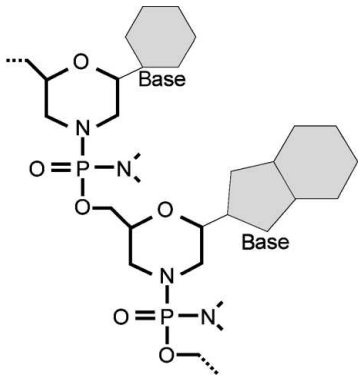

Fig. 6 Schematic representation of the backbone of a morpholino oligonucleotide (morpholino or MO). Instead of being linked to a ribose molecule (as is the case in RNA) or deoxyribose molecule (as in DNA), the bases in morpholinos are linked to a six-membered morpholine ring. These rings are connected via nonionic phosphorodiamidate groups (instead of an ionic phosphate group as in RNA and DNA). The bases linked to the morpholine ring are the same as in DNA: adenine, cytosine, guanine, and thymine.

codon of translation (ATG) or a crucial splice site in the mRNA of a targeted gene.

When injected into a cell, the morpholinos bind to their target sequence in the endogenous mRNA transcripts and block their translation into protein. The resulting effect of a morpholino injection is a phenotype that closely resembles or is identical to a loss-of-function mutant. In principle, any gene can be knocked down using morpholinos, including those that act early during development as maternally deposited mRNAs (a class for which it is relatively difficult to obtain homozygous mutants).

In zebrafish, morpholinos are generally injected into the egg yolk shortly after fertilization. They exert their effect almost immediately and effectively block the translation of the targeted mRNA for between three and four days of development (which in the zebrafish comprises the entire period of embryonic development). After that time, the effect of the morpholinos gradually diminishes as they are progressively diluted (and degraded) in the growing animal. As a consequence, only phenotypes that manifest themselves during this period can be observed, and genes acting later than three to four days after fertilization can generally not be targeted by morpholino injection.

Unlike nucleic acids used to knock down genes in other model organisms (''interfering RNA,'' RNAi; see below), morpholinos are not charged and not toxic even at high concentrations, allowing large amounts to be injected. Varying the amount of morpholino injected makes it possible to attain different dose-dependent strengths of a phenotype – not unlike the situation observable in allelic series.

Morpholinos are also very well suited to overcome the problem of redundancy of gene functions – a weakness of mutagenesis screens and homologous recombination experiments. By simultaneously injecting two (or more) morpholinos targeted to related genes, these genes can be inactivated simultaneously. Similarly, morpholinos can be used to knock down additional genes in a mutant background. This way, the knockdown of gene functions through morpholinos is likely to contribute considerably to elucidating the genetic networks acting in development.

Despite their advantages, the knockdown with morpholinos has significant limitations. Morpholino injections can only lead to lack-of-function phenotypes and never serve to generate the variety

of sophisticated mutations achievable with homologous recombination in mice (e.g. conditional knockouts and knockins). Moreover, the dilution of the morpholino as the embryo grows restricts the time when phenotypes can be reliably identified and characterized to the first, approximately, three days of development. Also, a morpholino knockdown phenotype is not as reliable and reproducible as a genetic mutant. In many instances, the knockdown phenotypes will faithfully phenocopy the mutant phenotype, but the injection of morpholinos can result in nonspecific phenotypes, such as widespread cell death and neuronal degeneration. These have to be separated from genuine phenotypes by including a control morpholino in each experiment (e.g. a morpholino with the same sequence except for three mismatched bases). Furthermore, a morpholino targeted at a particular gene may in some instances ''cross react'' and block the production of other gene products. Finally, the knockdown by morpholino injection is transient and not passed on to subsequent generations. This necessitates new injections for each experiment that is being undertaken with knockdown fish. However, many of these drawbacks are overcome by the TILLING technique to generate knockout mutants.

2.3.2 TILLING

TILLING is an effective method to isolate mutants with defined mutations, including the knockout of genes. It constitutes a random mutagenesis and the subsequent screening for mutations in target genes. The method was initially developed for *Arabidopsis thaliana* but has since been used in other species, including the zebrafish.

In TILLING, mutations are randomly induced in the genome via chemical mutagenesis (e.g. with ENU as described above). The mutagenized fish are mated with wild-type animals to produce F_1 fish, which carry individual mutations in a heterozygous state (Fig. 7). However, instead of using these F_1 fish to raise F_2 families and subsequently screening their offspring for phenotypes as would be done in a genetic screen, the F_1 fish are directly examined for the presence of mutations. This is done by taking biopsies (fin clips) from which genomic DNA is isolated. This DNA is then screened for mutations in (known) genes of interest. Screening can be done either by sequencing parts of the genes with specific primer pairs flanking a region of interest or with an enzyme-mediated assay based on the property of the plant endonuclease CEL-I to recognize and cleave heteroduplexes. The possibility to automate certain steps of the TILLING procedure allows the screening of large numbers of mutagenized genomes for mutations in genes of interest. Once a mutation of interest has been identified in the genome of a particular fish, outcrossing this individual to a wild-type fish generates more offspring carrying the mutation. Incrossing of this F_2 generation results in homozygous F_3 individuals, which can be phenotypically analyzed.

The TILLING procedure has recently been successfully tested in the zebrafish and is now used on a large scale to generate zebrafish knockout mutants in a broad range of genes (see www.zf-models.org). In a test study, a library of 4608 male and female F_1 zebrafish derived from ENU-mutagenized founder fish was screened for mutations in 16 genes. The overall mutation frequency in this experiment was one mutation in approximately 235 000 bp. For the majority of target genes, only one PCR amplification product (amplicon) was screened for

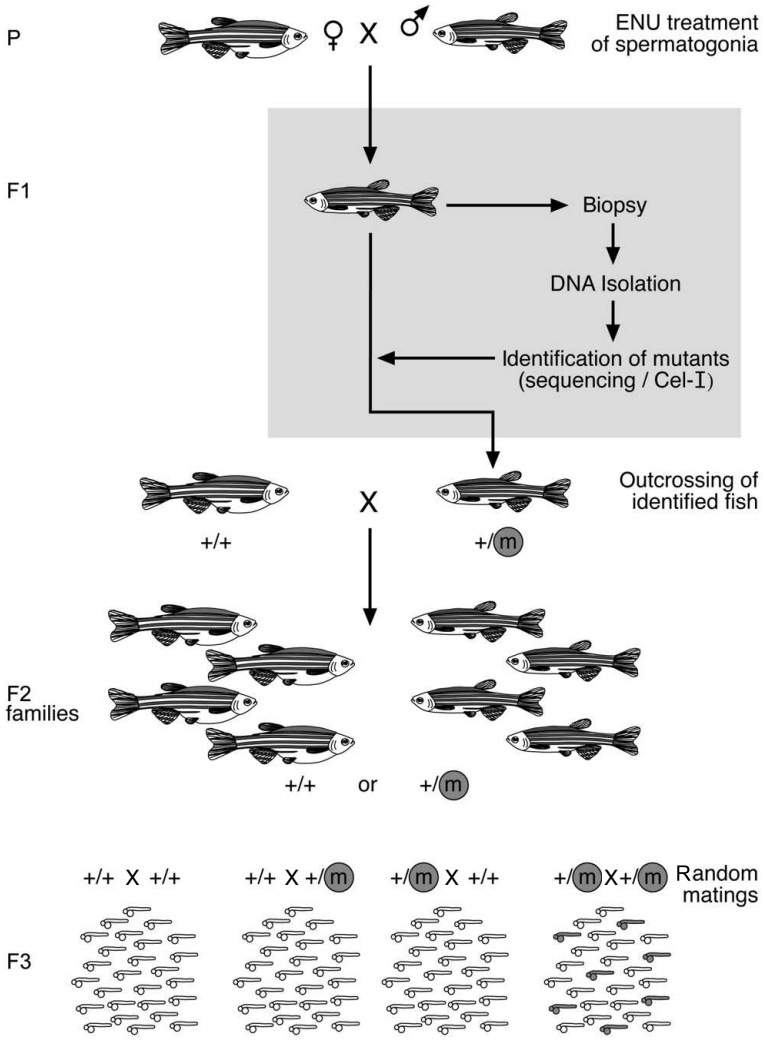

Fig. 7 Schematic illustration of the procedure used to generate, identify, and recover TILLING mutants. For details on the procedure see text.

mutations. The size of the amplicon was such that, on average, one-quarter of the coding sequence was screened. In addition to coding sequence, these amplicons comprised an average of 26% noncoding sequences, such as untranslated regions and intronic sequences.

This approach resulted in the identification of 255 mutations. The majority (80%) of all mutations found were located in coding sequences, whereas 20% were found in noncoding regions. Of the mutations identified in coding regions, most were missense mutations resulting in the exchange of an amino acid, roughly one-third were silent, and approximately one in ten were nonsense, resulting in a premature STOP codon (14 in total). Of the mutations

identified in noncoding regions, approximately 10% (seven in total) altered splice donor or acceptor consensus sequences and are presumed to cause a change in the splicing of the affected genes. A detailed characterization of the mutants arising from this TILLING project has not yet been done. However, it is presumed that the 14 nonsense mutations and the seven mutations affecting splice donor/acceptor sites will most likely give rise to complete loss-of-function or knockout phenotypes for these genes. This would signify that, in total, 21 null mutations (roughly 10%) could be identified in 13 of the 16 target genes in a period of a few months.

These pilot studies suggest that TILLING can be performed in a high-throughput setup in the zebrafish. Importantly, the study has shown that the TILLING technique is sufficiently sensitive to detect mutations against a background of naturally occurring single nucleotide polymorphisms (SNPs) – a finding of particular importance for species such as the zebrafish for which no extensively inbred lines exist. It must, however, be noted that in contrast to methods relying on homologous recombination in mice, TILLING cannot be used to introduce designed mutations. Instead, it relies on the spectrum of mutations inducible randomly by chemical mutagenesis.

2.3.3 RNA Interference

Similar to the knockdown with morpholinos, RNA interference (RNAi) is a method to transiently knockdown specific gene products. RNAi relies on a conserved cellular response to double-stranded RNA (dsRNA). When dsRNA is introduced into a cell, it leads to a series of events resulting in the sequence-specific degradation and translational inhibition of the homologous endogenous mRNA and thus the posttranscriptional silencing of the targeted gene. Since its discovery in *C. elegans* in 1998, RNAi as a mechanism to silence genes has been employed in a variety of fungi, plant and animal species, including model organisms such as *Neurospora, Arabidopsis, C. elegans, Drosophila*, and mice.

There have also been attempts to establish RNAi-mediated knockdown protocols for the zebrafish. However, the ratio of specific phenotypes was generally low and variable, and there have been studies reporting significant nonspecific effects of RNAi on the development of zebrafish. Although dsRNA-mediated posttranscriptional silencing appears to be an almost universal cellular mechanism and it should be possible to develop protocols to overcome these problems in principle, this has not yet been achieved, and morpholino injection is currently the method of choice to generate knockdown phenotypes in the zebrafish.

2.4 Parthenogenesis

As the fertilization of the eggs in zebrafish occurs outside the body of the female, the process can be manipulated experimentally, for instance, to induce the development of gynogenetic and androgenetic haploid or diploid embryos. The generation of individuals with a genome derived from only one parent (uniparental inheritance) can be useful for F_1 mutant screens as such screens require significantly fewer progeny to be raised in order to identify recessive mutations of interest than conventional diploid screens, which necessitate the production of an F_3 generation (see above). Moreover, gynogenetic and androgenetic individuals

can be used to determine the frequencies of meiotic recombination events during gametogenesis in either females or males, as well as to study genomic imprinting and sex determination.

For an overview of the procedures employed to generate gyno- and androgenetic haploid and diploid embryos, see Fig. 8.

Generation and development of gynogenetic haploid embryos. Haploid embryos are generated by fertilizing eggs with sperm that has previously been inactivated by irradiation with UV light. UV irradiation destroys the sperms' DNA but does not affect their capability to activate the eggs. The developing embryos accordingly

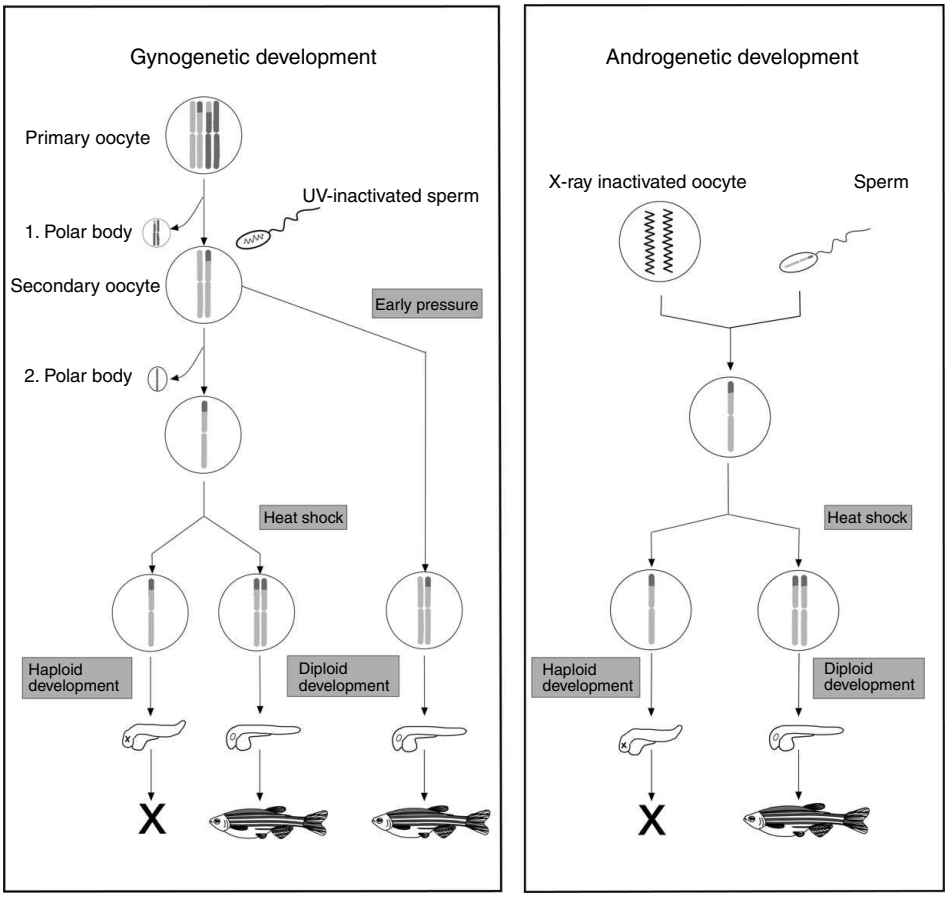

Fig. 8 Schematic representation of the methods used to generate gyno- and androgenetic haploid and diploid zebrafish embryos. For simplicity's sake, only one chromosome is shown. The colors (red and blue) denote the parental origin (maternal and paternal, respectively) of a chromosome/part of a chromosome in the oocyte or the sperm. The presence of two colors in a single chromosome arm indicates a recombination event(s) between the maternal and the paternal chromosome that occurred in the first meiosis leading to the germ cells. The X in the lower row signifies that the respective fish are not viable. For details on the procedures see text. (See color plate p. xxxi).

are haploid, lacking the paternal genetic complement. In consequence, any mutation(s) present in the maternal genome will manifest themselves in the developing haploid progeny. This can be exploited, for example, to directly screen the offspring of mutagenized females or of heterozygous F_1 females arising from the mating of a mutagenized male. If a mutation is present in both DNA strands of a locus (e.g. all insertions and all ENU mutations in the F_1), 50% of the progeny of these females will show the mutant phenotype. The phenotypes resulting from the induced mutations in the maternal genome are frequently similar to the phenotype in diploid individual homozygous for the mutation, although the haploid phenotypes tend to be stronger.

However, these advantages of haploid screens are counterbalanced by significant drawbacks. The viability of haploid embryos is significantly reduced when compared to diploid individuals. They complete embryogenesis but generally arrest quite early during larval development. Haploid embryos usually die by day four or five of development (none live to maturity). As a consequence, haploid screens are only really practical to uncover mutations that produce a phenotype within, approximately, the first three days of development. Moreover, haploid embryos typically display a set of background phenotypes, such as smaller cells, a shorter, thicker, and occasionally bent body axis, as well as defects in organogenesis (e.g. less distinct brain morphology, variable number of ears, defects in the cardiovascular system: swollen pericardial cavity, reduced circulation of blood) against which mutant phenotypes have to be identified. However, as these background phenotypes are relatively consistent, an experienced screener can often distinguish them from genuine phenotypes resulting from a mutation. Additionally, as with all genetic screens, the ratio of individuals showing a particular phenotype to those not showing the phenotype is a useful measure to decide. Nonetheless, the haploid background phenotypes may impede the observation of some phenotypes. Owing to these disadvantages, haploid screens are of only minor significance. However, they may prove valuable to identify mutations that affect early development with comparatively less effort. Once a mutation has been identified, the carrier fish can be bred to produce individuals diploid for the mutation.

Generation and development of gynogenetic diploid embryos. In contrast to haploid embryos, parthenogenetic diploid embryos display less severe developmental abnormalities, and can even survive to become fertile adults. This considerably facilitates the identification of mutant phenotypes and removes the restriction to day three of development up until which phenotypes can be identified in a haploid background. The generation and screening of gynogenetic diploid fish is particularly useful for the identification of maternal-effect mutations as well as of recessive mutations affecting adult traits.

Gynogenetic diploid embryos are generated by diploidizing haploid embryos produced through the fertilization of eggs with UV-inactivated sperm. Following the activation of an oocyte with UV-inactivated sperm, there are two phases during which there are two complements of the maternal genome in the zygote: prior to the completion of the second meiotic division (i.e. before the second polar body is extruded from the zygote) and later during the first mitosis (after the DNA has been replicated, but before zygote undergoes the first cleavage division). If either the extrusion of the

second polar body or the first cleavage is prevented, the embryo will possess a diploid maternal complement (see Fig. 8).

Exposure of eggs in the metaphase of the second meiotic division to a high hydrostatic pressure causes the spindle to disintegrate and the two complements of chromosomes are not separated. As a consequence, there is no extrusion of the polar body, and the egg carries a diploid female complement, which is replicated and distributed to the daughter cells as a normal diploid zygotic complement would. This method to prevent the formation of the second polar body is known as *early pressure* (*EP*). The survival rate following a diploidization with EP typically ranges between 50 and 80%. The gynogenetic diploid fish are viable, develop normally, and become fertile but are not as robust generally as diploid fish with a paternal and a maternal complement.

Despite the fact that the genome of EP-induced gynogenetic diploid fish derives from a single complement, not all loci are identical (i.e. homozygous). The heterozygosity is due to the fact that the sister chromatids present in the oocyte in the second meiosis have already undergone recombination during the first meiosis. The probability of a given locus to be homozygous in an embryo depends on the distance of this locus from the centromere. Loci closely linked to the centromere will be homozygous in nearly all embryos (i.e. 50% of embryos are homozygous for one allele and the other 50% are homozygous for the other allele). The greater the distance of a locus from the centromere, however, the fewer embryos will be homozygous for this locus. As a consequence, EP-based mutagenesis screens show a bias toward the identification of loci nearer the centromeres. Moreover, the fact that the ratio of phenotypically wild-type to mutant embryos is not constant owing to the unpredictable occurrence of recombination events, which hampers the reliable distinction of mutant phenotypes from background phenotypes.

An alternative method for generating gynogenetic diploid embryos is through a heat shock. The separation of the chromosomes and the ensuing cytokinesis of the first mitotic division can be prevented by exposing the egg to a heat shock (generally for 2 min at a temperature of 41 °C starting at 13 min following fertilization of the eggs with UV-inactivated sperm). The efficiency of this procedure to produce diploid embryos is not as high as that usually obtained with EP. Generally, only between 10 and 20% of the individuals survive the procedure and grow up to become fertile adults. Following the heat shock, development continues normally with cleavage divisions. What would have been the second such cleavage is now the first and produces the first two daughter cells.

The outcome of a diploidization induced by heat shock is different from that resulting from exposure of the egg to EP. In embryos created through heat shock, the meioses of the oocyte have been completed, and one set of sister chromatids of the remaining female complement of chromosomes extruded in a polar body. As the diploid state of these embryos is achieved through the replication of a single set of chromatids (i.e. one double helix), the embryos are homozygous for all loci, and 50% of the progeny will carry any given locus in a homozygous state. This advantage of (heat shock) HS-induced gynogenetic diploidy is, however, counterbalanced by the lower survival rates when compared to EP-based methods.

Generation and development of androgenetic haploid and diploid embryos. Similar to the production of gynogenetic diploid embryos carrying only a maternal genetic contribution, androgenetic haploid and diploid embryos can be produced. In these cases, the DNA of the oocytes is destroyed by exposing them to X-rays or UV light, and they are subsequently fertilized with normal sperm. The efficiency of androgenetic haploid production ranges from 10 to 50%. These embryos can either be left to develop as haploid androgenetic embryos or they can be diploidized by preventing the first mitotic cleavage division by heat shock as described above.

The androgenetic haploid and the diploid embryos also show distinct phenotypes. Like gynogenetic haploid embryos, androgenetic haploid embryos display a characteristic set of phenotypes, including a shorter, broader body as well as smaller melanocytes, and their development arrests around day four. The fact that both androgenetic and gynogenetic haploid embryos display very similar phenotypes indicates that these are due to the haploid state of these fish and independent of the parental origin of the genome. Androgenetic diploid embryos exhibit a retarded embryonic and larval development compared to normal diploid embryos, but later catch up in size and develop into fertile adult fish. However, the irradiation of the eggs necessary for androgenesis frequently causes sufficient cellular damage to make the phenotypic screening of the resulting embryos very difficult.

2.5 Transgenesis

The expression of exogenous genes or endogenous genes under the control of modified enhancer/promoter elements is a commonly used way of studying the functions of a gene *in vivo*. There are techniques to achieve both transient and stable expressions of transgenes in the zebrafish. For transient expression studies, the DNA constructs are generally injected into fertilized eggs or early embryos. However, these transient expressions generally result in only half of the injected embryos showing an expression in the expected cell types (e.g. as compared to *in situ* hybridization patterns obtained for the gene). Moreover, the expression is frequently not found in all the cells of the expected cell type. In order to achieve an expression of a transgene that faithfully mimics the expression of an endogenous promoter in the zebrafish, a stable transgenic line has to be created.

To achieve a stable transgenic zebrafish line, several techniques have been developed. These include the infection with retroviral vectors, penetration with DNA-coated microprojectiles, and electroporation. However, the introduction of transgenes is commonly achieved by microinjection of plasmid DNA into the embryo at the one-cell stage. This technique is fast (over 100 eggs can be injected in an hour) and comparatively gentle on the embryos. Furthermore, it results in high rates of integration of up to 25% for transient transfections and between 5 and 30% for stable transgenic lines (with germ lines mosaic for the transgene; between 1 and 50% of the F_1 offspring of these transgenic fish are hemizygous for the transgene).

In recent years, several genetic tools have become available that allow a sophisticated control and analysis of the expression of transgenes in zebrafish. These include:

– Reporter genes, such as the green fluorescent protein (GFP) as well as its derivative cyan (CFP) and yellow (YFP) versions under the control of

tissue- or cell type–specific promoters and enhancers for promoter/enhancer studies or cell lineage experiments.
– Promoters (e.g. the hsp70 promoter) that can be activated by heat shock for analyses of the effect of a transgene at specific times during development.
– The Gal4-UAS system to efficiently drive the expression of transgenes.

Owing to the transparency of its embryos, the spatiotemporal expression of fluorescent transgenes, such as GFP, in the various organs and tissues can be particularly well observed and imaged. This possibility has been exploited in numerous studies and is currently being used in a GFP-based enhancer trap screen performed by the laboratory of T. Becker at the University of Bergen in Norway.

2.6 Microarrays

Microarray hybridization allows to study the expression of thousands of genes in parallel. Probes representing individual transcripts are spotted or synthesized on a glass slide or silicon chip, and hybridized with fluorescently labeled target cDNA from a mutant, knockdown, or other conditions of interest. Microarrays are either based on cDNA clones or oligonucleotides. For a species like zebrafish where a large amount of genome sequence has already been generated, oligonucleotide arrays are advantageous as cross-hybridization can be ruled out by selecting unique oligonucleotide sequences for the probes. Two sets of 16 399 65-mer and 14 240 50-mer zebrafish oligonucleotides, as well as a photolithographically synthesized array representing 14 900 transcripts, are commercially available for spotting. Microarrays have only recently been introduced in the zebrafish field but hold great promise to unravel regulatory pathways in development and to discover genes of interest that are not accessible by reverse genetics methods because of redundant functions.

3 Mapping of the Zebrafish Genome

3.1 Genetic Mapping

Genetic mapping of mutant loci in the zebrafish can be carried out either by half-tetrad analysis or by genome scanning, usually with microsatellite markers. The latter is generally the method of choice because it is technically less demanding and more accurate.

Four genetic maps have been generated for the zebrafish (HS, MGH, MOP, and GAT; cf. Table 2). The established reference map for the zebrafish is the meiotic MGH map produced by the laboratory of M. Fishman at the Massachusetts General Hospital, Boston. It is based on microsatellite markers (CA repeats) scored on a panel of 44 diploid F_2 fish from a cross between the strains AB and India. When the MGH map was published in 1998, it contained 705 markers covering 2350 centimorgans (cM) and was already complete, that is it had one linkage group for each of the 25 zebrafish chromosomes. Production of the map continued until 2001 when a total of 3845 markers was scored.

In order to place a zebrafish mutation on the MGH map, mutant carriers are crossed with a polymorphic reference line. F_1 brothers and sisters are mated, and phenotypically mutant F_2 fish and their wild-type siblings are collected. A genome scan is then carried out by amplifying a subset of the MGH markers both from

Tab. 2 Mapping panels for the zebrafish.

Name	*Type*	*Markers placed as of February 2004*	*Laboratory*

a mutant and from a sibling pool and comparing the band intensities of the marker alleles between the pools (batched segregant analysis, Fig. 9). If a significant difference is detected, the marker in question is likely to be linked to the mutation. This potential linkage can be confirmed by repeating the PCR with the individual mutant and wild-type F_2 fish that were used for the pooling, and counting the recombinations. An unambiguous map position can be obtained by identifying linkage to additional markers. To date, over 400 zebrafish mutations have been mapped at a resolution of approximately 1 cM (600 kb) by genome scanning with a set of 192 microsatellite markers, mainly by the laboratory of R. Geisler. An alternative to this approach is the typing of single nucleotide polymorphism (SNP) markers by microarray hybridization, which has been demonstrated by W. Talbot. Microarrays offer the prospect of performing batched segregant analysis for a very large number of markers in parallel once sufficiently accurate detection methods are available.

Results of such rough mapping can be sufficient for cloning a mutation of interest if a suitable candidate gene can be identified, and if evidence such as a matching expression pattern or a morpholino-induced knockdown phenotype can be obtained for the gene. In the absence of good candidate genes or supporting evidence, however, the map position needs to be refined. This involves identifying the closest polymorphic MGH markers and collecting recombinants for these markers from a large number of individuals (typically 1000–2000 embryos, corresponding to 2000–4000 meioses). The recombinants are then used for mostly SNP-based mapping of genomic clones or expressed sequence tags (ESTs) from the region of the mutation. SNP are typically identified and typed by sequencing. Genome sequencing showed that SNPs within the Tü strain occur at an average frequency of 1/200 bp. In the vicinity of the mutation, recombinations should be lost. The region in which no recombinations are detected on either side is referred to as the critical region; when starting out with a sufficient number of recombinants, it can be reduced to a single contig of the zebrafish genome sequence, or even to a single genomic clone. Transcripts of the critical region are

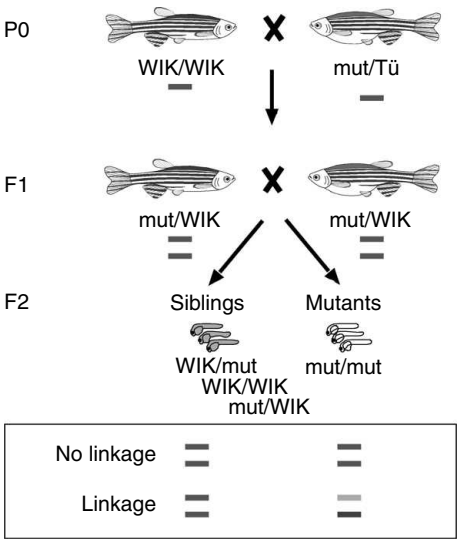

Fig. 9 Map cross and bulked segregant analysis of a recessive zebrafish mutation. WIK/WIK, reference fish; mut/Tü, fish carrying the mutation in Tü background. Band sizes and intensities of a representative SSLP marker are indicated schematically. In case of no linkage between the mutation and the marker, the intensities in the mutant and sibling pool are the same. In case of a linkage, the Tü band is stronger in the mutant pool and the WIK band in the sibling pool (Figure from Geisler, R. (2002) Mapping and Cloning, in: Nüsslein-Volhard, C., Dahm, R. (Eds.) *Zebrafish, A Practical Approach*, Oxford University Press, Oxford, UK, pp. 175–212.) (See color plate p. xxx).

identified and, if necessary, cloned based on annotation available at the ENSEMBL website, and then sequenced in order to find the mutation.

3.2 Radiation Hybrid Mapping

Mapping panels for radiation hybrid (RH) mapping are generated by fusing lethally irradiated cells of the species of interest with mouse or hamster cells. Hybrid cell lines are then grown, each of which retains a large number of random fragments of the species of interest, either inserted into the host chromosomes or as separate minichromosomes. Markers to be mapped are tested for their presence or absence in DNA of the cell lines by PCR. If two markers are present in many of the same RH lines (i.e. they have a similar RH score vector), they are likely to be close to each other in the genome. By ordering markers such that the ones with the most similar score vectors are next to each other, maps can be generated. Radiation hybrid mapping is thus similar to genetic mapping, with radiation-induced breaks in place of genetic recombination sites. Distances are given in centirays (1 cR indicates 1% breakage). The main advantages over genetic mapping are a higher resolution and the ability to map almost any sequence-tagged site (STS) marker without the need to identify a polymorphism (since RH lines are interspecies hybrids). For these reasons, RH mapping has become the method of choice for mapping of genes and genomic clones in the zebrafish.

The T51 radiation hybrid panel for the zebrafish was produced by the laboratory of P. Goodfellow. A map of the zebrafish genome based on the T51 panel containing 1451 STSs was generated by the laboratory of R. Geisler in 1999, demonstrating the feasibility of radiation hybrid mapping in a nonmammalian vertebrate. Since then the laboratories of R. Geisler and Y. Zhou have added several thousand STS markers to the map, mainly ESTs and BAC ends. As of January 2004, 14 989 markers could be placed on the T51 map, corresponding to an average marker spacing of 100 kb. The map is anchored on the meiotic MGH

map by microsatellite markers scored on both panels.

The LN54 radiation hybrid panel for the zebrafish was produced by a consortium led by I. Dawid. It has a lower resolution than the T51 panel and was used for the mapping of 4192 markers. Mapping services are available for the RH maps; markers are either mapped on request or RH DNA is provided to interested researchers by the mapping labs, and the resulting data can be submitted online.

Data from these mapping efforts have been used for studies of the conserved synteny between zebrafish and human, which revealed that 80% of the genes belong to conserved synteny groups. Although a genome duplication is believed to have taken place in the teleost lineage, most human genes have only one ortholog in zebrafish, perhaps indicating an extensive loss of duplicated genes (and those paralog pairs that do exist in zebrafish are sufficiently diverged so that they do not pose a problem for mapping).

3.3 Physical Mapping

A physical map of even higher resolution than a radiation hybrid map can be obtained by fingerprinting of genomic clones with large inserts such as Bacterial Artificial Chromosomes (BACs, 100–200 kb insert size). This method identifies contigs made up of overlapping genomic clones. Overlaps are detected either by hybridization with oligonucleotide probes (oligonucleotide fingerprinting) or by restriction digest (restriction fingerprinting). In the former case, clones are deemed to overlap if they hybridize with the same probes, in the latter, if they share a sufficient number of restriction fragments of similar size. In the zebrafish, the oligonucleotide fingerprinting method was used only on chromosome 20, while restriction fingerprinting was carried out on the entire genome by the laboratories of R. Geisler, S. Humphray, and R. Plasterk. Four BAC libraries were constructed from the Tü line for the purposes of fingerprinting and sequencing. A total of 213 000 BACs from these four libraries were fingerprinted by restriction digest with the enzyme HindIII, resulting in 3775 contigs with a combined 21-fold genome coverage. Contig data are available online for use in the positional cloning of zebrafish mutations, and are also used by the Sanger Institute to select BACs for the clone-based sequencing of the zebrafish genome. Furthermore, the contigs are being anchored on the T51 radiation hybrid map by mapping of BAC ends in a collaboration of R. Geisler and Y. Zhou. Most of the contigs are expected to be anchored by the end of 2004. The resulting physical map of the zebrafish genome is used by the ENSEMBL project for assembling of the genome sequence.

Cytogenetics in the zebrafish is lagging behind since the 25 chromosome pairs are relatively small and similar in size and are therefore difficult to identify visually. No sex chromosomes are known. An alternative is offered by fluorescent *in situ* hybridization (FISH), but because of the relative ease of genetic mapping, this is not commonly carried out in zebrafish, and FISH data are available only for some chromosomes. As a consequence of this, the zebrafish community agreed in 2003 to number zebrafish chromosomes following the numbering of the genetic linkage groups (LGs), in contrast to other organisms where chromosomes are numbered by size.

3.4 Genome Sequencing

The sequencing of zebrafish transcripts is largely based on the EST approach. ESTs are obtained by single-pass sequencing of cDNA clones and offer rapid access to transcribed sequences as well as information on genetic polymorphism. In the zebrafish, EST sequencing has been carried out mostly by the WashU-Zebrafish Genome Resources Project led by S. L. Johnson, which has generated over 200 000 ESTs, while smaller numbers have been produced by the laboratories of C. C. Liew and J. Peng. The WashU ESTs have been and assembled in over 25 000 ''WZ'' clusters, which represent the majority of all zebrafish genes, while those of J. Peng have been assembled in ''IMBC'' clusters. In a separate effort, zebrafish ''UniGene'' clusters are being assembled by the NCBI. Complementing these efforts, the Zebrafish Gene Collection is a recent NIH-sponsored effort to generate full-length cDNA libraries and sequences. Curated information on zebrafish genes is available from NCBI's LocusLink service as well as from the ZFIN and ENSEMBL websites.

In February 2001, the Sanger Institute began a zebrafish genome project, which follows a combination of two strategies: sequencing of BAC clones selected from the physical map of the genome and whole-genome shotgun sequencing. The BACs are selected to represent a minimum tiling path across the fingerprint contigs. The genome size is estimated to be 1.5 to 1.6 Gb. As of February 2004, 1.0 Gb of BAC clone sequences (0.6-fold coverage) and 9.1 Gb of whole-genome shotgun sequences (5.7-fold coverage) have been generated. In addition, sequencing of BAC ends has been carried out both by the Sanger Institute and by the laboratory of S. Schuster. A finished genome sequence (with approximately 10-fold coverage) is expected to be available by the end of 2005.

Assembly of the zebrafish genome sequence has proved more difficult than in other organisms because of two factors:

1. There is a high degree of polymorphism that is visible in genome sequencing because both the BACs and the whole-genome shotgun library used for sequencing were made from sperm or embryos derived from several adult fish (due to constraints of the DNA isolation method employed).
2. Additionally, the zebrafish genome contains a high number of repeats. A repeat library was compiled by R. Waterman that contains repeats found more than 50 times and which covers approximately 40% of the genome. Masking of repeats is therefore essential when performing similarity searches or designing PCR primers for zebrafish sequences.

As of February 2004, the sequence was assembled into 62 895 supercontigs (which still contain short stretches of unknown sequence). These supercontigs are mostly based on FPC contigs, which are in turn anchored on the T51 RH map by BAC ends, thus providing rough chromosomal positions. The genome sequence is subsequently annotated by the ENSEMBL project of the Sanger Institute and the European Molecular Biology Laboratory and is accessible with annotations through a genome browser on the ENSEMBL website.

4
Resources on the Internet

4.1
General

The Zebrafish Information Network ⟨http://zfin.org/⟩

Community database and repository of genome data, which provides information on genes, maps, stocks, expression patterns, publications, researchers, and suppliers.

4.2
Mapping

MGH Zebrafish WWW Server ⟨http://zebrafish.mgh.harvard.edu/⟩

Homepage for the MGH genetic map.

Tübingen Map of the Zebrafish Genome ⟨http://wwwmap.tuebingen.mpg.de/⟩

Homepage for the T51 RH map (calculated with RH TSP Map software), mutant mapping, data submission to the T51 map.

The Children's Hospital Zebrafish Genome Project Initiatives ⟨http://zfrhmaps.tch.harvard.edu/ZonRHmapper/⟩

Alternate homepage for the T51 RH map (calculated with SAMapper), instant mapping service.

4.3
Sequencing

ENSEMBL Zebrafish Genome Browser ⟨http://www.ensembl.org/Danio_rerio/⟩

Assembled and annotated zebrafish genome sequence.

The Sanger Institute: Danio rerio Sequencing Project ⟨http://www.sanger.ac.uk/Projects/D_rerio/⟩

Information and links on genome sequencing, database of fingerprinting contigs, online RepeatMasker.

WashU-Zebrafish Genome Resources Project ⟨http://zfish.wustl.edu/⟩

Database of ESTs and EST clusters, BLAST server for EST clusters.

NCBI Zebrafish Genome Resources ⟨http://www.ncbi.nlm.nih.gov/genome/guide/zebrafish/index.html⟩

Homepage for NCBI resources and services including sequence databases, BLAST, and a map viewer.

Zebrafish Gene Collection ⟨http://zgc.nci.nih.gov/⟩

Full-length cDNA libraries and sequences.

4.4
Resource Centers

Zebrafish International Resource Center ⟨http://zfin.org/zf_info/stckctr/stckctr.html⟩

Wild-type and mutant zebrafish stocks, miscellaneous clones, antibodies and materials, zebrafish pathology, and health services.

RZPD German Resource Center for Genome Research ⟨http://www.rzpd.de/⟩

cDNA and genomic libraries, library pools and filters, and individual clones.
